The Electric Lighting of ss. "Normannia."—The most recent contribution to the fleet of Atlantic racers is named the "Normannia," the gross tonnage of which is 8,500 tons, and which is owned by the Hamburg-American Steam Packet Company. The "Normannia" lighted throughout with the electric light by Messrs. Siemens and Halske, of Berlin; the London firm of Messrs. Siemens Bros. and Co. having done all the fitting up. There are four 36 kilowatt (100 volts × 360 amperes) dynamos. As the total number of lamps in the ship is only 1,100 of 25 candle-power, and as each dynamo is capable of supplying 600 lamps, only two of the four need be kept running. Each dynamo is coupled direct to a high-speed engine, making 360 revolutions per minute, and developing 50 brake horse-power. Steam is supplied from the main boilers at a working pressure of 160lb. to the square inch. The lamps are by the Edison-Swan Company, and are of frosted glass. In the decorated parts of the ship they are fixed in brass holders of roses and lilies, and in some cases little reflecting globes are fitted up in the semblance of buds. On the deck and at suitable places there are groups of three lamps with large concave reflectors and a glass framing in front. In the well above the saloon there is an electrolier with a large number of lamps, making an effective illumination. There are a number of portable lamps in the engine and boiler rooms, and portable reflector lamps for the stokehold. The skin of the ship is used as the return.

The Trouvé Electric Erygmatoscope.—At a recent meeting of the Académie des Sciences, M. G. Trouvé described an electrical appliance devised by him to facilitate the inspection of the geological strata pierced by the boring tool. The apparatus consists of a powerful incandescent lamp enclosed in a cylinder. One of the hemicylindrical surfaces of this cylinder constitutes the reflector; whilst the other, which is of thick glass, allows the luminous rays to pass through it, and light up the successive strata through which the lamp descends. At the base of the instrument there is an elliptical mirror, while the top is open, so as to enable an observer placed at the head of the boring and armed with suitable glasses to see on the mirror the reflected image of the stratum illuminated by the lamp, which is arranged so that its upward rays are intercepted. The whole apparatus is suspended from a cable formed by the two conducting wires. This cable is wound on a drum, the trunnions of which are insulated from one another and connected to the leads, current being obtained by two rubbing contacts attached to the poles of a portable battery. This arrangement enables the instrument to be raised and lowered without difficulty and without interrupting the observations. The erygmatoscope as at present arranged gives excellent results down to a depth of over 600 feet, and with a more powerful lamp it could be used at still greater depths. An expedition which has been sent out to the Mozambique coast by the Portuguese Government, to search for coal beds and other mineral deposits has been supplied with erygmatoscopes.

Atmospheric Electricity.—In a Paper recently read before the Vienna Academy, Herren Elster and Geitel give the results of a year and a-half's observations of atmospheric electricity on the north side of Wolfenbüttel (bordering an extensive meadow). They used a stand carrying a petroleum flame, and connected by insulated wire with an electroscope. A marked difference was found in the phenomena of spring, summer, and autumn, on the one hand, and winter on the other. It appears to the authors that other factors than humidity, with which Exner seeks to explain the variations, are concerned in the case. When the temperature goes below zero, cold mist being then generally present, there is often rather a sharp rise in the values, the aqueous vapour having then less action. Rainfall in a neighbouring region lowers the fall of potential both in winter and summer, and a disturbance of the normal course will announce a coming change in places still unclouded. Snow, it seems, rather raises the values. It has been shown by Linss that the course of the fall of potential is inversely as the coefficient of dispersion of the air for electricity; which, again, depends not only on the dust and aqueous vapour present, but also, according to Arrhenius's theory, on a sort of electrolytic or dissociative action of the sun's rays on the atmosphere (thus it has been shown that electricity escapes from a conductor under the influence of ultra-violet rays). The authors find their results support this latter view. They consider that the electric processes during formation of precipitates are the chief cause of the disturbance of the normal condition.

The Maintenance of High-Tension Circuits.—In an interesting article in the *Western Electrician*, Mr. Alex. Dow remarks:—"There are few new circuits these days which do not give a perfect test when first completed. The attainment of high insulation is an everyday occurrence. Its maintenance for many days under ordinary conditions of operation is rare. Look to your lineman," says Mr. Dow. "What shall it profit if the insulation be one megohm per mile for 99ft. between poles, and the last 6in. of each stretch be split and ruined by a too tightly-twisted tie-wire? The moral is, that after a good wire is selected, it must be well strung and well jointed. Another consideration is the insulation of supports. The glass insulator is about as satisfactory a support, mechanically and electrically, as can be devised; especially if it be of the double petticoat pattern. Those who have had experience with long telegraph lines know that the shape of the insulator has much to do with the insulation resistance; and the adoption of the double petticoat shape by the British Government Telegraph Department is a strong endorsement of its advantages. Porcelain knobs are not fit for high-tension work. Their enamel cracks, and they absorb moisture. Their shape is convenient sometimes, but glass insulators of the same shape can be had, and are much superior. The glass is usually the last insulation of the circuit. This need not be, for the pin and cross-arm which support it are wood, and dry wood is a very good insulation. Buy unpainted pins and arms, dry them, and paint them thoroughly with the paint used for joints. Troubles will come while there remain with us bad weather, and telephone men, and the total depravity of inanimate things; but the troubles that are due to bad construction, and the ordinary wear and tear, and causes that may be foreseen, should disappear for ever."

Street Railway Amenities.—The "mule line" at Springfield (Ill.) has, it appears, been trying to hold valuable franchises without giving the people any service, and there has been a strong opposition to this policy, which recently culminated in an open struggle. According to a correspondent of the *Western Electrician*, the Citizens' Company, known as "The Mule Line," has a franchise to extend its track, but has not taken advantage of it, and its operations generally have been unsatisfactory. At one o'clock one Sunday morning the Electric Street Railway Company set a large force of men to work laying a track on Spring-street, past the end of the Citizens' track, so as to get ahead of them, and capture the Spring-street line. They had only three rails laid when they were stopped by the Mayor and a posse of police force. The Electric Company claimed the privilege under a State charter of laying tracks anywhere in the city. The Mayor was obdurate, and refused to let them proceed until the Council gave them permission. The Electric Company kept its men on the ground all night. At 1 o'clock on the following day the President of the mule line, at the head of a force of men, attempted to lay a track parallel to that of the Electric Company. They came to blows, but the fight was stopped by the police. Then the citizens took a hand, and, throwing off their coats, laid about a block and a half of the Electric Company's track, and the police did not interfere. While all the police force was busy on Spring-street preserving order, the President of the Electric Street Railway Company took a large force of men and laid about 2,000 feet of track on South Grand-avenue, two miles away, where the mule line had another charter track it would not use. The police did not find this out until about seven o'clock in the morning. The whole police force, says this correspondent, in conclusion, has been watching the 300 men the car companies have employed.

The History of Electric Tanning.—In a recent article in *La Lumière Electrique*, M. Rigaut says: "Like all other discoveries and inventions, that of using electricity in tanning is not a new one. About 1850, a currier named Crosse, invented an apparatus to utilise what he called the 'effects of electricity or galvanism for tanning purposes.' Two electrodes were placed in a tan-pit, one made of lead, the other of zinc. The pit was then filled with water and skins, and, after an interval of three days, tan was added in small proportions, in order to concentrate the liquor. Ten years later, an Englishman named Ward, of Lancashire, made a series of experiments. Instead of electrolysing the skins in water before adding the tan, he used electricity in the tanning baths. At Paris, in 1861, a M. Rebu invented a system of electric tannage. This is said to have been very complicated. The skins were treated with carbonic acid and hydraulic pressure; and then submitted to the action of salts of lime, of magnesia, and of iron. Currents of electricity were passed through the skins while they were immersed in the above mixtures and the usual tanning solutions. In 1874 M. de Mertens tried another system. At the bottom of a large vat was placed a layer of carbon, connected with the positive pole of a dynamo. On this skins covered with tan were placed. On the top of this heap a plate of zinc was placed, connected to the negative pole. The vat being filled with tanning liquid, the current was passed through. M. Mertens' system has been employed in nearly 600 pits for some years past at a tanyard in the environs of St. Petersburg, and by it about thirty-five days is required to tan the skins. In 1876, Gaulard and Kresser brought out another process, and in 1883 skins tanned by Gaulard's process were exhibited in England. In 1887, in Sweden, Messrs. Abom and Landin brought out a method for the use of electricity, and this has been in operation for two years at Noorköping, in Sweden, with good results, forty-five days being required for tanning. Some months before this Messrs. Worms and Balé, at Paris, had worked a process for the rapid tanning of skins by the aid of the electric current.

A Statue to Gay-Lussac.—At Limoges, on the 11th inst., a statue of Gay-Lussac was unveiled before the Minister of Commerce and the Association Scientifique de France. It may not be out of place, remarks *La Lumière Electrique*, to call attention to the fact that this illustrious member of the Académie des Sciences played a somewhat important part in the history of electrical science at the commencement of the century. As is generally known, he gained considerable renown by his balloon ascent of 1804. He started from the Conservatoire des Arts et Métiers, and attained an altitude of 7,000 metres (23,100ft.). This celebrated ascent was undertaken to test the assertion made by Robertson, the aeronaut, in a communication to the Société Galvanique de Paris, that the magnetic force of the earth greatly diminished at a short distance from its surface. Gay-Lussac's observations were held to have definitely disproved Robertson's statements. It should be mentioned, however, that the methods of observation employed by the celebrated physicist were of such a rudimentary character that his results would probably not have been considered conclusive but for the fact that they agreed with what seemed probable having regard to the smallness of the altitude compared with the radius of the earth. To test Robertson's statements it was necessary to go up as high as he did. A few days previous to the successful ascent, Gay-Lussac, accompanied by Biot, had failed to attain the necessary altitude, and the latter, therefore, gave up the idea of accompanying his colleague. Biot accepted Gay-Lussac's conclusions without hesitation, and manifested no wish to emulate his exploit. As to Gay-Lussac he never again set foot in the car of a balloon. When Napoleon I. heard of the achievements of Davy's battery he expressed a desire to have one like it in France, Gay-Lussac therefore undertook the construction of the well-known battery at the École Polytechnique. Together with Thénard he repeated the experiment of decomposing the alkaline bodies, and it was in the course of this work that some potassium injured his eyes, rendering him blind for a month, until Dupuytren took him in hand and restored his sight. The various experiments carried out by means of this battery were described in the first volume of the new memoirs of the Société Philomatique, under the title of "Etudes sur le Pouvoir Chimique de la Pile." During the last years of the first Empire and during the days of the Restoration, Gay-Lussac was editor of the *Annales de Chimie*. He was head of the committee engaged in investigating questions connected with lightning conductors, and the subject of atmospheric electricity occupied his attention from time to time. He did not believe that electricity was generated either by the evaporation or condensation of vapour; for him, clouds were simply conductors on which atmospheric electricity accumulated. He travelled through Italy with Humboldt, and studied the magnetic phenomena of the peninsula, as well as the electricity of the torpedo-fish and of dry batteries. Gay-Lussac died in 1850, just at the dawn of the electric telegraph.

PROF. OLIVER LODGE, F.R.S.

The subject of our sketch was born in 1851 at Penkhull, a village near the Staffordshire Potteries. At the age of eight he was sent to Newport (Salop) Grammar School, where he was thoroughly grounded in the old-fashioned manner, and with the aid of constant corporal punishment, in the rudiments of Latin, Greek, and Mathematics. At fourteen he was put into business with his father in the Potteries, and remained there for six or seven years. During this time he informs us that he made his first acquaintance with science by reading an odd monthly number of the *English Mechanic*, and afterwards picking up what he could from the articles of the "Penny Cyclopædia." Later, while on a visit to London, he heard a course of six lectures on Heat by Tyndall at Jermyn-street, and also attended a private course on elementary chemistry. He then began to attend evening classes in chemistry under the Science and Art Department at the Wedgwood Institute, Burslem; and in 1872 was permitted a winter's course at the South Kensington Chemical Laboratory, on the annual examination list of which he came out bracketed first.

In 1871, by working at odd hours, he matriculated at the University of London, and after two years of private study passed the Intermediate Examination for a Science degree, having failed in Botany at the first trial. In this examination he obtained honours in Chemistry and Physics, standing alone in the first class in the latter subject. He next tried for a scholarship at St. John's College, Cambridge; but, not succeeding in getting nearer than *proxime accessit*, he went to study mathematics at University College, London, where Prof. Carey Foster enabled him to live without much home aid by teaching in exercise classes. In 1875 he took his B.Sc. degree; and the post of Demonstrator of Physics at University College was created and offered to him about the same time. In the same year he published, in conjunction with Prof. Foster, several Papers on the flow of electricity in a plane conductor, in which the forms of the lines of flow and equipotential lines are found practically and mathematically for various shapes of conductor, and for different positions of the electrodes.

It was during a holiday visit to Heidelberg in 1876 that he read and analysed the first volume of Maxwell's Electricity, and the same year he exhibited before the British Association a model, consisting of a string on which are threaded, either loosely or rigidly, balls attached by elastic bands to fixed supports. The various parts of the model each represent some electric property, and its purpose was "to illustrate mechanically the passage of electricity through metals, electrolytes, and dielectrics, according to Maxwell's theory." It is now well known to every reader of "Modern Views of Electricity;" and it showed very clearly the charge and oscillatory discharge of a Leyden jar, though at that time the meaning of the inertia of the balls was not known; indeed, Dr. Lodge says in a note at the end of his communication on the subject (*Phil. Mag.*, 1876) that after reading Thomson's paper on oscillatory discharge he does not understand his constant, "the electrodynamic capacity of the discharger." In the same note he frankly confessed that he had not then read the second volume of Maxwell. In those pre-telephone days how little was known to ordinary people about self-induction! With this exception the views of Dr. Lodge on this subject were almost as advanced 14 years ago as they are to-day, and his subsequent work in this department has been directed towards investigating the nature and insisting upon the importance of self-induction.

In June, 1877, he published a paper describing a modification of Mance's method for measuring battery resistance, in which a condenser and galvanometer are used in place of the ordinary Wheatstone's bridge galvanometer. Later in the year appeared his suggestion for a standard Daniell cell, in which the copper sulphate solution is prevented from getting to the zinc rod either (1) by having to diffuse through a very long column of zinc sulphate; or (2), by connecting the two liquids by a fine capillary layer of sulphate of zinc. In the same year he took his degree of Doctor of Science, choosing Experimental Electricity as his special subject. In the autumn of 1877 he became Assistant Professor of Physics at University College, and undertook lecturing duties. He was also Lecturer in Physics at Bedford College, London. Afterwards, in addition to these appointments, he assisted the late Prof. W. K. Clifford in the Mathematical Department of University College.

During this period two other events of importance took place. The first of these was his marriage in 1877. The other was the appearance in Chambers's Series of a treatise by Dr. Lodge on "Elementary Mechanics." Since its first publication this book has had a very successful sale, having run through several editions.

The original work of this period was an extended series of observations on the thermal conductivity of metals and crystals. The first researches had for their object the determination of the absolute conductivity of crystals and rare substances. The method was to insert a piece of the crystal, cut into the shape of a short circular cylinder with parallel faces, between the ends of two similar bars of metal, the further ends of which were maintained at 100° C. and 0° C. respectively. The curve of temperature along each bar was noted. The conductivity of tourmaline was determined in this way. The same apparatus, using only one bar of metal, was afterwards used in an investigation into the change of thermal conductivity with temperature in the case of metals; but the results obtained were somewhat uncertain, owing to the want of constancy in the amount of radiation from the surface of the bar. Dr. Lodge had a new and larger apparatus made for the same purpose in 1885, and some work was done with it, but the subject is by no means exhausted, and it is to be hoped that he will some day return to it, considering the close relation which exists between the coefficients of electrical and thermal conductivities of metals.

In November, 1879, Dr. Lodge undertook the measurement of the resistance of some alloys of copper and tin made by Prof. Chandler Roberts (now Roberts-Austen). The results showed that sudden changes in resistance occur even for small changes in the percentage composition of the alloy; and there are well-marked maxima and minima of resistance corresponding to definite chemical compounds. For example—Sn Cu_4 has a minimum of conductivity.

About this time the telephone and the Hughes Induction Balance came into prominence, and directed the attention of physicists more closely to the phenomena of self and mutual induction. Moreover, the article of Chrystal in the "Encyclopædia Britannica" shed a clear light on the subject, and obtained many new readers for the hitherto uncut pages of the second volume of Maxwell. Amongst other things, it led Dr. Lodge to publish a mathematical theory of intermittent currents and the induction balance. The facts observed by Hughes were here accounted for and somewhat extended. The effects of making and breaking a circuit were also discussed more fully than in Chrystal's article. But possibly the greatest value of the Paper lay in the fact that it familiarised students with the nature and action of self and mutual induction in closed circuits.

In 1881 Dr. Lodge was elected to the Professorship of Physics and Mathematics at the new University College in Liverpool, and entered upon his duties by an inaugural address delivered in October of that year, the subject being "The Spread of Education." During the greater part of the College Session 1881-2 his time was occupied in superintending the construction and equipment of the Physical Laboratory. In addition to this he delivered all the courses of lectures both in Physics and Mathematics. At the end of a year the chair of Mathematics was endowed, and Prof. Lodge was thus relieved of this part of his onerous task, retaining the Professorship of Physics, which he still holds. He then commenced a series of experiments to ascertain the behaviour under different circumstances of secondary cells with plates of various materials and with different liquids, and acted as scientific adviser to the Electrical Power Storage Company during the two years, 1884-86, following their early days of difficulty and discouragement. In 1884 he took out a patent for the use of mercury sulphate along with zinc negatives in secondary cells. He likewise

Digitized by Google

found among other things that plates of zinc and peroxide of lead in sulphuric acid gave a steady electromotive force of about 2·5 volts, the highest which he could obtain from any single practicable cell. He proved experimentally that the reason of the sudden drop in the E.M.F. of ordinary secondary cells was the scumming over of the negative plate with sulphate of lead.

In September, 1882, he found time to contribute his quota to a discussion then occupying the columns of the *Philosophical Magazine* regarding English and German views of the dimensions of a magnetic pole in the electrostatic system of units. Prof. Clausius had introduced some confusion by ignoring the dimensions of the magnetic constant; Prof. Lodge, along with others of the Maxwell school, insisted on the retention of the permeability factor.

In the spring of 1883, Prof. Lodge secured the friendly co-operation of the late Mr. J. W. Clark as demonstrator; and in 1884 published, in conjunction with him, a classical Paper on the behaviour of dusty air near illuminated bodies. This communication bears the melancholy words "Part I." on its title-page. The second part has been delayed, possibly altogether lost, by the untimely death of Mr. Clark, whose loss Dr. Lodge felt very deeply.

The British Association meeting at Montreal in 1884 was a very busy time for him. He was chosen to deliver one of the evening discourses, and took for his subject "Dust." In addition to this, he was one of the secretaries of Section A, and also opened the first formal discussion ever held in that Section. The discussion was "On the Seat of Electromotive Force in the Voltaic Cell." The controversy on this point had been raging for almost the whole of the century, and the subject was very eagerly debated on both sides. Prof. Lodge found himself entertaining views almost diametrically opposite to those of such authorities as Sir William Thomson. He consoled himself, however, by the conviction that Maxwell, had he been alive, would have supported him. The discussion was followed a little later by a Paper from Prof. Lodge on energy paths in voltaic circuits, showing how Poynting's views really settled the question completely. After the success of the 1884 discussion Dr. Lodge established his reputation as a controversialist, and was asked to open a discussion on Electrolysis at the next (Aberdeen) meeting of the Association. In it he reviewed the state of electrolytic theories up to that date, and after the discussion took up the subject with a view to obtaining data for the rate of migration of ions in electrolysis. Indeed, during the years 1886-7 his experimental work was mainly devoted to the subject of electrolysis. In these two years a considerable portion of his time was taken up by the duties of the Electrolysis Committee, of which he was (and still is) a Secretary. For the 1886 Report he translated and reviewed several foreign memoirs on the subject.

In the autumn of 1887 Prof. Lodge began his researches on waves in conductors and on Leyden jar discharges. The first experiments were described in the Dr. Mann Lectures, which were delivered before the Society of Arts in March, 1888. Since that time his experiments have proved that pulses travel along isolated wires with the velocity of light, and he has investigated the conditions indicated by theory and perfectly borne out by fact, under which an electrical discharge is oscillatory in character, and has shown that the case of a lightning discharge may, and in general does, satisfy those conditions. He has always emphasised the fact, first clearly published by Heaviside in these columns, that oscillatory discharges or impulsive rushes tend to keep to the outside of a conductor, and his most recent communication on the subject was mainly directed to showing how a closed conductor may be used to afford protection from a lightning flash to telegraphic installations.

The interest of these experiments was greatly increased by the discussion at the British Association at Bath in 1888 on Lightning Conductors, in which Prof. Lodge again took a leading part.

The researches just mentioned refer mostly to waves in metallic conductors; but the simultaneous and overlapping work of Hertz on the propagation of electric waves through dielectrics has been eagerly followed by Dr. Lodge. All Hertz's experiments have been repeated at Liverpool, and about Easter of last year two pitch lenses were cast in order to verify that the laws of refraction of these waves are the same as those of visible light. Since then Prof. Lodge has attempted to account for the action of the eye by supposing transverse oscillations to take place in the rods and cones; and he has even gone so far as to construct an artificial "electric eye" to illustrate his views. Oscillators for producing electric waves have been made by him of all shapes and sizes, giving waves from 1 inch to 2,000 miles in length. Indeed, during the past three years the lecture theatre of the College at Liverpool has constantly been adorned either by a maze of wires for the Leyden jar discharge experiments, or by these oscillators and their corresponding resonators; a notable feature being the large oscillator with its plates each 4ft. square and 12ft. apart, suspended in mid-air. At the end of 1887 Prof. Lodge published in *Nature* his views on the ether theory, and the mechanics of the propagation of light and electricity. These articles were collected into a book, and issued in the *Nature* series in 1889, under the title "Modern Views of Electricity."

Some further idea can be got of his activity from the fact that Prof. Lodge delivers on an average ten or twelve lectures weekly during eight months of the year; but this is not all. He is member of the Council and of the Library and Building Committees of the College, and in the case of an institution growing so rapidly as that at Liverpool, these take up a considerable amount of time. He is also one of the Examiners in Sound, Light, and Heat for the Government Science and Art Examinations, and has just been elected an Examiner in Physics at the University of London, having previously (1876-79) held the post of Assistant Examiner. As Professor at one of the three constituent Colleges he is also an Examiner for Victoria University. In 1885 he was one of the jurors at the International Inventions Exhibition, and wrote for the official handbook a short article on progress in electricity during the past 25 years.

In the spring of 1888 the University of St. Andrews conferred upon him the honorary degree of LL.D., and shortly afterwards he was admitted a Fellow of the Royal Society. He has been a member of the Physical Society since 1875, and is now on the Council. He is also President of the newly-formed local Physical Society at Liverpool. In connection with the British Association, besides the offices already mentioned, he was one of the secretaries of Section A from 1878 to 1884, and has served on many committees. Prof. Lodge is also a Member of the Institute of Electrical Engineers. Moreover, he is interested in the subject of hypnotism, and has communicated papers at various times to the Society for Psychical Research, of whose Council he is a member.

In 1889 he applied his Leyden jar experiments to a measurement of the value of "v," the ratio between the electrostatic and electro-magnetic units of electricity, working in the Cavendish Laboratory, Cambridge, in conjunction with Mr. Glazebrook. The results of this research are not yet quite complete.

The clear terse way in which Dr. Lodge sets forth his ideas and describes his experiments has awakened in the minds of many an interest in his work which the ordinary theorist finds himself unable to create. This lucidity of statement contributes greatly to his success as a controversialist, while in his College lectures it is especially felt and appreciated. Moreover, it makes him welcome everywhere as a writer or lecturer on scientific subjects. In a stranger his fine physique and commanding presence possibly create a certain sense of awe; but this is quickly dispelled after coming into more intimate contact with him and experiencing the influence of his intense enthusiasm. To his assistants his unceasing thoughtfulness, kindness, and sympathy render him something more than a friend. The quality and quantity of his work serve to place him in the very foremost rank of the younger School of Physicists; and we sincerely hope that he may, for many years yet, take an active part in demonstrating the properties of that Ether which he has been so instrumental and successful in transferring from the realms of mathematical conception to the domain of actual physical fact.

MAGNETISM IN IRON AND OTHER METALS.*—XXX.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 456.*)

§ 112. **Whitworth's Mild Steel.**—Figs. 82 and 83 give a corresponding selection of Hopkinson's results, for a specimen of mild steel contained 0·126 per cent. of carbon. Its critical

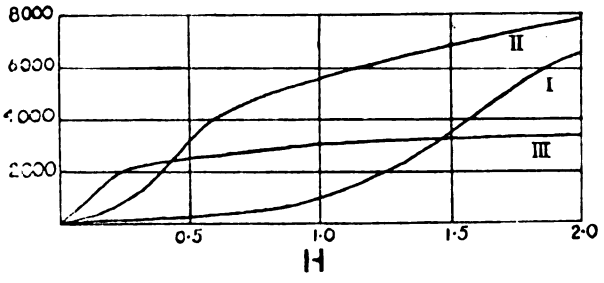

Fig. 82.—Magnetisation of Mild Steel at Various Temperatures.

temperature was 721°C., above which the permeability was only 1·12. The curves reproduced here correspond to the following temperatures:—Curve I., 12°C.; curve II., about 620°C.; curve III., about 715°C. It will be seen that these

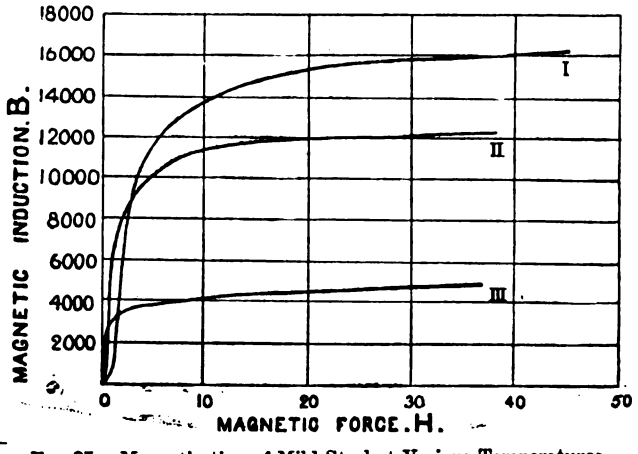

Fig. 83.—Magnetisation of Mild Steel at Various Temperatures.

present the same characteristics as the corresponding curves for iron. With a force of 0·3 the highest permeability is over 9,000, and this is found at a temperature only a very few degrees below the critical point.

§ 113. **Whitworth's Hard Steel.**—Fig. 84, taken from the same source, relates to a sample of hard steel containing 0·96

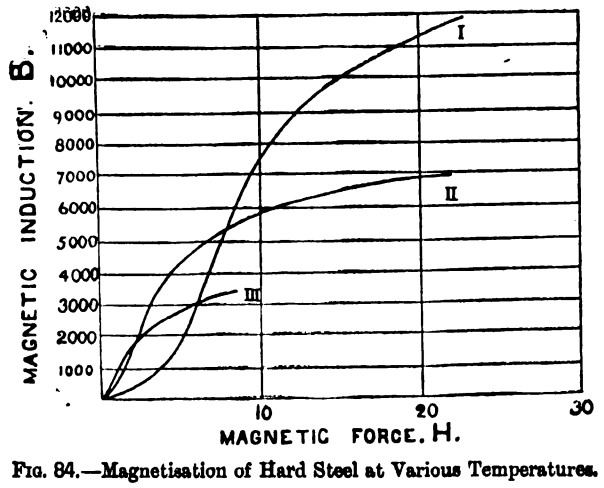

Fig. 84.—Magnetisation of Hard Steel at Various Temperatures.

per cent. of carbon. The sample was annealed before the observations were made. The three curves, I., II., and III.,

* All rights are reserved.

are for three temperatures, 9°C., about 522°C., and about 678°C. respectively. Fig. 85 is the curve of μ and temperature for the same sample, the magnetising force being 1·5. The loss of magnetic quality at the critical temperature is scarcely so sudden as in wrought iron and mild steel, and the influence of heating is more uniformly distributed at lower temperatures; but the same general characteristics are again obvious.

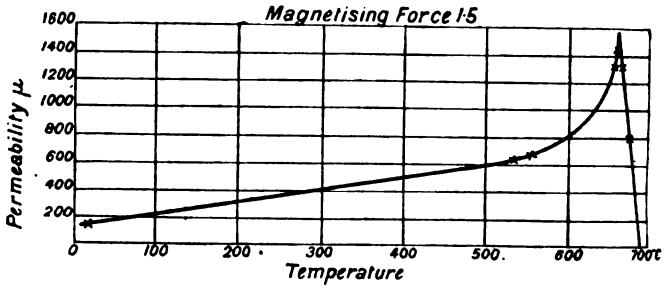

Fig. 85.—Relation of Permeability to Temperature in Hard Steel.

§ 114. **Hopkinson's Experiments with Nickel.**—In dealing with nickel, Hopkinson* has pursued the same method of experiment, using a ring, and finding, by the ballistic method, curves of magnetisation, while the ring was maintained at one or another of a series of temperatures which ranged up to the critical point at which magnetic susceptibility disappears. The specimen tested was impure, containing 95 per cent. of nickel, with about 1 per cent. (each) of iron, cobalt, and carbon, and 1½ per cent. of copper. Its critical point was about 310°C. A little below that temperature the susceptibility diminished very rapidly with rise of temperature, though there was no such excessively rapid loss of susceptibility as iron shows (under weak magnetising force) when the critical point is approached. At lower temperatures the susceptibility was observed to increase with rise of temperature when the magnetic force was low, but to decrease with rise of temperature when the magnetic force was high, in accordance with what has been already described as characteristic of the effects of temperature upon all the magnetic metals. Thus, taking curves of **B** or of **I** and **H** at any two temperatures (both well below the critical point) it is found with nickel, as with iron, that the curve for the lower temperature lies at first below and afterwards above the other. Figs. 86 and 87 give a selection of Hopkinson's curves. In Fig. 86 the curves of **B** and **H** are drawn for five temperatures: one is an ordinary atmospheric temperature, and the other four are high temperatures tending towards the critical point. At the first of these (245°C.) there is a marked gain of susceptibility for forces lying below 45 or 50; the whole group illustrates how the loss

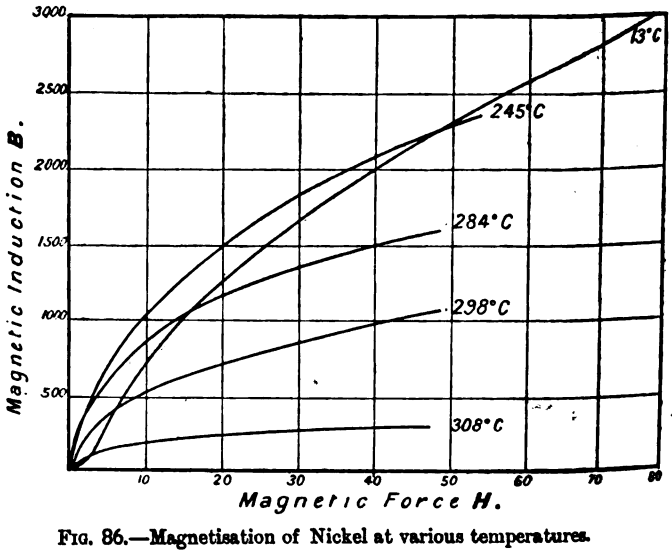

Fig. 86.—Magnetisation of Nickel at various temperatures.

of magnetic quality supervenes when the temperature is sufficiently raised.

* *Proc.* Roy. Soc., Vol. XLIV., 1888, p. 317.

Digitized by Google

The same results are shown in a different manner in Fig. 87. There the induction B is represented as a function of the temperature—the induction, namely, that is reached when the metal is magnetised at constant temperature by the application of the force which is specified separately for each curve. These curves should be compared with the curves of μ and temperature which have been given for iron and steel (Figs.71—81, and 85.

The main points of difference in the magnetic behaviour of nickel and iron with respect to temperature are, that in nickel the effects of temperature, when the temperature is low, are more considerable than they are in iron; that in nickel the critical point is much lower; and that in nickel the change from the magnetic to the non-magnetic state is much less

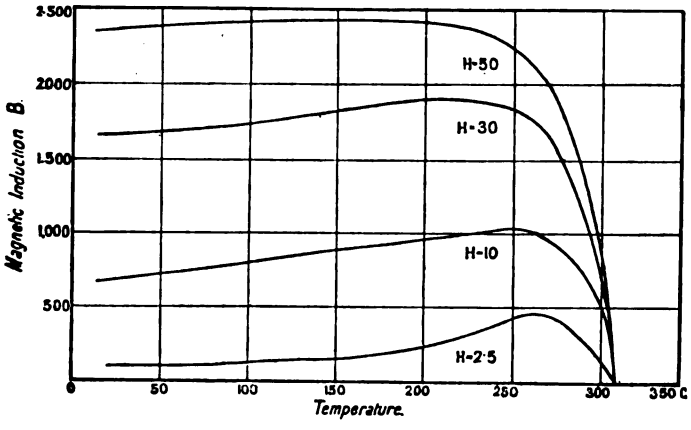

FIG. 87.—Magnetisation of Nickel at various temperatures.

abrupt than in iron. Perhaps for this reason the change is not associated with any such striking physical changes as accompany it in iron. Nickel does not recalesce, and an experiment of Hopkinson's* shows that the change from the non-magnetic to the magnetic state, as the metal cools, is attended by no sudden liberation or absorption of heat. Notwithstanding the fact that the specimen tested by Hopkinson was not pure the critical point found with it appears to be fairly representative of the critical point in nickel. In another sample tested by Du Bois†, the critical point again occurs about 300° C.

ON THE ELECTRO-DYNAMICS OF STATIONARY BODIES.‡

BY H. HERTZ.

(Continued from page 458.)

It will be noticed from the expression already given for the electro-magnetic energy that the quantities X. Y, Z, L, M, N have been defined in such a way as to have their physical dimensions the same for each. It follows from (1) and (2) that if we regard μ and ϵ as simple numbers, the quantity A is the inverse of a velocity. This quantity is, in fact, a constant of the ether itself, and does not depend on the existence of other bodies.

Multiply the equations given in (1) and (2), by L, M, N, X, Y, Z respectively, add them together, and multiply the resulting equation by $\frac{1}{4\pi A}\,d\tau$, when $d\tau$ is an element of volume. Integrate throughout a space bounded in any given manner, and let the normal to one of the surface elements, $d\omega$, make with the axes the angles (n,x), (n,y), (n,z). When the integration is performed, we obtain

$$\frac{d}{dt}\int\left\{\frac{\epsilon}{8\pi}(X^2+Y^2+Z^2)+\frac{\mu}{8\pi}(L^2+M^2+N^2)\right\}d\tau = \frac{1}{4\pi A}\int\begin{vmatrix}\cos(n,x) & \cos(n,y) & \cos(n,z)\\ X & Y & Z\\ L & M & N\end{vmatrix}d\omega \qquad (4)$$

This equation shows that the variation of the electro-magnetic energy contained in a given volume can be expressed in terms of quantities which only depend on the surface of the volume considered.

We may replace the quantities ϵ and μ by unity if we are considering the ether alone; and even for non-conductors the equations can be simplified by substituting for X, Y, Z, the quantities $X/\sqrt{\epsilon}$, $Y/\sqrt{\epsilon}$, $Z/\sqrt{\epsilon}$, and for L, M, N, the quantities $L/\sqrt{\mu}$, $M/\sqrt{\mu}$, $N/\sqrt{\mu}$, if at the same time we substitute $A\sqrt{\epsilon\mu}$ for A. The preceding reasoning has to be re-examined if we cannot suppose the body in question to be homogeneous; but investigation shows that, although for crystalline media the formulæ become much more complicated, the results arrived at are of the same general character.

Distribution of Electric Force in Good Conductors.—In those bodies which have been hitherto considered, every variation of electric force appears to be determined by the existence of magnetic force. If within a given space the magnetic force is zero, all cause capable of producing such disturbances disappears, and until magnetic perturbations penetrate within the region the electric forces remain constant. But this is not true of all bodies, for in a great number of substances electric forces when left to themselves diminish with more or less rapidity, and, in such cases, magnetic force is absolutely necessary to preserve the electric forces from variation. We shall call such substances good conductors. The most simple hypotheses we can make with regard to them are, that the diminution of electric force occurring in unit time is proportional to the strength of the force, and that the magnetic force tends to produce a variation independent of this loss, and equal to that taking place in connection with the bodies previously studied.

By the introduction of a new constant λ we can express the first hypothesis with regard to the component X of the electric force by the equation

$$A\epsilon\frac{dX}{dt} = -4\pi\lambda A X$$

The second hypothesis completes the first, and leads to the statement that a magnetic force exists whose variation takes place in accordance with the equation

$$A\epsilon\frac{dX}{dt} = \frac{dM}{dz}-\frac{dN}{dy}-4\pi\lambda A X$$

The constant λ may be called the specific electric conductivity of the body. Its dimensions are those of the inverse of a velocity. It follows that the quantity $\frac{\epsilon}{4\pi\lambda}$ is a time, that during which the electric forces when left to themselves diminish to a fraction $\frac{1}{e}$ of their former values, where e is the base of Napierian logarithms. We are thus led to the following equations, which are in perfect accordance with experiments:—

$$\left.\begin{aligned} A\epsilon\frac{dX}{dt} &= \frac{dM}{dz}-\frac{dN}{dy}-4\pi\lambda A X\\ A\epsilon\frac{dY}{dt} &= \frac{dN}{dx}-\frac{dL}{dz}-4\pi\lambda A Y\\ A\epsilon\frac{dZ}{dt} &= \frac{dL}{dy}-\frac{dM}{dx}-4\pi\lambda A Z\end{aligned}\right\} \quad \ldots\ldots\ldots (5)$$

These equations replace equations (2) which only hold true for non-conducting bodies. Equations (1), however, are true for both conductors and non-conductors.

If the body, instead of being homogeneous, is heterogeneous, a further modification must be made. If the properties of a body vary from point to point it is not true that electric forces allowed to subside naturally diminish till they ultimately vanish. The final value is constant, but not zero. It is independent of time, and is found greatest where the variation of chemical properties per unit length is most rapid. We shall modify our equations by supposing that the diminution occurring in electric forces abandoned to themselves is proportional, not to the absolute values of such forces, but to the excess of

* Hopkinson, *loc. cit.*, 319. † Du Bois, *Phil. Mag.*, April, 1890.

‡ An abstract of a paper published in the "Nachrichten von der Königlichen Gesellschaft, der Wissenschaften," for March, 1890; and reprinted in *La Lumière Électrique*, July, 1890.

Digitized by Google

the absolute values over the final ones. Thus, if X', Y', and Z' be the final values of X, Y, and Z respectively, equations (5) become

$$\left.\begin{aligned} A\epsilon\frac{dX}{dt} &= \frac{dM}{dz} - \frac{dN}{dy} - 4\pi\lambda A(X - X') \\ A\epsilon\frac{dY}{dt} &= \frac{dN}{dx} - \frac{dL}{dz} - 4\pi\lambda A(Y - Y') \\ A\epsilon\frac{dZ}{dt} &= \frac{dL}{dy} - \frac{dM}{dx} - 4\pi\lambda A(Z - Z') \end{aligned}\right\} \quad \ldots \quad (6)$$

For crystalline conductors, the properties of which vary with direction, it cannot be assumed that when the electric forces are abandoned to subside naturally the rate of diminution of each component of electric force is proportional to the value of that component. We must assume it to be a linear function of the three components. Thus, equation (1) must be modified so that each left-hand member is replaced by a linear function of $\frac{dL}{dt}$, $\frac{dM}{dt}$, and $\frac{dN}{dt}$. A similar modification occurs with the left-hand member of equation (6), and also with the last term on the right-hand side.

Boundary Conditions.—It is easy to see that equations (1) and (6) (modified when necessary for crystalline conductors) may be made to represent all possible cases by a suitable choice of coefficients. If now we consider these coefficients as functions of the coordinates we may regard the surface of separation of two heterogeneous bodies as a space in which, although the coefficients vary with extreme rapidity, the equations are nevertheless fully applicable and should enable us to obtain the boundary conditions. In order to arrive at them in the simplest manner possible, let us suppose that the plane of x y coincides with the surface of one of the elements.

If there is no electromotive force between the bodies in contact we see, from consideration of (1) and (6), that the values of $\frac{dX}{dz}, \frac{dY}{dz}, \frac{dM}{dz}, \frac{dN}{dz}$ remain finite from one side of the boundary to the other. If we indicate by suffixes $_1$ and $_2$ the side of the boundary to which a quantity refers we have

$$Y_2 - Y_1 = 0 \qquad M_2 - M_1 = 0$$
$$X_2 - X_1 = 0 \qquad N_2 - N_1 = 0$$

Thus the tangential component of the force at the surface of separation remains constant.

We also deduce from the last equation of (1) and of (6) that the quantities

$$\mu\frac{dN}{dt} \text{ and } \epsilon\frac{dZ}{dt} + 4\pi\lambda Z$$

have the same values on each side of the surface. The reciprocal dependence of the normal components of the force on each side of the surface takes the form

$$\mu_1\frac{dN_1}{dt} = \mu_2\frac{dN_2}{dt}$$

$$\epsilon_1\frac{dZ_1}{dt} - \epsilon_2\frac{dZ_2}{dt} = -4\pi(\lambda_1 Z_1 - \lambda_2 Z_2).$$

If there is an electromotive force across the bounding surface, we may assume that the component Z' of the force normal to the surface is infinitely great in the bounding layer, but of such value that the integral $\int Z'\,dz$ across the layer preserves a finite value, whose amount we may determine without knowing anything about the way in which Z' changes. We shall satisfy these suppositions by making the hypothesis that the quantity $Z - Z'$ remains finite throughout the bounding layer, as also the quantities L, M, N, X and Y. The quantity Z is thus infinite, but we can still suppose that $\frac{dZ}{dt}$ remains finite. Thus from the last equation of (6) we obtain

$$\int Z\,dz = \int Z'\,dz = \phi,$$

and if we integrate with regard to Z the first two equations of (1) and of (6) across the bounding layer, we obtain the following conditions, since, owing to the infinite thinness of the layer, the integral of each finite quantity vanishes.

$$Y_2 - Y_1 = \frac{d\phi}{dy},$$

$$X_2 - X_1 = \frac{d\phi}{dx},$$

$$M_2 - M_1 = 0, \qquad L_2 - L_1 = 0.$$

These equations, in conjunction with the third equations of (1) and (6), show that the quantities

$$A\mu\frac{dN}{dt},$$

$$A\epsilon\frac{dZ}{dt} + 4\pi\lambda A(Z - Z'),$$

have the same value on both sides of the separating surface; so that by comparison with the expressions obtained when no electromotive force was acting, we see that if the material on both sides of the bounding surface is homogeneous, the existence of the electromotive force has no influence on the conditions which connect the forces acting on the two sides. If the material is crystalline the same line of reasoning can be pursued, and leads to expressions identical with the above, except that for N we must substitute a linear function of L, M, and N, and for Z a similar function of X, Y, and Z.

As the boundary conditions, after all, only consist of particular aspects of equations (1) and (6), we need not in future complicate matters by troubling about the modifications in our expressions necessary to represent what happens at the surface separating different media. If we sometimes neglect to give the proof that these modifications are quite determinate, it will not be because we judge such proof superfluous, but because the above example will serve as a model for obtaining it.

In what we have hitherto studied, each section has added to the number of facts embraced by the theory, and in this respect the following sections will exhibit a contrast; for they will not add to the fundamental facts, and their value will consist partly in a simpler manner of expression, and partly in the union which they will establish between our theory and old views on electrical science.

(To be concluded.)

TESTS OF ACCUMULATORS OF VARIOUS MAKERS.*

Although the results of numerous tests of the best known accumulators have been published, a series of tests carried out simultaneously on different accumulators for the purpose of effecting as close a comparison as possible between them is not without interest. The test carried out recently by M. R. Kopp, and described in *La Lumière Électrique*, related chiefly to accumulators made by the Oerlikon firm, the Huber accumulator made at Marly-le-Grand, the Julien accumulator made by the Société l'Électrique of Brussels, and the Tudor accumulators made by Busche and Müller, of Hagen (Westphalia). These tests were carried out at the Physical Laboratory at Zurich Polytechnic. In every case differences of potential were measured by means of a well-standardised high-resistance (20,000 ohms) Wiedemann galvanometer. The current was measured by means of a tangent galvanometer with an eccentric magnet. The resistance was calculated by the general formula $r = \frac{E - e}{I}$. As, however, the difference $E - e$ at the middle of the discharge was only a few hundredths of a volt, its value was somewhat uncertain. The charge was stopped when the E.M.F. ceased to sensibly increase, and the discharge was pushed until the E.M.F. fell to 1·85 volts.

The Oerlikon Accumulator.—Tests were made of three distinct types of cell: one of old design; one of new design, with gelatinous electrolyte; and another of new design, with the ordinary electrolyte.

The non-gelatinous accumulator contained seven positive and eight negative plates, 14·5 × 14·8 × ·6 cm. thick. The plates were placed in an ebonite box at a distance apart of about ·9 to 1 cm.

* Translation of an article in *L'Électricien* by M. G. Roux, being an abstract of an article in *La Lumière Électrique* by M. R. Kopp.

Digitized by Google

This type of accumulator is used for the lighting of the trains between Zurich and Geneva. The weight of the plates is 14·4 kg., and that of the accumulator, when full, 20·4 kg. About ten preliminary charges and discharges were taken, and the accumulator was then overcharged and next discharged until the E.M.F. reached 1·9 volts. The density of the electrolyte varied from 1·17 to 1·25. The charging current was 14·5 amperes, and the discharging current 18 amperes.

Calling

Q_c the number of ampere hours put into the cell,
Q_d the number of ampere-hours taken out,
W_c the watt-hours $\int e_c I_c \, dt$ put in during the charge,
W_d the watt-hours $\int e_d I_d \, dt$ given out during discharge,
F_q the quantity efficiency,
F_w the energy efficiency,

we have the following results :—

Table I.

Number of test.	Q_c	Q_d	W_c	W_d	F_q	F_w
1	135·92	130·31	303·9	255·0	95·9	83·9
2	138·65	123·69	310·1	242·7	89·2	78·3
3	137·57	125·79	308·7	254·3	91·5	79·5

For some time the Oerlikon firm has been making gelatinous accumulators. The electrolyte consists of three volumes of acid having a density of 1·1, and of one to three volumes of silicate of sodium having a density of 1·2. The mixture is run into moulds and left for some time. It is then cut into slices of the requisite thickness and placed between the plates. It has been found necessary to keep this gelatinous mass wet by watering it from time to time.

An electrolyte of this kind has several advantages for traction work. It cannot be spilt, keeps the plugs in their places, and prevents short circuits. On the other hand, it has the inconveniences of retarding diffusion, thus increasing the resistance of the cell, especially at the end of the charge and discharge. Moreover, such an accumulator is quickly exhausted, and consequently its capacity is diminished.

The accumulator of the type C had the same dimensions as the previous one, but the plates were only 3 cm. thick. It contained 11 positive and 12 negative plates 6 cm. apart. The weight of the plates was 12 kg., and the total weight of the cell 18 kg. The normal rate of discharge of the cell was only 7 amperes, probably on account of the slowness of diffusion. The discharge was continued in this instance until E attained a value of 1·8 volts.

The results of the tests are given in Table II. :—

Table II.

Number of test.	Q_c	Q_d	W_c	W_d	F_q	F_w
1	112·76	94·15	244·82	176·5	83·5	72·1
2	112·66	94·73	244·79	177·7	84·1	72·6

If the rate of discharge was six or seven times greater, the efficiencies fell to 75·2 and 55·2 per cent. The resistance of the accumulator varied from ·003 to ·01 ohm.

The Huber Accumulator.—The Huber accumulator tested was of the portable type. Its plates were very thin, so that its capacity per kilogramme of plate was large. On the negative plates the square blocks of active material were pierced by circular holes 2 cm. in diameter, in order to increase the active surface. The dimensions of the plate were 15·5 × 16·7 × ·3 cm. The weight of the plates was 6·5 kg., and that of the accumulator complete 12 kg. The charging current was 12·5 amperes ; the discharging current 16 amperes. The results obtained are given in

Table III.

Number of test.	Q_c	Q_d	W_c	W_d	F_q	F_w
1	89·49	84·97	202·63	168·56	95	83
2	92·58	84·34	213·46	165·70	91	77
3	91·68	81·56	208·75	162·88	89	77
4	81·98	77·99	183·93	155·12	95	84

The resistance of the accumulator varied from ·003 to ·006 ohm, and the density of the liquid from 1·19 to 1·126. In other tests, when the discharge was pushed to the end instead of stopping at 1·85 volts, the efficiency was not diminished.

The Julien Accumulator.—The box of the accumulator tested was of wood, lined with lead. The seven positive and eight negative plates measured 23 × 18·5 × ·4 cm. They weighed 20 kg., the complete accumulator weighing 33 kg. The charging current was 24 amperes, and the discharge 28 amperes. The results obtained are given in Table IV.

Table IV.

Number of test.	Q_c	Q_d	W_c	W_d	F_q	F_w
1	251·6	224·7	570·8	445·5	89·3	78·0
2	247·9	225·5	562·2	446·8	90·9	79·5
3	250·7	230·9	572·0	450·4	92·1	80·3
4	247·5	226·7	555·1	447·7	91·6	80·7
5	248·9	223·7	551·9	447·5	89·9	81·1
6	246·4	229·2	560·3	445·5	93·0	81·4

The resistance of the accumulator varied from ·001 to ·002 ohm, and the density of the solution from 1·24 to 1·15.

The Tudor Accumulator.—The type of accumulator tested was intended for stationary work, consequently the plates were very thick. There were five positives and four negatives, measuring 16 × 19 cm ; the thickness of the negatives being ·7 cm., and that of the positives 1·6 cm. The weight of the plates was 25 kg., that of the cell complete 38·9 kg. The accumulators had been in use for several years, and the distance between the plates was sufficient to permit the plugs to fall freely to the bottom without danger of short-circuiting. The results of the tests carried out with this accumulator are given in Table V.

Table V.

Number of test.	Q_c	Q_d	W_c	W_d	F_q	F_w
1	98·05	92·29	214·07	179·10	94·1	83·7
2	100·10	86·15	218·56	168·42	86·0	77·0
3	91·34	84·65	197·20	164·35	92·7	83·3
4	93·84	86·95	205·63	171·78	92·6	83·5

The resistance of the cell varied from ·002 to ·003 ohm, and the density of the solution from 1·2 to 1·15.

Table VI.

Systems.	Useful capacity in ampere-hours.	Useful work in watt-hours.	Quantity efficiency per cent.	Energy efficiency per cent.	Weight of plates in kilogrammes.	Weight of accumulators in kilogrammes.	Useful capacity per kilogramme of plate.	Useful energy per kilogramme of plate.	Useful capacity per kg. of useful weight.	Useful energy per kg. of useful weight.	Total weight per h.p. hour.
Oerlikon accumulator, liquid electrolyte	126·6	250·6	92·2	80·6	14·4	20·4	8·8	17·4	6·2	12·3	59·8
Gelatinous electrolyte	94·4	177·1	83·8	72·4	12·0	18·0	7·9	14·8	5·2	9·8	75·1
Huber accumulator.	82·2	163·1	92·5	80·7	6·5	12·0	12·7	25·1	6·9	13·5	54·5
Julien accumulator.	226·8	448·7	90·9	80·2	20·0	33·0	11·3	22·4	6·9	13·6	54·1
Tudor accumulator.	85·8	168·0	92·6	83·7	25·0	39·0	3·4	6·7	2·2	4·3	171·2

In Table VI. is given a comparison of the accumulators under consideration. The Tudor accumulator being, as mentioned before, intended for stationary work, does not compare favourably with the rest. It is much to be regretted that M. Kopp did not indicate the useful capacity per square decimetre of *active service*, as this would have been a much more interesting factor than the capacity per kilogramme of active material.

The Peral Submarine Torpedo Boat.—The Spanish Government, says *Industries*, will soon publish the official report of the Naval Commissioners appointed to report on the trials of this submarine vessel lately made in Cadiz Bay. It seems that the report, though drawn up in very flattering terms for Lieutenant Peral, nevertheless recommends the Government not to construct any vessel of this class, as the trials have proved that the vessel is unseaworthy, and that it does not offer the conditions required for submarine navigation, even on coasts and in fine weather.

"THE ELECTRICAL WORLD" OF NEW YORK *can be obtained from* "THE ELECTRICIAN" *Office, Salisbury-court, Fleet-street, London, E.C. The Rate of Subscription (payable in advance), is* **£1 1s.** *per annum. Single Copies* **price 6d. each; post free, 8d.**

ELECTRIC LIGHT AND HEALTH.

In giving a *résumé* of the arguments for and against the supply of electrical energy by Local Authorities in his recent lecture at Brighton, Mr. PREECE certainly dealt impartially with the question although he felt himself compelled to begin with an expression of admiration of our "Grandmotherly Government," on the ground that cleanliness of dwellings, drainage of towns, removal of filth and of nuisance, purity of good water and air, have been controlled in a truly parental manner by Acts of Parliament. We do not propose to discuss in these columns the knotty question as to what extent domestic legislation is to be desired; but we would remark *en passant* that in all these examples the function of the State or of the Local Authority has been to ameliorate matters by the suppression of noxious elements, rather than by any new introduction, development, or supply, such as that of electrical energy. It is one thing to define the minimum quantity of deleterious impurities with which the gas companies may pollute the air we breathe, to say nothing of the carbonic acid, which amounts for each burner to the exhalations of ten persons. It is quite another to engage in purveying electric current. Whatever may have been the causes which have conduced to the carrying out of hygienic provisions and the enforcement of sanitary principles by the Home Office and the Local Government Board, it is hardly to be imagined that any Local Authority, among the many

Digitized by Google

that have applied for Orders, has been moved to do so by any regard for sweetness.

The arguments and figures given last week before the Sanitary Institute are interesting and not without value in themselves, but we can hardly hope that they will assist the development of electric lighting, since so little practical interest is taken in sanitary matters by the general public. The success of the Health Exhibition was not due to those who went to study patent traps and to examine new ventilators. Door-scrapers are more common than filters, though the cleansing effects of the latter are of greater importance than the obtrusively visible results of the former. While many people who would not hesitate to spend a hundred pounds in re-arranging the drains of a house prefer a gas burner to a pair of candles in their bedrooms, we can hardly expect that statistics about products of combustion will have much effect. Anything short of actual illness, whether it be due to bad atmosphere or errors of diet, receives but little attention. Several years ago Mr. Crompton drew a touching picture of the beneficial effects of electric light in the nursery; but it is difficult to induce people to realize the noxious influence of unseen mischief-working agents, such as microbes or carbonic acid. The serious amount of carbonic acid which is actually given off by gaslighting is due to the large amount of light which is commonly produced. Many people prefer to write by the light of two candles, and a similar illumination is considered sufficient for most dressing tables; but if gas is used a fourteen or sixteen candle burner is provided, often in an inconvenient position selected by the builder; and it is enclosed in a shade which cuts off from a quarter to half the light. The sulphur, sulphur compounds, and the unburned gas which are given off, are much more harmful than the simple carbonic acid, the amount of which given off by gas is, light for light, a little less than for sperm candles. An equally insanitary effect of gas is the great heat emitted both by radiation and as hot vitiated vapour-laden air. A glow lamp gives out, and as radiant heat alone, only one forty-seventh part of the heat given by a gas-burner of the same power.

The main question with the large majority of those who inquire about electric light is its price, as compared with that of gas. While we cannot at present see how a station on as large a scale as that at Deptford, and with an economy of production as great as that of the Kensington and Knightsbridge or the St. James and Pall Mall Company, can produce light from glow lamps to compete with gas at 2s. 3d. per thousand feet, we may be quite sure that we have not yet arrived at the finality which has been practically attained by gas. That industry, while it has by no means come to a standstill as regards new improvements, has reached a stage at which it is unlikely that any invention will be introduced which will reduce the price by two or three pence per thousand; but there is every probability that electric light will be cheapened to a considerably greater extent, even without any radical change in the efficiencies of lamps or in the systems of distribution.

But to return to the pros and cons from the sanitary point of view. Mr. Preece repeats a statement which he made some time ago as to the effect of electric light on the health of those who have to work in rooms where it is used. Since lighting by electricity has been introduced into the large and substantial building in Queen Victoria Street, which contains the chief offices of the Savings Bank Department of the Post Office, the extra work which has been done there, owing to the decreased number of absentees among the twelve hundred persons employed, has actually been sufficient to pay for the running expenses of the electric light, and a similar result has been observed at Liverpool and other places. The causes of ill health are generally invisible, but a result of this kind is of a very visible and objective character; and though it can only be distinctly recognised and quantitatively estimated in a thoroughly organized establishment such as that of a Post Office Department, it may be confidently asserted that it can be attained elsewhere by similar means.

We alluded recently to another tangible asset which may be credited to the electric light; and it is one which, as in the case of the Post Office *employés*, can be estimated in pounds, shillings, and pence, which appeal too often more eloquently to the employer than the pale cheeks and ailing of the workers. The absence of dirt and smoke, and the resulting decrease in the cost of redecoration, is very marked where the electric light replaces gas, even when the latter is carefully arranged. The cost of the pure light is so little greater than that of gas that the difference is amply made up by saving in renewals of decoration. Moreover now that we are aware of the enormous waste of energy which takes place in producing light, a great change will surely come before long, which may sweep away our modern dynamos. Though a glow lamp needs less than one twenty-seventh part of the energy required by an oil lamp giving an equal amount of light, and the arc light takes only a hundred and fifteenth part of that required by gaslight, the actual energy needed to set up the oscillations which we call light is vastly less. The day will come when, either by subjecting them to stewing and electrolysis after the manner of M. Dubois, which is described in another column, or by the patient watching of their habits and study of their mode of life by another Darwin, the glow-worm will be compelled to yield its secret, and the fire fly its mysterious economy, and we shall use the methods of these humble creatures who set the ether in vibration with so little apparent trouble.

NOTE ON THE USE OF SAUNDERS' CAPACITY KEY IN COMPARING CAPACITIES.

BY DR. ALEX. MUIRHEAD.

In *The Electrician* of June 20, page 170, an illustration and short description was given of Saunders' capacity key. This instrument is used in the following method of comparing condensers.

The method now generally adopted by telegraph engineers in comparing telegraph cables with condensers of known capacity was first published by Sir William Thomson in Vol. I. of the *Journal* of the Society of Telegraph Engineers, pages 397 and 398; and it may be considered as the converse of De Sauty's method of comparing the capacities of condensers by Bridge system (see page 379 of Sabine's "The Electric Telegraph," 1867). A description of the method will be found in the fourth edition of Kempe's Handbook of Electrical Testing, under the title of Gott's method, pages 339 and 340. The formula given by Kempe in connection with this method, viz., $F_1 = \frac{R_2}{R_1} F_2$. [$F_1$ and F_2 being the capacities of the two condensers compared, $\frac{R_1}{R_2}$ the ratio of the potentials to which they are charged respectively] is correct only when the balance of potential between F_1 and F_2 has been obtained immediately after the application of the battery and before the difference in the absorption of the two condensers has had time to take place.

That is to say: After making contact with battery, supposing the charging of the condensers in series to be instantaneous and the absorption *nil*, the formula would be correct, for there

Digitized by Google

will then be an initial charge on each condenser of $Q = v\,F_1 = (V - v)\,F_2$, where v is the potential of the junction of the two condensers and V the full potential of the slides, Fig. 1.

$$\frac{V - v}{v} = \frac{R_2}{R_1} \therefore F_1 = \frac{R_2}{R_1} \cdot F_2.$$

Should there be, however, when condensers which differ in their rates of absorption are compared, any delay in obtaining a balance or reading on the slides, the potential of the junction of the condensers will vary, until at any instant it becomes, say, v_1, then, at that instant, the charges in the two condensers will be $(F_1 + f_1)\,v_1$ and $(F_2 + f_2)\,(V - v_1)$ respectively, where f_1 and f_2 are the apparent increase in the capacities due to absorption or soaking in of charge.

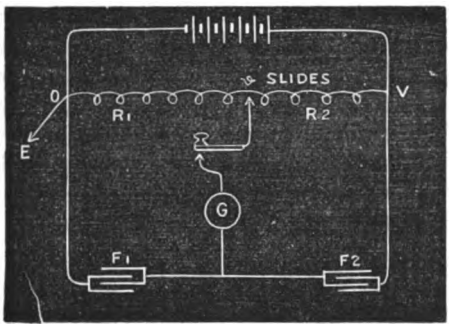

Fig. 1.

And on disconnecting the armature of F_2 from the slides and putting it to 0 or earth, its potential falls from V to 0, and immediately afterwards the potential of the junction of the condensers will be not 0, but, say, v_2; so that

$$F_1 v_1 - F_2 (V - v_1) = (F_1 + F_2)\,v_2.$$

Hence, $$(F_1 + F_2)\,v_1 - F_2 V = (F_1 + F_2)\,v_2;$$

or, $$(F_1 + F_2)\,(v_1 - v_2) = F_2 V;$$

or, $$\frac{F_1}{F_2} = \frac{V - (v_1 - v_2)}{v_1 - v_2}.$$

Therefore, in the above formula v_2 is the proper correction to make in order to reduce the observed v_1 to the true value at which it would have were there no absorption. It is necessary that v_2 should be measured at once before the oozing out of the charge absorbed by the dielectrics of the condensers begins, in which case $v_1 - v_2 = v$, otherwise it will slowly change and a wrong value will be obtained.

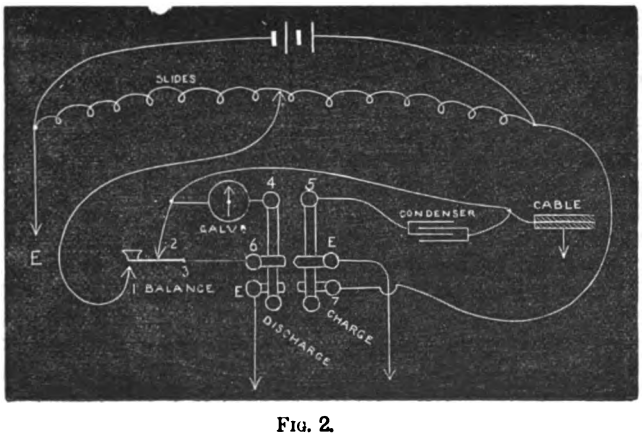

Fig. 2.

V and v_1 are known, and v_2, when a galvanometer is used, can be measured without delay in the following manner:—

As soon as v_1 has been observed, break the galvanometer circuit and shift the index of the slides down to zero quickly, then directly after bringing the armature of F_2 from potential V to zero, close the galvanometer circuit again, and observe the instantaneous throw α, which is a measure of v_2, the potential of the junction of F_1 and F_2. To get the value of v_2 from α, break the galvanometer circuit, and move the index of the slides up—say, 10 studs, again close the galvanometer circuit, and observe the throw β, then $v_2 = \frac{10\,\alpha}{\beta}$. If the throws α and β are in opposite directions, the equation given above is correct; if in the same direction it becomes

$$\frac{F_1}{F_2} = \frac{V - v_1 - v_2}{v_1 + v_2}$$

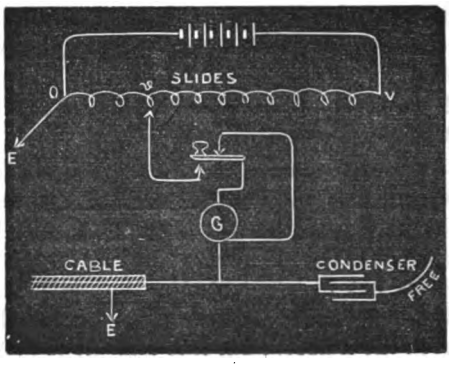

Fig. 3.

With the key designed by Mr. Saunders, Electrician-in-Chief of the Eastern Telegraph Company, all the operations described above in comparing capacities according to Sir William

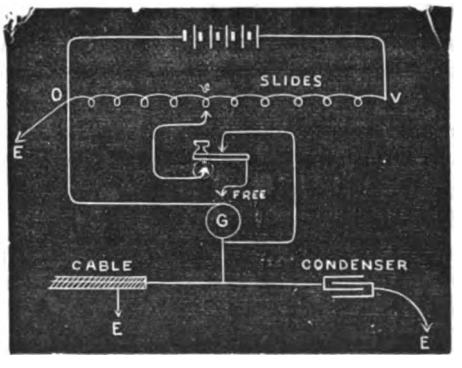

Fig 4.

Thomson's original method, can be quickly and effectively carried out. All the parts of the key are shown diagrammatically in Fig. 2, with the connections to slides, standard con-

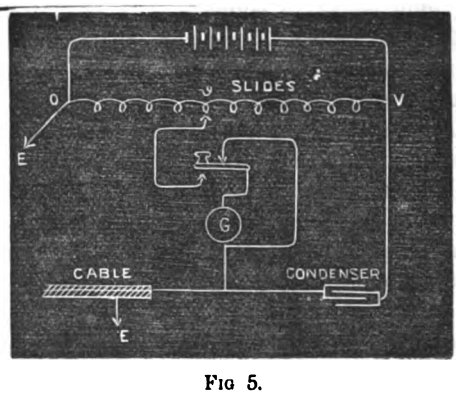

Fig 5.

denser, and cable, when joined up for capacity testing. When both levers of the key are "*up*" the connections are as shown in Fig. 3. Fig. 4 shows the connections when the lever marked "discharge" is "*down*," both cable and condenser being then to earth. On depressing the lever marked "charge," the condenser and cable are connected up in series to the battery and slides, as shown in Fig. 5. On depressing the "discharge" lever, the "charge" lever is automatically raised by means of the ebonite bar pivoted below the levers, which device is seen

Digitized by Google

in the illustration of the key on p. 170. During the descent of the lever the connections are as shown in Fig. 6, removing the condenser from the slides and putting it to earth, and afterwards, as shown in Fig. 4, discharging both condenser and cable through the galvanometer to obtain the correction throw a.

To illustrate the importance of making a correction for absorption in the method above described, I give the following tables, taken from a report by Mr. Lilley, electrician on board the ss. Chiltern. Table I. is the result of a comparison of a mica condenser of ·3366 microfarad capacity against 1·4 knots of gutta-percha core at my laboratory; and Table II. of the

NOTES ON HIGH VACUA.*

BY J. SWINBURNE.

I.

In a series of Papers on "Incandescent Lamp Manufacture" contributed to *The Electrician* in 1887, I called attention to the great superiority of the Geissler to the Sprengel form of mercury pump. Several kinds of Sprengel pump were successively connected to a Geissler, and both were worked at the same time. The Sprengel invariably stopped taking air down before the Geissler, in fact, the Geissler never stops. It acts as its own McLeod gauge, and never indicates a perfect vacuum. The probable reason why the merits of the Geissler have been so underrated is that it needs the greatest care in securing perfect dryness of the bulb and valve. Not only will traces of water vapour condense under the floating valve instead of lifting it and going through, but it is probable air does so too. About a century ago Davy showed that if the mercury were allowed to run up gently in an imperfect Torricellian vacuum, a bubble was left; but if allowed to rise suddenly, it indicated a perfect vacuum, the air being condensed against the glass. In the Lamp Papers I described a form of pump which avoids difficulties due to small condensations. The main bulb discharges into a small chamber sealed by a little V tube, so that a pressure of 1/100 A would move the mercury.

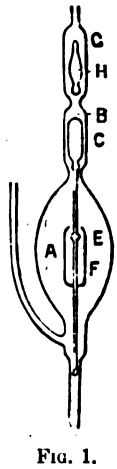

Fig. 1.

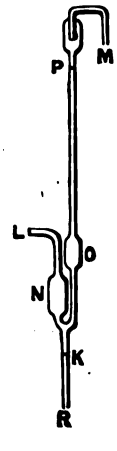

Fig. 2.

This chamber exhausts into a larger globe, exhausted mechanically, and sealed by a floating valve. The small chamber is thus as thoroughly exhausted as an ordinary pump can pump it; but the pump proper, exhausting into high vacuum, can thus work better. The condensed air and water cannot expand back into it. It is thus really a double pump, or two mercury pumps in series. The only drawback is that it needs some pressure to open the first valve or sealing, so that there might, after all, be some condensation under it. I have lately devised and used a pump made as follows:—A (see Fig. 1) is the body or chamber of the pump proper. This exhausts into the small chamber B, sealed by the valve C, and this exhausts into the chamber G, sealed by the floating valve H. G is connected to a reservoir and mechanical air-pump. The valve C has a long thin glass rod passing down through A into the lower tube, which acts as a guide. A loose sleeve, F, is strung on this rod. There is a swelling at E which fits the lower end of the sleeve, and is small enough to pass through the neck in putting the pump together. When the mercury rises in the globe A it lifts the sleeve till the lower end catches on E, which closes it. The mercury rises, and floats the sleeve, thus lifting the valve C. The mercury that sealed C then runs out, and there is a clear passage through into B; so no condensation takes place in A. The mercury rises till it floats H. When it falls, the valve C acts again, for the mercury has filled the sleeve F over the top, and C is heavy enough to sink the sleeve and rod when the sleeve is full of mercury. I have tried electro-magnetic and other arrangements; but this is the best as far as I have gone.

* Paper read before the British Association in Section A, Leeds, September, 1890.

When using a pump it is best not to let air, and perhaps moisture, run through it more than can be helped. By the use of a sort of siphon it is possible to seal on new work to be exhausted without letting the air-pressure into the pump.

The point K (see Fig. 2) is the barometric height at which the mercury normally stands in the tube R. There is then a clear passage between L, which is connected to the tubes to be exhausted, and M, which goes to the drying tubes and pump. When a tube has been sealed off and a new one is to be put on, the mercury reservoir at the foot of the arrangement is raised so that the bulb N is filled. A tap at the foot of the tube R is closed and the vacuum in L is broken. The mercury then runs up to the new barometric height P. The new tube is then sealed on and exhausted by a mechanical pump, the connection being then sealed off. The mercury in the long tube then stands only half an inch or so above that in N, and on opening the tap at the foot of R, the communication is made again to the pump. The small bulb O, and the trap at the top are to prevent a plug of mercury from going round into the phosphoric tubes.

The pump is driven by water so as to be self-acting, and can be left running for any length of time. Those who have worked much with mercury pumps will realise the value of this. Nothing makes one feel the futility of life more than to exhaust something by hand which cracks at the last stage, when five hours of life have been ticked off.

II.

In the same Papers on Lamp Making I urged that the methods of measuring high vacua were inaccurate and completely misleading. The McLeod gauge and the induction coil are usually relied on for testing vacua. In incandescent lamp work the induction coil is almost exclusively used. With the test by induction sparks, I have, at present, nothing new to add, and will confine myself to the McLeod gauge. In measuring vacua with this gauge it is assumed that the mercury itself has no vapour tension. The vapour tension of mercury has been given by Regnault as about 50 millionths of an atmosphere. If it is anything like this, of course a vacuum of one millionth, or of ·005 millionth, as some experimenters profess to have reached, is absurd. When discussing this subject at the Society of Arts after Dr. S. P. Thompson's well-known Paper on "Mercury Pumps," Prof. Ramsay gave ·25 millionth of an atmosphere, or, as I shall write it shortly, ·25M. as the vapour tension of mercury at ordinary temperatures.

The whole action of a pump is consistent with a vapour tension of from 25 to 50M. A Geissler does not reduce the pressure in geometrical progression; but when it gets a good vacuum it takes out very little air each stroke, worked fast, and much more if worked slowly. This looks as if when the tension of mercury vapour was nearly reached, the air taken out at each stroke was what diffused into the mercury vapour. This would also explain why a Geissler, which goes on long after a Sprengel stops, does not so readily make a sparkless tube. A Sprengel stirs up the mercury, and gives the tube being exhausted more chances of getting filled with mercury vapour, which is a non-conductor. This also explains why so many experimenters get better vacua with hot mercury. Of course a new pump should be heated to get the moisture off the glass, but not when it is in ordinary use.

To test this more directly I attached two McLeod gauges to the same pump. They communicated till a fair vacuum was reached. One was then sealed by raising the mercury past the elbow tube. The gauges were allowed to communicate by lowering the mercury every now and then, and it was always lowered before taking a reading. By this arrangement, when the pressure was reduced nearly to the vapour pressure of mercury, one gauge might have little but mercury vapour, and show a good vacuum; while the other had air at the same pressure, and showed a pressure equal to the vapour tension of mercury, or nearly so. The gauges are graduated by finding $p\,v$ corresponding to one-millionth of an atmosphere, and graduating accordingly. The pressure in millionths is then the product of the reading on the closed tube and the difference in the column. Each reading is thus readily taken at several pressures to make sure there is no condensation of any vapours or gases. The readings obtained varied in an extraordinary way. When the exhaustion was carried so far that the open gauge registered 2M or 3M, the closed registered from 20M to 60M. The least difference in temperature seems to make a large difference in the readings. In some cases, when the vacuum was still low, the open gauge was heated till the mercury sputtered, and condensed about the bulb. The bulb was then warmed to evaporate the mercury and drive all the air out, and the elbow tube sealed by raising the mercury. When the gauge was cool both were unsealed and readings taken. The gauge that had been warmed sometimes gave 1M against no less than 230M in the other. Ten minutes' connection generally brought the readings equal. Obviously the movement of the air need not depend on diffusion only; for a very small difference of temperature would cause mercury to evaporate in one gauge and condense in the other, driving the air with it.

I made a gauge with an alloy of about equal parts of potassium and sodium, which is liquid at ordinary temperatures. It would, of course, absorb any mercury vapour, and has probably a low-vapour tension. It was very troublesome, for it could not be exposed to the air for a moment, and heavy hydrocarbons would prevent the pump's working. The alloy always gets some moisture, and gets coated with a thin film of oxide which prevents drops from uniting, and they can only be run together by heating under a hydrocarbon of low boiling point. I eventually got the gauge fitted up, but the alloy acted on the film of moisture on the glass, and the bubbles formed seemed to drive plugs of it about. It has a very low specific gravity, and pistons of it began to stray about inside the pump, and I was afraid they might get to the mercury, and by combining explosively, smash the pump, so the experiment was abandoned. In one experiment a plug of the alloy wandered into the mercury in R and cracked the tube.

Fusible alloy was next tried. It worked better, but the vapours of some sulphur that was used to trap any mercury vapour blackened the surface, and only two readings were obtained. These gave a pressure of only 13·5M as the vapour tension of mercury.

Whether it is really 13M or 50M is of comparatively little importance; but there seems to be quite enough evidence that the readings of ·01M and higher vacua that have been given are inaccurate to the extent of some hundreds of thousands per cent. This is important in many investigations pursued by means of mercury pumps, for instance, experiments on the "Fourth State of Matter." The question is also important in lamp making, as it shows that better vacua are possible, and they may be an advantage. I do not know whether pumps worked with alloy of sodium and potassium will come into commercial use.

ON A NEW METHOD AND DEPARTMENT OF CHEMICAL RESEARCH.*

BY DR. G. GORE, F.R.S.

Method of Working.

In an investigation "On the Change of Potential of a Voltaic Couple by Variation of Strength of its Liquid" (Roy. Soc. *Proc.*, 1888, XLIV., p. 296), I showed that by immersing a small pair of unamalgamated zinc and platinum plates in distilled water, then adding to the water successive small and equal quantities of a particular halogen, acid, or salt, until a more or less saturated solution was formed, and measuring by the method of balance with a galvanometer in the circuit, with a suitable thermo-electric pile (see *Proc.* Birm. Phil. Soc., IV., p. 130: also *The Electrician*, 1884, XII., p. 414), aided when necessary by a zinc-platinum distilled water-cell, or a Clark's standard cell, the change of electromotive force produced by each addition of substance, did not vary by a regular gradation. And I stated that "by plotting the quantities of dissolved substance as ordinates to the degrees of electromotive force as abscissæ, each substance or mixture of substances yielded a different curve of electromotive force on uniformly changing the degree of strength of its solution." And that "with a given voltaic couple at a given temperature, the

curve was constant and characteristic of the substance." The examples given in this Paper illustrate these statements, and the measurements were made by the above method.

Instead of employing a thermopile, the following plan with the "voltaic balance" might be adopted :—1st. Balance two small zinc-platinum voltaic cells with distilled water in each, and a galvanometer of 100 ohms resistance in the circuit, then add gradually sufficient of the exciting substance to one of the cells to just visibly upset the balance, and note the quantity added. 2nd. Balance the cells with a very weak solution containing one unit quantity of the substance in each cell ; then add a sufficient excess of the substance to one cell to again upset the balance, and note the amount of excess. 3rd. Balance the cells with a two-unit quantity solution, and upset the balance again in like manner. And so on through such a series of strengths of solution as may be desired to obtain a curve. The proportions of excess of substance added to the amount of water in the cell represent the relative amounts of voltaic energy of the different strengths of liquid.

This method is very much more sensitive than the one with the thermopile, for whilst the latter only divides the range of difference of potential between water and chlorine for example (= ·753 volt), in practical working into about 15,000 parts, the former divides it into 1,200 millions. On the other hand, whilst by the thermopile method the values of the unit of measurement are equal throughout a series, those of the numbers obtained by the voltaic-balance one vary with the degree of strength of the solution.

A. Curves obtained by Varying the Strength of the Solution at Both Metals.

Nearly all the measurements of electromotive force given in this Paper were made with highly pure substances, and in Section "A," with the exception of one instance only, each curve starts from the potential of unamalgamated zinc and platinum in distilled water at about 16° C. = 1·127 volt. The quantity of distilled water employed as the solvent was in nearly every case 155 grains, and the series of degrees of strength of the solutions of each substance were usually such as could best be worked by the process, *i.e.*, neither too strong nor too weak, and were with different substances either the same or so arranged as to best enable comparisons to be made between the results of the different series of measurements ; they were not always sufficiently strong to fully develop the most characteristic curves. For each separate measurement, with the solutions of the halogens and the strong ones of the acids, a fresh portion of the original liquid was taken ; with those of other substances the zinc was so feebly acted upon and the liquid so slightly altered in composition, that this was not found necessary. With solutions of salts, the presence of films of oxide upon the zinc was tested for by replacing the saline liquid by distilled water, and then observing whether the cell was still exactly balanced by a zinc-platinum water one. No trouble was experienced from polarization caused by hydrogen in the platinum plates, nor by atmospheric air dissolved in the water.

Curves of Chlorine, Bromine, and Iodine (Fig. 1).

The range of strength of the solutions of each substance was from ·001 to ·01 grain in 155 grains of water. With solutions of these substances the degree of electro-motive force increased somewhat with the period of immersion ; this difficulty was due to the great chemical energy of the substances, and was overcome by making the fluctuations of the galvanometer-needles equal on each side of zero.

Curves of HCl, HBr, *and* HI.

a. *Weak Solutions* (Fig. 1).

Each acid was pure and colourless. The solutions were of the same range of degrees of strength as those of the halogens, in order to compare the effects of the two groups of substances ; and the curves are all drawn on the scale of magnitude in each direction as those of the halogens.

Curves of HCl, HBr, *and* HI.

b. *Strong Solutions* (Fig. 2).

These solutions were one hundred times stronger than the previous ones in order to fit them for comparison with those of the corresponding salts ; they contained from ·10 to 1·0 grain of substance in 155 grains of water. The degrees of electromotive force of the solution of hydrochloric acid were variable, and those of the other two acids less so. These curves are drawn upon a scale 2·92 times as large vertically as those of the previous ones, in order to fit them for comparison with those of the corresponding salts ; the curves are more characteristic and present a much greater degree of irregularity of form ; this was a genuine effect, and was not due to temporary fluctuations of the current.

Curves of KCl, KBr, *and* KI (Fig. 3).

All the substances were highly pure, colourless, and inodorous ; the iodide was very faintly alkaline. The solutions were of the same range of degrees of strength as the strong ones of the corresponding acids, viz., from ·1 to 1·0 grain of substance in 155 grains of water. The electromotive force of the zinc-platinum couple increased somewhat with the period of immersion. The absence of solid films upon the zinc was proved by occasionally replacing the saline liquid by distilled water, and observing whether the cell was still exactly balanced by a zinc-platinum water one.

Curve of KBr *at* 60°C. (Fig. 4).

The range of degrees of strength of the solution in this case was the same as in the previous one, when the liquid was at 18°C., and was from ·10 to 1·0 grain of substance in 155 grains of water.

On comparing the two curves obtained at the two temperatures we find considerable differences, viz. :—1st. A great unlikeness of general form. 2nd. A general and large diminution of electromotive force at the higher temperature. And 3rd. A much smaller increase of that force on the addition of the first portion of the substance. The differences would probably have been less conspicuous if the solutions in each case had been much weaker. These results support the conclusion that potassium bromide behaves to a certain extent like a different substance at each different temperature.

Curves of Isomeric Electrolytes (Fig. 5).

I have already shown (see *Phil. Mag.*, October, 1889, p. 289, "On the Molecular Constitution of Isomeric Solutions") that aqueous isomeric electrolytes yield different amounts of voltaic energy with a zinc-platinum couple. In the present case I employed the same pair of mixed aqueous solutions as were used in that research, viz., an unstable one, "A," having a composition represented by the formula $Na_2SO_4 + 2HNO_3$, and yielding an average voltaic energy = 77,446 ; and its stable isomer, "B," represented by $2NaNO_3 + H_2SO_4$, and yielding 32,722. The degrees of strength of the series of solutions employed were those which were the most easily worked, and were from ·01 to ·1 grain of the mixture in 155 grains of water. The constituent solutions of "A," previous to being mixed, contained ·01 grain of substance per cubic centimetre ; if they were stronger than this there was risk of the liquid undergoing a chemical change during the mixing.

These curves show, much more completely than any single pair of measurements of voltaic energy could do, the considerable differences between the molecular and chemical constitutions of the two liquids. Nearly throughout its entire range the curve of "A" shows a greater degree of electromotive force than that of "B." As the unstable liquid "A" is readily changed into the stable one "B" by merely heating it to nearly 100° C. in a stoppered glass flask during 15 minutes, and then would give the curve of "B," it is evident that the method of examining aqueous solutions by means of curves of electromotive force is applicable for detecting and measuring chemical and molecular changes in them.

B. Curves by Varying the Strength of the Solution at One Metal only.

The kind of apparatus employed is shown by the annexed sketch (Fig. 6), and is formed of glass. A weak solution, containing one grain of the substance in 465 grains of water, was put, together with the negative metal, platinum, into the short leg of the tube, and successive portions of solution, of regularly decreasing strength, in 465 grains of water, were put, together with the positive metal, unamalgamated zinc, into the long leg, and the electromotive force with each strength of solution was measured. The positions of the metals were then reversed, and the measurements repeated. The glass tap was closed during the process of changing each strength of liquid. In consequence of the much greater conduction resistance in the constricted portions of the solutions, the degrees of electromotive force were all much smaller than if the two metals had been near each other in the same leg. Fig. 7 shows the results obtained with solutions of KBr.

The curves show that the variation of strength of the liquid had a large effect upon the electromotive force at the surface of the zinc, but scarcely any such effect at that of the platinum ; and we may conclude that when such variation of strength occurs at both metals simultaneously, the effect upon the electromotive force, and consequently also upon the form of the curves, is nearly wholly due to changes of chemical action at the surface of the zinc, and but little to such changes at the platinum.

C. Curves by Varying the Temperature of the Solution at Both Metals.

The solution contained ·01 grain of HCl in 155 grains of water, and the electromotive force was measured every five centigrade degrees from 10°C. to 100°C.

Digitized by Google

The curve in Fig. 8 shows:—1st. That the electromotive force varies with the temperature. And 2nd. That a regular variation of temperature of the solution is attended by an irregular change of electromotive force. It is probable that the curve obtained by varying the temperature is characteristic of the substance, and would be different with every different substance and degree of strength of its solution.

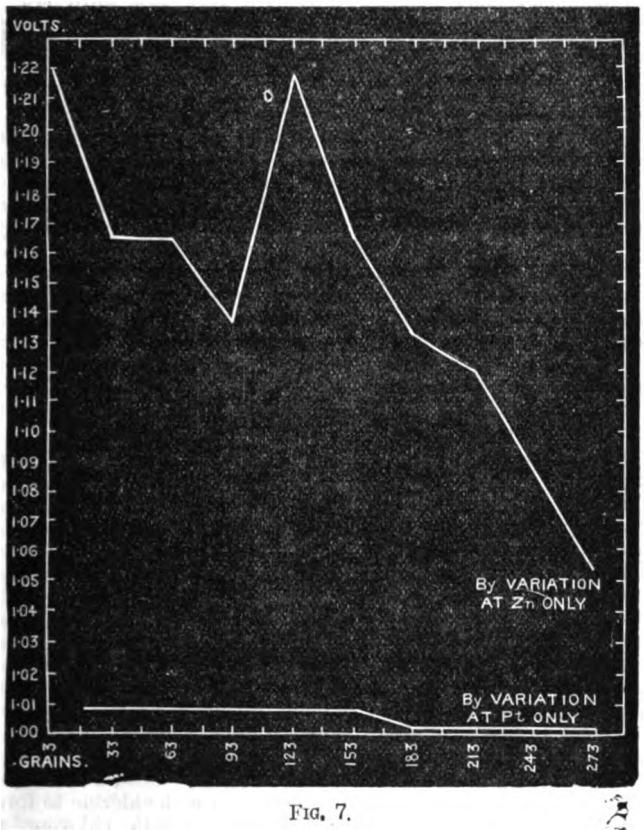

FIG. 7.

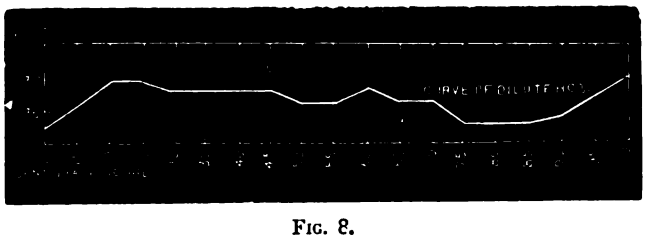

FIG. 8.

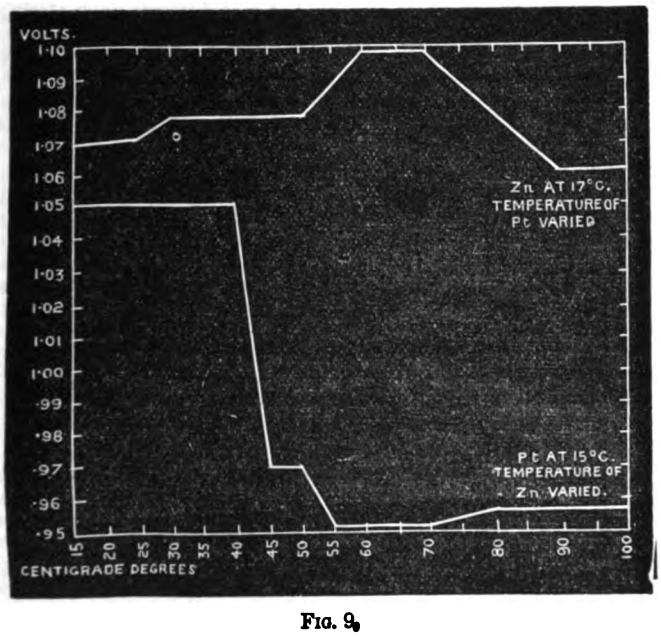

FIG. 9.

D. CURVE BY VARYING THE TEMPERATURE OF THE SOLUTION AT ONE METAL ONLY.

In these measurements the large bent glass tube was employed (*see* Section "B"). The liquid consists of 39 grains of potassium chloride dissolved in 465 grains of previously-boiled distilled water. In one series of measurements the zinc was immersed in the heated portion of liquid, and the platinum in the cold portion; and in the other series the reverse. Fig. 9 shows the curves obtained.

The two curves are very different. The greatest variation of electromotive force was at the zinc, and was = ·103 volt, whilst that at the surface of the platinum was only = ·04 volt. The results show that the change of electromotive force which occurred on gradually heating an electrolyte and the two metals in it is a concrete effect of two influences, one of which is situated at the surface of the positive metal and the other at that of the negative one. Each of these two influences itself would also probably be a compound effect of the separate actions of heat upon the metal and upon the liquid. These general effects of variation of temperature described in Sections "C" and "D" are very similar to those of change of strength of liquid given in Sections "A" and "B."

E. GENERAL AND THEORETICAL CONSIDERATIONS.

The evidence obtained by this research shows:—1st. That every different electrolytic substance when in aqueous solution gives, by varying the degree of strength of its solution (or by varying its temperature), a different curve of electromotive force. 2nd. That this curve is characteristic of the substance. 3rd. That under these conditions, substances which constitute a recognised chemical group yield a series of curves which usually exhibit a gradation of likeness of form. 4th. That the degrees of electromotive force of such a group usually vary in magitude inversely as the amounts of the atomic and molecular weights of the substances. 5th. That a much greater increase of electromotive force is usually caused by the first amount of substance added to the water than by the subsequent amounts. 6th. That the chemical union of two substances to form a soluble salt is attended by a definite decrease of electromotive force and a definite change of form of curve. 7th. That the substitution of one halogen, acid, or metallic base for another in the composition of a soluble electrolytic salt, is accompanied by a definite amount of change of that force and of the form of its curve; and it will be possible to trace, by means of these changes, the presence of each halogen, acid, and metal in the various solutions of its salts. 8th. That isomeric solutions of electrolytic substances give different curves under the same conditions, and may thus be distinguished from each other. 9th, That molecular and chemical changes and their rates, in electrolytes, may be examined and measured by this method. And 10th. That if the solutions of the substances are too weak, the characteristic forms and differences of the curves are not fully developed, and if they are too strong the measurements of electromotive force are more difficult to make. As the measurements were made at the null point when no current was passing, the curves represent the electromotive forces and molecular motions which exist under that condition; when the current passes, the molecular movements are greatly altered.

The changes of electromotive force and forms of curve obtained, —1st, by the same variations of strength of the same solution at two different temperatures; 2nd, by varying the temperature of a solution without changing its strength; and 3rd, by varying its temperature at the positive metal only, or at the negative one only, support the general view that each substance becomes more or less a different substance at each different temperature, and that the degrees of property of each substance at different temperatures are practically infinite in number.

The results in general support the kinetic theory that the most fundamental attribute of matter is motion, that a mass of matter is a mass of motion, that each substance consists essentially of a collection of molecular motions, and that the chief properties of bodies are consequences of such motions. Changes of volta-electromotive force are now generally recognised as being due to those motions, and as being disturbances of the universal ether which pervades all bodies and all space. Each degree of such force may also be regarded as a concrete result of an extensive series of molecular vibrations of extremely varied degrees of amplitude; this series being characteristic of the particular material combination producing it, analogous to the collection of vibrations producing a beam of light of a particular burning substance. The curves represent in addition the changes in amount of these motions; and by observing these changes in a single substance under a sufficient variety of conditions, a more or less complete graphic delineation of them as representing that particular substance might be obtained. When we are able to fully interpret the language or meaning of these curves, we shall learn a very great deal respecting the internal motions and changes of substances, and the conditions of conversion of potential into kinetic energy.

Digitized by Google

As each curve is a geometrical and quantitative representation of a series of such changes, a complete collection of such curves, yielded by all kinds of aqueous solutions, would constitute an extensive system of representations of the molecular motions of substances somewhat like that of the luminous spectra of bodies; and the magnitudes and harmonic relations of the degrees of electromotive force represented by the curves will form a very large basis of study for mathematicians, such as the spectra of bodies now afford. The entire subject appears to be nearly as large as that of spectrum analysis, and is not altogether unlike it.

The whole system of curves may be viewed as being in some respects analogous to the absorption-spectra of liquids, and in a less degree to the spectra of gases. The relations between the different curves are probably more complex than those between the spectra of liquids, because the electrodes take part in the action: and still more complex than those between the spectra of gases, because of the influences of the solvent and of the electrodes, and because each dissolved substance is in the liquid state and under the influence of cohesion.

As the magnitudes and forms of the curves are manifestly related to the atomic and molecular weights of the dissolved sustances, they are doubtless also related to the periodic series, and in this direction a study of them by mathematicians will lead to the acquisition of new knowledge. And as they reveal the kinetic changes which isomeric and other substances undergo when they pass from one state of chemical equlibrium to another in cases of chemical union, substitution, and decomposition, &c., they are evidently related very intimately to Newton's third law of motion.

With regard to the latter suggestion, in several researches (see "Relative Amounts of Voltaic Energy of Electrolytes," Roy. Soc. *Proc.* November, 1888, XLV. p. 266; "On Loss of Voltaic Energy of Electrolytes by Chemical Union," *Proc.* Birm. Philos. Soc., December, 1888, VI. p. 225; "Relative Amounts of Available Voltaic Energy of Aqueous Solutions," *ibid.* VII. part 1; "Examples of Solution Compounds," *ibid.* and *Chemical News*, April, 1890), I have largely shown, by means of the "voltaic balance" method, that chemical union in definite proportions by weight of substances *whilst in aqueous solution together* is apparently universal; that elements unite with elements, with all kinds of acids, and with all classes of acid, neutral, and basic salts; that acids unite with acids, each with every other one, and each acid with every salt; and salts with each other in almost endless variety; and apparently that all kinds of dissolved chemical compounds, with but few, if any, exceptions, unite together more or less distinctly, in those definite proportions indiscriminately and without limit of kind, provided no separation of substance by precipitation or otherwise occurs. Also, by repeatedly doubling the molecular weight of a "solution compound" by successive additions to it of other dissolved substances of equal chemical value, each addition producing a new state of chemical equilibrium, in which chemical action and reaction are equal, I have by the same method shown that chemical union of substances whilst in aqueous solution together extends to large aggregates of molecules of the most varied kind and of considerable degrees of complexity (*Proc.*, Birm. Phil. Soc., VI., p. 225). This universality of chemical union of substances whilst in solution together indicated the existence of an equally general cause of such union, and that cause must be a molecular one.

"The theory most consistent with these facts is a kinetic one, viz, that metals and electrolytes are throughout their masses in a state of molecular movement. That the molecules of these substances, being frictionless bodies in a frictionless medium, and their motion not being dissipated by conduction or otherwise, continue in motion until some cause arises to prevent them. That every different metal and electrolyte has a different class of motions, and that the molecular motion of each substance varies at a different rate by rise of temperature." This theory has been employed by me to explain certain thermo-electric phenomena in electrolytes (*see* Roy. Soc. *Proc*, 1883, XXXVI., pp. 54-55). "In accordance with this theory chemical action is an effect of molecular motion, and is one of the modes by which that motion is converted into electric current." "These statements are also consistent with the view that the elementary substances lose a portion of their molecular activity when they unite to form acids or salts, and that electrolytes have usually a less degree of molecular motion than the elements of which they are composed" (*ibid.*).

A kinetic theory must agree with mechanical laws; we cannot create motion or energy, all motion arises from pre-existing motion, every efficient cause of material change is a kinetic one; the immediate source of all chemical change is the latent molecular motion of the combining or mutually acting substances. As neither mere difference of substance, nor union in definite proportions by weight, is in itself an active influence, neither can it be the immediate kinetic cause of chemical change; but as both these circumstances invariably attend chemical union, and no such union occurs without them, we may conclude that they are necessary conditions of the union.

By adopting the above theory, "that electrolytes are throughout their masses in a state of molecular movement; that the molecules of these substances, being frictionless bodies in a frictionless medium, and their motion not being dissipated by conduction or otherwise, they continue incessantly in movement until some cause arises to prevent them," and associating it with Newton's third law of motion, viz, that "the actions of bodies upon one another are always equal and in opposite directions," we are driven to the inference that what we term "chemical affinity," or the immediate active cause of chemical union, is latent or potential molecular motion and the mutual impact and momentum of the molecules of the uniting substances. When two dissolved substances are brought by admixture of their solutions into mutual contact, a portion of the molecular motion of the one substance is neutralised by an equal amount of opposite motion of the other, and the two portions are converted into free heat, electric current, or other form of energy, and the molecules thus brought into near proximity retain their new positions and distances: this agrees with the usual evolution of heat, loss of voltaic energy, depression of electromotive force, and frequent increase of density, which occur during chemical union. According to this view, every dissolved chemical compound is an instance of balanced molecular motion, and it is the neutralised portions of motion which escape as heat and electric current. How far there is any originality in these ideas I leave to other persons to decide.

Many of the facts evolved by the several researches I have referred to point towards the conclusion that measurements of volta-electromotive force and voltaic energy are essentially measurements of "chemical affinity" between the dissolved substance and the positive metal. An analogous idea has already been suggested by other investigators. E. F. Herroun, adopting a view of Helmholtz's, has inferred that "the electromotive force of a voltaic cell is a measure of the actual transformation of free energy," and concluded that it "furnishes a more accurate measurement of the free energy, and therefore of true chemical affinity, than data derived from calorimetric observations" (*Phil. Mag.*, 1888, XXVII., pp. 230, 233). The amounts of voltaic energy lost by two substances during their act of chemical union clearly indicate to a large extent the quantities of opposite molecular motion neutralised by their union. For instance, a much larger amount of such motion is neutralised by the union of sodium with chlorine to form sodic chloride than by that of hydrogen with chlorine to form hydrochloric acid: and, no doubt, by investigating the losses of electromotive force and voltaic energy attending the chemical union of substances in aqueous solution, we may learn a very great deal respecting the quantitative relations of "chemical affinity" between metals and electrolytes; but a great obstacle to making accurate measurements of such "affinity" by this method is the unmeasured portion of energy lost by "local action." It may be further remarked that, disregarding "local action," this chemical union and neutralisation of opposite molecular motions only occurs whilst the circuit is closed; and that at the instant of closing the circuit, potential energy is converted into kinetic energy, and a multitude of electro-magnetic waves of very varied lengths are generated and radiated into space: the conversion of energy, therefore, in this kind of case depends upon closing of the circuit.

The results obtained by varying the strength or the temperature of the liquid at each metal separately support the conclusion that, in an ordinary voltaic cell, nearly the whole of the energy is due to action at the zinc, and but little to that at the platinum; and that the latter acts nearly wholly by obviating the greater counter electromotive force which would occur by using a more corrodible metal, and by diminishing the resistance which a less conducting substance would offer. The more absence of an obstacle to a change cannot be an active cause of that change; and any substance which takes an essential part in any physical or chemical action, and (like the platinum plate) remains exactly the same in every respect after the action as it was immediately previous to it, cannot have been a real cause of that action, or of any loss or gain of energy attending it. The presence of the negative metal is only a static permitting condition; it enables, without any expenditure of energy on its own part, the opposite potential molecular motions of the positive metal and the liquid to neutralise each other and to be converted into voltaic current.

The method described in this Paper is not merely a technical one of detecting substances, nor is it specially fitted for such a purpose; but it is an extensive new department of chemical and molecular research, and a general system of representation by means of geometrical curves, not only of individual substances, but of some of the fundamental changes of molecular motion of substances which are inseparably related to their chief chemical properties; and it will in this way supply mathematicians with a new and extensive series of facts, representing, in terms of electromotive force, the degrees of volta-chemical action of metals and electrolytes upon each other. One of the chief uses of it as a method of research will be to examine the molecular structure and chemical

Digitized by Google

composition of dissolved substances, to detect differences and changes in them caused by heat, light, chemical union, substitution, or decomposition, &c.; and to detect and measure molecular and chemical differences in isomeric liquids. It may be used to detect and measure the changes gradually produced by light and heat in chlorine water and bromine water, the influence of light upon nitric acid, the degrees of retarding effect of coloured glass screens, &c., upon various chemical changes caused by light, the gradual oxidation of a solution of sulphurous anhydride by exposure to air, the spontaneous decomposition of aqua regia, the rate of decomposition of a solution of potassic iodide by chlorine water, the speed of displacement of one acid by another, &c. The examples given and researches suggested are sufficient to indicate the very great extent of the subject.

THE BRITISH ASSOCIATION AT LEEDS.

The second meeting of the British Association at Leeds opened on Wednesday morning by the assembling of the General Committee, under the presidency of Professor Flower, F.R.S., the retiring president, to receive the report of the council for the year 1889-90, and to elect the sectional officers.

After the reception of the report and the adoption of various recommendations, the committee proceeded to elect the sectional officers for the ensuing meetings. The following gentlemen were elected in Sections A and G.:—

A.—Mathematical and Physical Science.—President, J. W. L. Glaisher; vice-presidents, Professor O. J. Lodge, Professor Rucker, Lord Rayleigh, Professor H. H. Rowland, Sir Wm. Thomson, Professor E. Mascart; secretaries, R. T. Glazebrook, Professor A. Lodge, W. N. Shaw, Professor W. Stroud.

G.—Mechanical Science.—President, Captain A. Noble; vice-presidents, Professor L. F. Vernon Harcourt, G. F. Deacon, Professor V. Dwelshauvers-Dery, A. Greenwood, Sir James Kitson, B. Walker; secretaries, E. K. Clark, C. W. Cooke, W. Bayley Marshall, E. Rigg (recorder).

The evening meeting took place at 8 o'clock in the Coliseum, Cookridge-street, when Sir F. Abel delivered the following address:—

Sir Frederick Abel's Presidential Address.

After referring in touching terms to the gaps created in the ranks of those who were prominent at the meeting of the British Association at Leeds 32 years ago, Sir FREDERICK ABEL said:—To not a few of those who have flocked to Leeds to attend the annual gathering of this Association, our present meeting place is doubtless known chiefly by its proud position as one of the most thriving manufacturing towns of the United Kingdom; of ancient renown, especially in connection with one of the chief industries identified with Great Britain in years past. But this good town of Leeds, whose cloth market was described by Daniel Defoe, 160 odd years ago, as "a prodigy of its kind, and not to be equalled in the world," and whose present position in connection with divers of our great industries would have equally excited the enthusiasm of that graphic writer, is famous for other things than its prominent association with manufactures and commerce. Not many of our great industrial centres can boast of so goodly an array upon the scroll of their past history of names of men eminent in the sciences, the arts and manufactures, in divinity and letters, and in heroic achievements, such as are identified with Leeds and its immediate vicinity—Thomas, Lord Fairfax, one of the most prominent heroes of the Commonwealth; Smeaton, an intellectual giant among engineers; William Hirst and John Marshall, illustrious examples of the men who by their genius, energy, and perseverance placed Great Britain upon the pinnacle of industrial and commercial greatness which she so long occupied unassailed; Richard Bentley, the eminent classic and divine; John Nicholson, the Airedale poet; John Fowler and Peter Fairbairn, worthy followers in the footsteps of Smeaton; Isaac Milner, weaver and mathematician, afterwards Senior Wrangler, Smith's Prizeman, Jacksonian Professor, President of Queens' College, Vice-Chancellor of Cambridge University, Dean of Carlisle, and a most illustrious Fellow of the Royal Society; Thoresby, antiquary and topographer; Benjamin Wilson, painter and industrious contributor to the development of electrical science; William Hey, the eminent surgeon, and friend and counsellor of Priestley; Sadler, political economist and philanthropist; the brothers Sheepshanks—Richard, the astronomer, and John, the accomplished patron of the arts and munificent contributor to our national art treasures; Edward Baines, whose conspicuous talents and energy developed a small provincial journal into one of the most powerful public organs of the country; his talented sons, of whom not the least conspicuous and highly respected was the late Sir Edward Baines. I might swell this voluminous list by reference to illustrious members of such families as that of Denison, of Beckett, of Lowther, but the men I have referred to fitly illustrate the remarkable array of worthies whose careers have shed lustre upon the town in or near which they were born. Yet that illustration would be altogether incomplete if I failed to speak of one whose career and works alone would suffice to place Leeds in the foremost rank of those English towns who can claim as their own men whose course of life and whose achievements have secured their pre-eminence among our illustrious countrymen. Needless to say I refer to Joseph Priestley, born within six miles of Leeds, whose name holds rank among the foremost of successful workers in science; who, by brilliant powers of experimental investigation, rapidly achieved a series of discoveries which helped largely to dispel the shroud of mystery surrounding the art of alchemy and to lay the foundation of true chemical science. His great quickness of perception and power of experiment led him to the achievement of many novel and important results; but one cannot help contrasting his somewhat random search after new discoveries with the close logical reasoning and philosophic spirit which guided and pervaded the remarkable researches of him whose departure from amongst us since the last gathering of this Association is so universally deplored—of the great discoverer of the universal law of the conversion of energy, James Prescott Joule.

Among the branches of science in the practical applications of which the greatest strides have been made since the Association met at Leeds in 1858 is electricity. That year witnessed the accomplishment of the first great step towards the establishment of electrical communication between Europe and America, by the laying of a telegraph cable connecting Newfoundland with Valencia Island. Through this cable a message of 31 words was shortly afterwards transmitted in 35 minutes—an achievement which, though exciting great enthusiasm at the time, scarcely afforded promise of the succession of triumphs of ocean telegraphy which have since surpassed the wildest dreams of the pioneers in the realms of applied electricity. The development of the electric telegraph constitutes a never-failing subject of the liveliest interest. The experiments made more than a century and a-half ago by Stephen Gray, by Watson, and by Franklin, of transmitting frictional electricity through considerable lengths of wire—although they were followed by many other interesting and philosophical applications of frictional electricity to the transmission of signals—were not productive of really practical results. The work of Galvani and of Volta was more fruitful of an approach to practical telegraphy in the hands of Sömmering and of Coxe, while the researches of Oersted, of Ampère, of Sturgeon, and of Ohm, and especially the discoveries of volta-electric induction and magneto-electricity by Faraday, paved the way for the development of the electric telegraph as a practical reality by Cooke and Wheatstone in 1837. How remarkable the strides have been in the resources and powers of the telegraphist since that time is demonstrated by a few such facts as these: The first needle instrument of Cooke and Wheatstone transmitted messages at the rate of four words per minute, requiring five wires for that purpose; six messages are now conveyed by one single wire at ten times that speed, and news is despatched at the rate of 600 words per minute. Duplex working, which more than doubled the transmitting power of a submarine cable, was soon eclipsed by the application of Edison's quadruplex working, which has in its turn been surpassed by the multiplex system, whereby six messages may be sent independently, in either direction, on one wire. When last the British Association met in Leeds, submarine telegraphy had but just started into existence; 30 years later the accomplished President of the Mechanical Section informed us, at our meeting at Bath, that 110,000 miles of cable had been laid by British ships, and that a fleet of nearly 40 ships was occupied in various oceans in maintaining existing cables and laying new ones.

The important practical achievements by which most formidable difficulties have been surmounted step by step, in the successive attainment of the marvellous results of our day, have exerted an influence upon the advancement not merely of electrical science, but also of science generally and of its applications, fully equal to that which they have exercised upon the development of commerce and of the intercourse between the nations of the earth. Thus, the laying of the earliest submarine cables, between 1851 and 1855, led Sir W. Thomson, in conference with Sir George Stokes, to work out the theory of signalling in such cables, by utilizing the mathematical results arrived at by Fourier in his investigation of the propagation of heat-waves. The failure of the first Atlantic cable led to the survey of the bottom of the Atlantic, which was the forerunner of deep-sea explorations, culminating in the work of the "Challenger" expedition, and opening up new treasures of knowledge scarcely dreamt of when last the British Association met at Leeds. To the difficulties connected with the early attempts at submarine telegraphy, and the determination with which Thomson drove home the lessons learnt, we owe the systematic investigations into the causes of the variations in resistance of copper conductors, and the consequent improvements in the metallurgy of copper, which led to the realization of the high standard of purity of metal essential for the efficient working of telegraphic systems, and also to the extensive utilization of electricity in the production of pure copper. The rare combination of originality in powers of research and perspicuity in mathematical reasoning, with inventive and constructive genius, for which Thomson has for so long been pre-eminent, has placed at the disposal of the investigator of electric science and of the practical electrician instruments of measurement and record which have been of incalculable value, and which owe their origin to the theoretical conclusions arrived at by him in his researches into the conditions to be fulfilled for the attainment of practical success in the construction and employment of submarine cables. The mirror galvanometer, the quadrant electrometer, the syphon-recorder, and the divided-ring electrometer are illustrations of the valuable outcome of Thomson's labours; the combination of the last-named instrument with sliding resistance coils has rendered possible the accurate sub-division of a potential difference into 10,000 equal parts. The general use of condensers in connection with cable signalling, due to Varley's application of them for signalling through submerged cables with induced short waves, was instrumental in establishing

Digitized by Google

the fact that all electrostatic phenomena are simply the result of starting an electric current of known short duration round a closed circuit. The practical application of the Wheatstone bridge led to numerous important mathematical investigations, and induced Clerk Maxwell to devise a new mode of applying determinants to the solution of the complicated electrical problems connected with networks of conductors. The necessity for the universal recognition of an electrical unit of resistance led to the establishment, in 1860, of the Electrical Standards Committee of the British Association, whose long succession of important annual reports was instrumental in most important developments of theoretical electricity, and, indeed, served to open up the whole science of electrical measurement. Mattheissen's important investigations of the electrical behaviour of metals and their alloys and the preparation and properties of pure iron were the outcome of the commercial demand for a practically useful standard of electrical resistance, while Latimer Clark's practical standard of electromotive force, the mercurous sulphate cell, became invaluable to the worker in pure electrical research. The unit of resistance established by the British Association Committee received, in 1866, most important scientific application at the hands of Joule, who, by measuring the rate of development of heat in a wire of known resistance by the passage of a known current, obtained a new value of the mechanical equivalent of heat. This value differed by about 1·3 per cent. from the most accurate results arrived at by his experiments on mechanical friction, a difference which eventually proved to be exactly the error in the British Association unit of resistance; so that the true value of the unit of resistance, or ohm, was determined by Joule 15 years before this result was achieved by electricians. Clerk Maxwell's remarkable electro-magnetic theory of light was put to the test, through the aid of the British Association unit of resistance, by Thomson, in determining the ratio of electro-magnetic unit to the electro-static unit of quantity. Many other most interesting illustrations might be given of the invaluable aid afforded to purely scientific research by the practical results of the development of electrical science, and of the constant co-operation between the science student and the practical worker. No one could more fitly than the late Sir William Siemens have maintained, as he did in his admirable address at our meeting in Southampton, in 1882, that we owe most of the rapid progress of recent times to the man of science who partly devotes his energies to the solution of practical problems, and to the practitioner who finds relaxation in the prosecution of purely scientific inquiries. Most assuredly, both these classes of the world's benefactors may with equal right lay claim to rank the name of Siemens among those whom they count most illustrious.

After glancing at the early history of electric lighting and of the telephone, Sir Frederick continued:—Nine lighting companies either are now, or will very shortly be, actually at work, supplying, from central stations, districts of London comprising almost the entire western and north-western portions of the metropolis. As regards other parts of England, there are already 27 lighting stations actually at work in different towns, besides others in course of establishment, and many more projected. The town of Leeds has not failed to give serious attention to the subject of utilising the electric light, and although no general scheme has yet been adopted, the electricians who now visit this town will rejoice to see many of its public buildings provided with efficient electric illumination. While the prediction made by Siemens eight years ago, that electric lighting must take its place with us as a public illuminant, has thus been already, in a measure, fulfilled, important progress is being continuously made in developing and perfecting the arrangements for the generation of the supply, its efficient distribution from centres, and its delivery to the consumer in a form in which it can be safely and conveniently dealt with and applied at an outlay which even now does not preclude a considerable section of the public from enjoying the decided advantages presented by electric lighting over illumination by coal gas. Yet our recent progress in this direction, encouraging though it has been, is insignificant as compared with the strides made in the application of electric lighting in the United States, as may be gauged by the fact that, while in America the number of arc lamps in use in April of this year was 235,000, and of glow lamps about 3,000,000, there are at present about one-tenth the number of the latter, and one-hundredth the number of arc lamps, in operation in England. In some important directions we may, however, lay claim to rank foremost in the application of the electric light; thus, our large passenger ships and our war ships are provided with efficient electrical illumination; to the active operations of our Navy the electric light has become an indispensable adjunct; and our system of coast defence, by artillery and submarine mines, is equally dependent for its thorough efficiency upon the applications of electricity in connection with range-finding, with the arrangement and explosion of mines, and with the important auxiliary in attack and defence the electric light, which, while so arranged at the operating stations as to be protected against destruction by artillery fire and difficult of detection by the enemy, is available at any moment for affording invaluable information and important assistance and protection. Other important applications of the electric light, such as its use as a lighthouse illuminant, for the lighting of main roads in coal mines, and even for signalling purposes in mid-air, through the agency of captive balloons, are continually affording fresh demonstrations of the value of this particular branch of applied electric science.

The achievements of the telephone were referred to by Siemens in glowing terms eight years ago; but the results then attained were but indications of the direction in which telephonic intercommunication was destined speedily to become one of the most indispensable of present applications of electricity to the purposes of daily life. Preece, in speaking at Bath two years ago of the advances made in applied electricity, showed that the impediments to telephonic communication between great distances had been entirely overcome; and now, although considerably behind America and France in the use of the telephone, we are rapidly placing ourselves upon speaking terms with our friends throughout the United Kingdom. The operations of the National Telephone Company well illustrate our progress in telephonic intercommunication. That company has now 22,743 exchange lines, besides nearly 5,000 private lines, its exchanges number 272, and its call offices 526. The number of instruments under rental in England has now reached 99,000; but, important as this figure is compared to our use of the telephone a very few years ago, it sinks into insignificance by the side of the number of instruments under rental in America, which at the beginning of the present year had reached 222,430, being an increase of 16,675 over the number in 1889. Only thirteen years have elapsed since the telephone was first exhibited as a practically workable apparatus to members of the British Association at the Plymouth meeting, and the number of instruments now at work throughout the world may be estimated as considerably exceeding a million.

The successful transmission of the electric current is not alone illustrated by the efficiency of the arrangements already developed for the supply of the electric light from central stations. Siemens dwelt upon this subject at Southampton with the ardent interest of one who had made its development one of the objects of his energetic labours in later years, and also with a prophet's prognostications of its future importance. He pointed out that no further loss of power was involved in the transformation of electrical into mechanical energy than is due to friction, and to the heating of the conducting wires by the resistance they oppose, and showed that this loss, calculated upon data arrived at by Dr. John Hopkinson and by himself, amounted at the outside to 38 per cent. of the total energy. Subsequent careful researches by the brothers Hopkinson have demonstrated that as much as 87 per cent. of the total energy transmitted is realisable at a distance, provided there be no loss in the connecting leads used. The Paris Electrical Exhibition of 1881 already afforded interesting illustrations of the performance of a variety of work by power electrically transmitted, including a short line of railway constructed by the firm of Siemens, which was a further development of the successful result already attained in Berlin by Werner Siemens in the same direction, and was, in its turn, surpassed by the considerably longer line worked by Messrs. Siemens at the Vienna Exhibition two years later. Various short lines which have since then been established by the firm of Seimens are well known, and one of the latest public acts in the valuable life of Siemens was to assist at the opening of the electric tramway at Portrush, where the idea, so firmly rooted in his mind from the date of his visit to the falls of Niagara in 1876, of utilising water-power for electrical transmission—a result first achieved on a small scale by Lord Armstrong—was more practically realised than had yet been the case. Since that time Ireland has witnessed a further application of electricity to traction purposes, and of water-power to the provision of the required energy, in the working of the Bessbrook and Newry tramway, while London at length possesses an electric railway, three miles in length, to be very shortly opened, which will connect the city with one of the southern suburbs through a tram subway, and, although including many sharp curves and steep gradients, will be capable of conveying 100 passengers at a time, at speeds varying from 13 to 24 miles per hour. During the past year a regular service of tramcars has been successfully worked, through the agency of secondary batteries, upon part of one of the large tramways of North London, with results which bid fair to lead to an extensive development of this system of working.

The application of electricity to traction purposes has, however, received far more important development in the United States; at the commencement of this year there were in operation in different States 200 electrical tramroads, having a collective length of 1,641 miles, with 2,346 motor-cars travelling thereon. The idea cherished by Siemens of utilising the power of Niagara appears about to be realised, at any rate in part, as a large tract of land has been recently acquired by a powerful American association, about a mile distant from the Falls, with a view to the erection of mills for utilising the power, which it is also proposed to transmit to distant towns; and an International Commission, with Sir William Thomson at its head, and with Mascart, Turrettini, Coleman Sellers, and Unwin as members, will carefully consider the problems involved in the execution of this grand scheme. The application of electric traction to water traffic, first successfully demonstrated in 1883, is receiving gradual development, as illustrated by the considerable number of pleasure-boats which may now be seen on the Upper Thames during the boating season. Electrically transmitted energy was first applied in Germany to haulage work in mines by the firm of Siemens some years ago, and great progress has since been achieved herein on the Continent and in America. It is very interesting to note, on the present occasion, that the first successful practical application of electricity in this country to pumping and underground haulage work was made in 1887, in this neighbourhood, at the St. John's Colliery at Normanton, where an extensive installation is furnishing very satisfactory results in point of economy and efficiency. The gigantic installations existing for the same purposes in Nevada and California afford remarkable illustrations of the work to be accomplished in the future by electrically transmitted energy.

Among the many subjects of importance studied by Joule with the originality and thoroughness characteristic of his work, was the application of voltaic electricity to the welding and fusion of metals. Thirty-four years ago he published a most suggestive paper on the subject, in which, after dealing with the difficulties attending the operation of welding, and of the interference of films of oxide, formed upon the highly heated iron surfaces, with the production of perfect welds either under the hammer or by the methods of pressure (of which he then predicted the application to large masses of forged iron), he refers to the possibility of applying the calorific agency of the electric current to the welding of metals, and describes an operation witnessed by him in the laboratory of his fellow-labourer, Thomson, of fusing together a bundle of iron wires by transmitting through them, when imbedded in charcoal, a powerful voltaic

Digitized by Google

current. Joule afterwards succeeded in fusing together a number of iron wires with a current of a Daniell battery, and of welding together wires of brass and steel, platinum and iron, &c. In discussing the question of the amount of zinc consumed in a battery for raising a given amount of iron to the temperature of fusion, he points out that the same object would probably be more economically attained by the use of a magneto-electric machine, which would allow the heat to be provided by the expenditure of mechanical force developed in the first instance by the expenditure of heat; and he indicates the possibility of arranging machinery to produce electric currents which shall evolve one-tenth of the total heat due to the combustion of the coal used, so that 5,000 grains of coal applied through that agency would suffice for the fusion of one pound of iron. The successful practical realisation of Joule's predictions in regard to the application of electric currents, thus developed, to the welding of iron and steel, and to analogous operations, through the agency of the efficient machines devised by Professor Elihu Thomson, was demonstrated to the members of the Association by Professor Ayrton at Bath two years ago, and was shown upon a larger scale to visitors at the Paris Exhibition last year, and recently to highly interested audiences in London by our late president, Sir Frederick Bramwell. The latter demonstrated that the production of iron welds by means of the Thomson machines was accomplished nearly twice as rapidly as by expert craftsmen; the perfection of the welds being proved by the fact that the strength of bars broken by tensile strains at the welds themselves was about 92 per cent. of the strength of the solid metal. Another very simple system of electric welding, especially applicable to thin iron and steel sheets, hoops, &c., has been contemporaneously elaborated in Russia by Dr. Benardos, and is already being extensively used. The required heat at the surfaces to be welded is developed by connecting the metal with the negative pole of the dynamo machine, or of a battery of accumulators, the circuit being completed by applying a carbon electrode to the parts to be heated. This mode of operation appears to have been practised upon a small scale, some years ago, by Sir William Siemens, to whom we also owe the first attempt to practically apply electric energy to the smelting of metals. In his address in 1882 he pointed out that, although electric energy could, obviously, not compete economically with the direct combustion of fuel for the production of ordinary degrees of heat, the electric furnace would probably receive advantageous application for the attainment of temperatures exceeding the limits (about 1,800°C.) beyond which combustion was known to proceed very sluggishly. This prediction appears to have been already realised through the important labours of Messrs. Cowles. After very promising preliminary experiments, they succeeded, in 1885, in maturing a method of operation for the production of aluminium-bronze, ferro-aluminium, and silicium-bronze, with results so satisfactory as to lead to the erection of extensive works at Lockport, New York, where three dynamo machines, each supplying a current of about 3,000 amperes, are worked by water-power, through the agency of turbines, each of 500 horse-power, 18 electric furnaces being now in operation for the production of aluminium alloys. These achievements have led to the establishment of similar works in North Staffordshire, where a gigantic dynamo machine has been erected, furnishing a current of 5,000 amperes, with an electromotive force of 50 to 60 volts.

Turning next to the question of metallurgy, the President said: The careful systematic study of the modifications developed in certain physical properties of iron and steel by gradual changes of temperature between fusion of the metal and the normal temperature has shown those modifications to be governed by a constant law. This important subject, which was so clearly brought before the Association last year in the interesting lecture of Roberts-Austen, has been and is still being pursued by accomplished workers, among whom the most prominent is F. Osmond. The phenomenon of recalescence, or the re-glowing of iron and steel at certain stages during the cooling process, appears to be the result of actual chemical combination between the metal and its contained carbon at the particular temperature attained at the time; while the absorption of heat, or arrest in rise of temperature during its continuous application to the metal, is ascribed to the elimination, within the mass, of carbon as an iron-carbide perfectly stable at low temperatures.

After a short reference to the progress made by sanitary science since the period of the Crimean war, and to the approaching meeting in London of the International Congress on Hygiene and Demography, Sir Frederick Abel dealt with the subject of explosives, passing on then to the provisions for technical education at Leeds:—An examination into the present educational resources of Leeds places beyond any doubt the fact that her present prosperity in commerce and industries is in no small degree ascribable to the paramount importance long since attached here to the liberal provision of facilities for the diffusion of knowledge among the artisan and industrial classes, and especially for the acquisition of a sound acquaintance with the principles of the sciences and their applications to technical purposes, with particular reference to the prominent local industries, by all grades of those who pursue or intend to pursue them. There is probably no town in the kingdom more amply provided with efficient elementary and advanced schools for both sexes, while the special requirements of the artisan are efficiently met by the prosperous School of Science and Technology. The resources of the Yorkshire College provide, in addition, a combination of thorough scientific education with really practical training in the more important local industries; indeed, during the 16 years of its continually-progressive work, this institution has acquired so widespread a reputation, that students come from abroad to reap the advantages afforded by the unrivalled textile and dyeing departments of the Leeds College. The keen competition now existing between these departments and the corresponding branches of the much younger, but most vigorous sister college at Bradford, can only conduce to the further development of both, and to their thorough maintenance up to the requirements of the day. The very important pecuniary aid afforded to these establishments, and to a number of other technical schools in Yorkshire, by one of the most important of the ancient companies of the City of London—the Clothworkers—affords an interesting illustration of the good work in the cause of education performed by those guilds, and, especially of late years, by means of their flourishing institute for the advancement of technical education, which, through its two great instructional establishments in London, and through the operation of its system of examinations throughout the country, extending now even to the Colonies, has afforded very important aid towards eradicating the one great blot upon our national educational organisation. To have been first in the field in practically developing a far-reaching scheme for the advancement of technical education in this country must continue to be a source of pride to the City of London and its ancient Guilds in time to come, when the operation of efficient legislation, supported and extended by patriotic munificence and by the hearty co-operation of associations of earnest and competent workers in the cause, shall have placed the machinery and resources for the technical instruction of the people upon a footing commensurate with our position among nations.

The President then brought his inaugural address to a conclusion by referring to the national importance of Natural History and Natural Science Museums.

ELECTRICAL INDUSTRIES AND THE WORLD'S FAIR.*

BY J. P. BARRETT.

It has been stated by competent authority that had it not been for the exhibition of the speaking telephone at the Centennial Exhibition at Philadelphia, the telephone would have been ten years later in receiving popular recognition and becoming a success. It is well known that the individuals who were nearest the telephone invention looked upon it with distrust, considered it a toy, and an invention of no great practical importance. But Sir William Thomson, who was in 1876, as he is now, the recognised authority in electrical science, seeing the telephone at the Centennial Exhibition, became enthusiastic over it, and endorsed it so warmly that it directed public attention to the invention, and made it an immediate success.

Great as are the interests resulting from the telephone which was first publicly exhibited at the Centennial Exhibition at Philadelphia, the importance of this invention extends beyond the particular interests directly concerned. Fourteen years have passed since then, and in three years more the Columbian Exposition in Chicago will be looked on to exhibit the progress which has been made since that date, and to be commensurate with an industry so progressive as to have absorbed an investment of $500,000,000 in the past ten years. The rivalry in invention has led the United States to outstrip all other nations in the practical application of electricity. Thus it was that the electrical department of the United States Exhibition at the Paris Exposition saved the United States from complete disgrace; and yet the electrical department of the Paris Exposition was the weakest feature of the entire show. Probably the United States in the Columbian Exposition cannot hope to equal Paris in the matter of its general exposition; but in machinery, and in electrical matters particularly, we should do a great deal better.

In the first place, electricity will find numerous applications in the way of actual service in carrying out the plan of the Exposition. By this I refer to the fire alarm protection signalling apparatus, electric lighting, both arc and incandescent, transmission of power, telephoning and telegraphing. The location of the Main Exposition having been settled in favour of the Lake Front, which is practically in the heart of the city of Chicago, and within five squares of the telephone central office, the fire alarm central office, and the Western Union and Postal Telegraph Offices, it will be a matter of no serious difficulty to make such connections with the general city electrical service as will give the Exposition the benefit not only of its own special outfit in each of these directions, but also the advantage of its outside connections. Aside from this application of electricity to the utility and necessities of the Exposition, the features in which we are all particularly interested are those which illustrate the progress that has been made in the science and in the art. The success that has attended recent electrical exhibitions, such as the one in Philadelphia in 1885, and the one in the American Institute Fair in New York, give us some idea of what can be accomplished in this direction with the immensely multiplied facilities at the World's Fair at Chicago, and with the incentive to manufacturers and inventors which comes from having the attention of the whole world directed to their work.

The matter of telegraphy also should receive its due share of attention. The different forms of quadruplex, the use of dynamos

* Abstract of a Paper read before the National Electric Association, Cape May, August, 1890.

Digitized by Google

instead of batteries for furnishing the current, and other inventions in which the recent history of the telegraph is prolific, should each and all be suitably presented. Police and fire alarm apparatus of the latest design and the best manufacture, together with all appurtenances, will attract a large share of attention.

Motors for driving machinery, furnishing power for various purposes, running street cars, &c., will, perhaps, be even of more practical benefit than any other application of electricity; while electric lighting apparatus of various kinds will take the lead undoubtedly, as it now does, over all other electrical industries.

It is proposed to connect the two parts of the World's Fair, one situated on the Lake Front and the other at Jackson Park, by means of a railroad built out on the lake. The expediency of adopting electricity for motive power on this railroad is at once obvious. Thus the two features of usefulness and exhibition can readily be combined, and in addition to the direct transmission of power, storage batteries could be employed for traction purposes on this road.

It should be the aim of the people having the exhibition in charge, so to organise and classify the exhibits as to present clearly and forcibly the progress of the art and the present state of its various departments. A chaotic exhibition of the products of the different manufacturers would accomplish something in the way of creating astonishment and mystifying the beholder. It is not too early now to lay plans for the proper presentment of electrical industries for this great Exhibition of 1893. The Exposition should be made just what its name implies, a practical exposition of the progress and advances made in the several branches of the science of electricity, and the exhibits should be so arranged that the various improvements may be seen and appreciated at a glance. Thus will the real object of the Exposition be accomplished and a saving of much valuable time to the visitor be effected. For it is quite probable that fully 50 per cent. of the visitors to the electrical section will go there with the earnest desire to become thoroughly familiar by practical observation and study with all that has been done in some certain industry, either to aid in carrying on a certain line of study or with a view of selecting what they may there conclude is the apparatus best adapted to their needs. In either case, time will be an important and valuable factor, and how to enable each visitor to quickly and understandingly grasp the more important details and points of superiority of any exhibit should be the main object of the respective exhibitors. The usual method followed in the small expositions has been to allot a certain space to each exhibitor and allow him to place therein whatever he may desire to bring to the notice of the visitor. This is a good plan, and one which proves economical in many ways to the exhibitor. Another plan would be to allot space for the various types of apparatus, irrespective of the main display of the exhibitor. That is, to place all telephone apparatus and everything thereto pertaining in close proximity; the same with telegraphic apparatus, arc lighting dynamos, incandescent machines, motors, &c. The carrying out of such a plan will, of course, give two or more separate exhibits to each manufacturer, and thus entail some slight additional expense, both in the matter of suitable furniture, and possibly in the matter of attendance; but all this additional outlay would be more than returned in the excellent results attained, and in the simplifying of the study of any particular type of apparatus, to say nothing of the greater publicity given each exhibit. Of course there would be no objection to an exhibitor's reproducing a complete display of all his wares in the space allotted to him for his headquarters, irrespective of the fact that many articles may also be shown in the respective space to which they belong. In the space allotted to the display of testing instruments the showcases should be placed on a flooring above a foundation made sufficiently solid to prevent oscillation of the needle, or injury to the more delicate parts from vibration or other similar cause. Every article should have a neatly, printed card attached, of size uniform in proportion to the character of the object displayed, bearing the name of the article, the manufacturer's address, and a brief description of its intended use, the same appearing in English, French, German, and Spanish.

At the present time there are about 430 separate companies or individuals whom we can expect to apply for space, many of whom will have but a single article or two to exhibit. But every one of this number will probably defer action until the last possible moment, unless the importance of securing the necessary space and having his exhibit in readiness within the appointed time, is impressed upon him. Some of the manufacturers will have to be coaxed into making exhibits, while others will hesitate on account of the expense entailed. The chief or his secretary must attend to all of this, and must spare no pains to secure not only an exhibit, but the *best exhibit* possible for each manufacturer to make. Great assistance in carrying out a comprehensive and systematic plan for the Exposition may be expected from the United States Census, the report of the Electrical Department of which is looked for with great interest.

A PROPER BASIS FOR DETERMINING ELECTRO-MOTOR RATES.*

BY H. L. LUFKIN.

The equitable adjustment of motor rates, or rather the rates per month, or year, for the supply of current for the operation of electric motors, has long been a matter of considerable annoyance to companies supplying electric power. It is obvious that to invariably charge the motor user an arbitrary rate per horse-power for the motor which he uses, based on its rated capacity, and regardless of the work it is doing, is not satisfactory, for the reason that the manufacturer usually prefers to buy a motor somewhat more powerful than his work really requires and thus avoid the possible damage to his motor from overload, or the strain to which any piece of machinery is subjected when constantly operated above its normal working capacity. Again, the manufacturer may contemplate an increase in his plant in the near future, and, in buying a motor, will provide one of sufficient capacity to operate his prospective increase.

To illustrate graphically the practical operations of motors under load, I have taken a large number of records of motors in actual service, and from these records have laid out ampere curves or daily load diagrams, which illustrate very clearly the fluctuations in the current supplied to motors in actual practice. Other interesting features of these curves are the maximum, minimum, and average readings as related to each other; the current consumed in driving the shafting as related to the average current consumed; and the peculiarity of the records of motors operating elevators.

In one case, in which a 15 horse-power motor works lithograph presses, &c., the maximum reading is 75 amperes, or, approximately, 10 horse-power. The user is given a 10 horse-power rate, which in this case happens to be $60 per month, or a rate of $6 per month per horse-power based on maximum readings. As the average power delivered to this user is but 67 per cent. of the maximum reading, the station actually received at this nominal rate of $6 per horse-power an actual rate of $9 per month per horse-power for the power actually delivered.

The central station supplying this particular motor has adopted the "maximum reading system," and this rate of $6 per month per horse-power is their standard charge for motors showing a reading of 5 horse-power and over up to 15 horse-power. From 15 horse-power up their charge is $5 per month per horse-power. Their monthly bills are also subject to a discount of 5 per cent., I believe, if paid promptly on the first of each month.

The conditions as shown by the diagrams of the current load throughout the day are as follows:—

Average load on motor, 43·57 per cent. of its capacity.
Maximum load on motor, 68·24 per cent. of its capacity.
Average load on motor, 64 per cent. of maximum load.

Reducing these averages to dollars and cents we have the following results:—

A "maximum capacity" rate of $7 per month per horse-power pays the station $13.80 per month per horse-power for the power actually delivered. A "maximum reading" rate of $6 per month per horse-power pays the station $9.37 per month per horse-power for the power actually delivered.

$13.80 per month per horse-power is certainly a tempting price for power, but it is open to some serious objections. In the first place, at this price the electric motor, even with its much higher efficiency, cannot compete with the gas engine. A good gas engine uses about 20ft. of gas per hour per horse-power, or about 5,200 cubic feet per month. Giving gas at $1.50 per thousand (and in many places it is much lower than this), the gas engine will deliver power at a cost of $7.80 per month per horse-power. We can, without much trouble, obtain the $9.37 rate per month for a motor in competition with the gas engine, on account of its many and obvious advantages, but we can seldom obtain the $13.80 rate. This maximum capacity rate also very much hampers the user in a selection of a motor, and the motor salesman, in order surely to effect a sale, is very apt to underrate the prospective load on the motor, as the customer is governed in his purchase of a machine much more by the monthly charge than by the first cost of the motor.

Another feature which must not be lost sight of is the fact that a motor user who has bought and paid for his machine becomes your permanent customer, his income being entirely derived from the product of the work of his motor. His bills for power you are also sure of collecting, for the moment his power is shut off his earning capacity ceases. The motor becomes to him an absolute necessity instead of a seasonable luxury, as is the case with many electric lights.

* Abstract of a Paper read before the National Electric Association, Cape May, August, 1890.

Digitized by Google

Another very remarkable feature brought out by these diagrams is the fact that the average power consumed in doing serviceable work is but three-eighths of the total power used, and the remaining five-eighths (68%) is consumed in driving shafting. This enormous loss in shafting would indicate that the day may not be far distant when each machine will be equipped with its own direct-geared motor, and that the days of shafting and belting are numbered.

RESEARCHES ON THE PRODUCTION OF LIGHT BY ANIMALS AND VEGETABLES.*

BY RAPHAEL DUPOIS.

My object in the present researches has been to study the effects produced by the electrolysis of salt water rendered phosphorescent, either by mixing with it photogenic substances extracted from luminous animal tissues, or by luminous micro-organisms. I made particular use of the luminous mucus of the dactyle pholas, diluted with salt water. The luminous liquid was introduced into a U-shaped tube, the legs of which contained platinum electrodes, connected to a battery sufficiently powerful to electrolyse salt water. As soon as the water began to decompose, the light, after having slightly increased at the positive pole, began to get dimmer and dimmer, and was finally completely extinguished. The same phenomenon occurred at the negative pole, where the light persisted only at the surface of the liquid in contact with the air. The light was first extinguished in the portions of the tube occupied by the electrodes, but the process of extinction soon spread all over it, except at one point where there remained a luminous disc. This point was at the end of the positive electrode, and just where the electrolytic discoloration of some turnsole poured into the tube stopped. Since my last published researches upon the dactyle pholas, I have convinced myself that if this mollusc does sometimes contain luminous symbiotic micro-organisms in its syphon, which, at first, caused me to believe in the existence of a soluble ferment in the mucus secreted by this organ, it also possesses a luminosity proper, whose seat is the layer which I have described as the neuro-conjunctive layer. The photogenic tissue is not limited to the Polian vescicles, and these do not deserve the name of luminous organs as proposed by Panceri, although the light is more intense there than anywhere else. They are, as I have pointed out elsewhere, secretive organs, which seem intended, amongst other things, to evacuate migratory elements covered with rounded granulations (*vacuolides*). I have recognised that these migratory elements are the actual agents of the luminosity proper of the pholas, which must be distinguished from the symbiotic or parasitic luminosity.

These facts are easy to explain. In fact, I have already shown that we can extinguish either the luminous micro-organisms or the photogenic substances extracted from phosphorescent animal tissues by slightly acidulating the medium, and that we can restore their luminosity by making the medium alkaline again. Moreover, it has long been known that oxygen and water are necessary factors in the manifestation of luminous effects in animals and vegetables. Under the influence of electrolysis the medium becomes acid at the positive pole, and the light is extinguished at this point in spite of the abundance of oxygen and even ozonised oxygen which is liberated. At the negative pole it is the nascent hydrogen which produces extinction either by displacing the oxygen or as a reducing agent, although the medium is alkaline. The truth of this interpretation of the phenomenon can be shown by allowing a drop of liquid ammonia to fall into the extinguished solution of luminous mucus at the positive pole, when the light will immediately reappear. The same result ensues at the negative pole, when a little air is blown in by means of a fine tube. The experiment is somewhat more difficult when photogenic microbes are used instead of the mucus of the pholas. If the luminous liquid has been extinguished, either by a strong acid or by heat, in spite of the liberation of ozonised oxygen at the positive pole, and in spite of the alkalinity developed at the negative pole, the light does not reappear in any portion of the tube, even when liquid ammonia is added and air is insufflated. It is very difficult after this to assert that this light is merely an oxidation phenomenon ; and I am of opinion that it is rather a true respiratory effect, which can only take place in an alkaline, oxygenated and aqueous medium.† But in the luminous liquid obtained by diluting the phosphorescent mucus of the dactyle pholas with salt water there are, after filtration, no cellular elements at all, but only round granular bodies which are met with in all luminous tissues. Panceri considered them to be grease-like drops. This, however, does not agree with my own observations, which lead me to believe that they are protoplasmic granulations endowed with an obscure vitality like certain ferments. I have named these bodies *vacuolides* for reasons which I have given at length elsewhere.* They are due to dissociation of cellular protoplasma, which can be brought about by direct excitation, and seen with the eye in the ectodermic tissue of the Hippopodius Gleba.†

In electrolysed luminous liquids, the following phenomena are observable :—At the negative pole a scum is formed consisting principally of *vacuolides*. On the other hand, at the positive pole one meets, especially in the case of the mucus of the pholas, with those refracting, radio-crystalline granulations which take the place of the *vacuolides* in all tissues which have ceased to be luminous. In liquids rendered luminous by micro-organisms, these granulations are especially numerous at the positive pole, and the *vacuolides* at the negative pole.

To sum up, the researches which I have now made for several years lead me to definitely assert that the production of light is connected in the case of animals and vegetables with the transformation, under the influence of a respiratory phenomenon, of the colloidal protoplasmic granulations into crystalloid granulations.‡ In the first portion of my studies on photogenic phenomena, I had the mechanism more particularly in view, and I was able to supplement our knowledge and correct some errors. As to my investigations on the fundamental and general cause of the phenomenon, they have frequently led me to premature interpretations which I have been obliged more or less to abandon, as new facts showed their insufficiency. In judging my previous interpretations, however, I hope it will be remembered that they relate to experiments on a living substance, which can never be manipulated in large quantities, nor at all times and places.

AN EFFICIENCY TEST OF THE THIRD WARD RAILWAY AT SYRACUSE, N.Y.§

BY G. D. HULETT.

As will be remembered by many, about a year ago Dr. Louis Bell made a test of the Sprague electric railway at Lafayette, Ind., and found that the all-day efficiency was but 25 per cent.** The greater part of the loss occurred in the station itself, as the electrical horse-power delivered to the line was but 41 per cent. of the horse-power of the engine. The latter was a Hamilton-Corliss of 130 horse-power, which drove a line shaft, and belted to this were two Edison shunt-wound generators of 30,000 watts capacity each, which supply the car-line. The results seem to indicate that slow speed engines are ill-fitted to the requirements of street railway work with its constant and sudden variations of load ; and it was Dr. Bell's opinion at the time that the conditions of maximum efficiency would be brought about by the use of high-speed engines belted directly to the generators, which should be compound wound.

The present test was conducted upon the Thomson-Houston road at Syracuse, New York, some time ago by Mr. S. J. Larned and the writer, then students at Cornell University. This road is about four miles in length, connecting Geddes or West Syracuse with the centre of the city, and at the time of the test operated seven cars. The power is furnished by two Armington and Sims engines, each of 80 horse-power, to which are belted two compound-wound Thomson-Houston generators of 60,000 watts capacity, which are run in parallel. The equipment is thus seen to be far more than adequate for seven cars, and at present there are several more in operation. For this reason, therefore, the efficiency will be found rather low.

The test naturally divides itself into three fairly well-defined steps :—1st. To obtain the efficiency of the station. 2nd. The efficiency of the line. 3rd. The efficiency of the cars. The ratio $\frac{\text{E.H.P.}}{\text{I.H.P.}}$ was found by choosing favourable moments once about every 25 minutes, when the current remained constant for a few seconds, and then reading ammeter and voltmeter, while cards were taken from the engines. At the same time an attempt was made to have the mean E.H.P. computed from these readings agree as closely as practicable with that obtained from the recording instrument and mean voltage for the day. In this we succeeded very well, as the mean E.H.P. was 34·1 and

* From the *Comptes Rendus*, Tome CXI., No. 8.

† It is known that luminous tissues, or dried particles extracted from these tissues, may be preserved a long time without loss of photogenic power by keeping them in contact with the air, a fact which can always be tested by means of a drop of water.

* See *Les Vacuolides* (Soc. de Biol., March, 1887).

† *Loc. cit.*

‡ By using tubes of close porous earth, one always stops the luminous particles, and all my efforts to isolate a definite chemical substance capable of glowing spontaneously in air have failed. I have not, therefore, been able to cross the line which separates this biological phenomenon from a regular chemical action.

§ From the *Electrical World* of New York.

Digitized by Google

32·3 respectively. The efficiency of the station was thus found to average 62·8 per cent., which may be considered very good when we reflect that nearly double the number of cars could be operated with the same equipment. The highest efficiency observed was 82 per cent. when the I.H.P. was 108, the highest reading taken. As the I.H.P. was frequently below 30, and the resulting efficiency little above 40 per cent., and sometimes below, it is evident that even when run to its full capacity it is doubtful if the station efficiency would ever rise above 75 per cent.

The efficiency of the line calculated from voltage readings taken at the station and on the line simultaneously was found to average about 91 per cent.

The efficiency of the cars is rather a difficult thing to ascertain. The practice in the Thomson-Houston system is to throw out the whole of the rheostat as soon as practicable after starting, and consequently fully ¼ths of the entire distance traversed by the car is covered with the motor running at its maximum efficiency. This is certainly true at Syracuse, where the conditions are favourable for long runs without a stop in the thinly peopled district lying between Syracuse and Geddes. The method adopted was to find the maximum efficiency of an average car, with the external resistance entirely thrown out, by obtaining the work necessary to cover 350ft. upon the level track and the same distance upon a grade averaging 5·76 per cent. By combining the results of these observations, this efficiency was found to be 75·8 per cent. This shows up very well for the motors when we recollect that some 10 per cent. is consumed in the gearing. The efficiency of the car with the rheostat arm in other positions can be computed in the same manner, and then the all-day efficiency estimated from these results and the considerations mentioned in the beginning of the paragraph. In the present case 65 per cent. was taken to represent this mean efficiency, as closely as obtainable from the data at our command.

The efficiency of the entire system may, therefore, be found by taking the product of the efficiencies of station, line and cars, or $62·8 \times 91 \times 65 = 37$ per cent. Comparing this with the 25 per cent. obtained at Lafayette, as has been stated, it is seen that high-speed engines belted directly to the generators have a decided advantage over the slower running Corliss engines, which also must waste a considerable amount of power in a line shaft.

The coal consumption was 5,500 pounds. But steam was supplied to an adjacent shop from 7 a.m. to 6 p.m., and deducting 700 pounds as the equivalent amount used there, we have 4,800 required by the railway. The average horse-power for the day was 51·4, hence the coal per indicated horse-power hour was 5·3 pounds, and per electrical horse-power hour 8·4 pounds. Were the plant run up to its normal capacity these figures would be considerably reduced. As the cars ran 98 miles per day the electrical horse-power hours per car mile are easily computed and found to be ·82.

One point incidentally noticed in taking voltage readings upon the line was that the curves consumed more power than the grades. The lowest voltage observed upon the heaviest grade was 381, while 360 was read when rounding a curve upon a slight incline, and again while a car between the test car and the station was passing round the same curve. Since the drop in voltage is mainly due to the resistance of the line, the demand for current must have been very great. The practice of keeping the curves lubricated is a good one, for the friction is thus much reduced.

The mean voltage at the station was 487, although it frequently ran up above 500 and fell below 470. The greatest current was 225 amperes, and 200 was observed several times; but in all cases these large currents were held at the longest but a few seconds before a drop occurred.

REVIEWS.

Electric Light Fitting. A Handbook for Working Electrical Engineers, embodying Practical Notes on Installation Management. By JOHN W. URQUHART, author of "Electric Light," &c. (London: Crosby Lockwood and Son, 7, Stationers' Hall-court, Ludgate-hill, 1890.)

A demand has arisen for good plain text-books on practical details, and this Mr. Urquhart has attempted to provide at a price within the reach of all. "Electric Light Fitting," Mr. Urquhart's latest addition to the literature of electricity, is designed to serve as a companion to "Electric Light" by the same author, a little work which reached its third edition last November. This volume consists mainly of the every-day notes of a working electrician. It deals with what may be termed the mechanics of electric lighting, and is addressed to men who are already engaged in the work, or are training for it. The author assumes that his readers are familiar with the general principles of the science of electricity, and with the subject matter of his volume on electric lighting: the present work may be read as a sequel to it. Although small, it traverses a great deal of ground. The general scope of this book includes central station work, the localising of dynamo faults, observations respecting accumulators, switch-board and testing-work, systems of arc-light wiring and fitting, incandescent lamp wiring, and the lighting of ships. The text contains much miscellaneous matter, and deals with some of the practical difficulties ordinarily met with by the working electrician. Mr. Urquhart's aim is to produce elementary books which make no endeavour to assist the mathematical study of the science of electricity. At the same time, it is to be hoped that no one who reads them will be content with the smattering of knowledge which he has acquired, but will be incited to study the subject in a more thorough manner, and with the aid of an author of wider experience.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *August* 22, 1890.

National Electric Light Association.—The semi-annual Convention of the National Electric Light Association has just been held at Cape May, New Jersey. The active members of this Association are all central-station men, and as a result many interesting Papers relating to the details of central-station work, in theory and practice, are brought before it. The meeting occupied three days, and was full of interest to the members in attendance. The first morning session brought out one Paper of importance to central-station men in particular, as well as to political economists. It was read by Mr. M. J. Francisco, who dealt with the subject of Municipal Lighting. During the past few years Mr. Francisco's attention has been specially directed to the economical details of central-station management by municipalities; and the results he has reached have been the product of a very elaborate study. His Paper took up in detail municipal lighting in nearly every town in the United States that has tried it. The official reports usually show preposterously low expenses for such plants; and the author's investigation was in large part devoted to examining critically the conditions that produce such presumably favourable effects. It became very evident that the economy in such cases is only apparent, for the reason that municipal accounts do not show under the proper heading the real expenses of electric lighting. It is found in nearly every case that very important items of expense are either unaccounted for or are found charged to other departments than that of electric lighting. By reason of this the apparent expenses of municipal plants are very low, while the real expenses are in nearly every case higher than those of a plant conducted by a private corporation. Apparently, the real fact is that municipal plants are made to a greater or less extent subject to political jobbery, and consequently are not conducted on a proper commercial basis.

A second Paper that attracted great attention at the Convention was one by Mr. Lufkin on "The Proper Basis of Determining Electric Motor Rates." The author, the electrician of a large motor company, had to examine in detail the output of a large number of installations operating all kinds of machinery for very varied sorts of work. The figures showed that even the maximum load required by the work to which a motor is put is generally considerably below the capacity of the machine; in other words, that an unnecessarily large motor has been installed. If, then, the rates charged for supplying power to such motors are based on nominal horse-power, the charges would be necessarily excessive; and Mr. Lufkin laid down the proposition that the proper basis for charge was the maximum load required of the motor, quite irrespective of its normal capacity. This quantity can be readily determined by measurements of a simple enough character, and furnish a legitimate commercial basis for charge. Metering electricity for motor use has not yet come into very extensive use in this country, but several prominent central stations have adopted the method suggested, and find it very satisfactory both to themselves and to their customers. The details of the Paper give a great deal of very valuable information as to the actual

Digitized by Google

power required to operate various sorts of machinery, and form a most excellent basis for judging the proper size of motor to put in a given manufacturing establishment. Another interesting point brought out was the large amount of power consumed in the shafting usually employed in connection with motors. In many cases it would probably result in real economy to connect the motor directly to the given machine by coupling or belt. This plan, by the way, is carried into practice to a very large extent in the great factories of the Thomson-Houston Electric Company, at Lynn, Mass., where a very large number of separate machines are driven by individual motors with excellent results for economy.

A brief and very suggestive Paper was presented by Mr. Williams on "The Use of Triple Expansion Engines for Central Station Work." The author laid down the proposition that on the whole such machines would be found to give very satisfactory service, and the decreased consumption of fuel would in most cases pay for the extra cost of the more complicated engine in a single year. The cost of triple-expansion engines in this country is about 20 per cent. greater than that of ordinary compound engines; but the saving in fuel is usually found to be something like 20 per cent., so that there is a very considerable advantage to be derived from their use.

The committee work of the Association proved to be decidedly valuable, and efforts are being made to collect data concerning various problems that arise in central station operation. Efforts will be especially made to secure full details as to cost of generating power, a subject which has not yet received the attention that its importance demands.

A large number of members were in attendance, and in connection with the other work of the Convention many exhibits were shown of various devices and appliances used in central-station work. Most of the prominent electric supply companies were represented; and this feature of the Convention was, as it has been in past meetings, of considerable advantage. The meetings of the National Electric Light Association have resulted in some very interesting conferences between representatives of various interests more or less directly connected with electrical work. Especially at the present meeting was an effort made to secure co-operation on the part of the various insurance companies with reference to electrical risks. The committee on this subject was unable to make its final report, but some progress has been made toward formulating a general set of rules. The subject is, of course, a difficult one, but it is hoped that by the next Convention a code will be brought forward which will meet the approval both of the insurance companies and of those immediately interested in electric lighting. We have now various rules for installation in force in different parts of the country, and it is highly desirable that these should be reduced to a uniform basis, so that there may be some authoritative statement of the precautions to be taken in installing electric plants.

An interesting set of rules was brought forward at the meeting by Prof. Henry Morton, at the instance of the Employers' Liability Insurance Company, dealing especially with the precautions to be taken for the safety of workmen. These rules were of a most practical character, and were heartily endorsed by the members of the Association as likely to be of considerable value in future work, and as tending to promote the welfare of *employés*. The Convention was on the whole a successful one. A great amount of valuable work was accomplished, and plans were laid for still further widening and increasing the usefulness of the Association to all branches of electrical industry.

CORRESPONDENCE.

ELECTRICAL DRILLING MACHINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am much surprised to find, on page 454 of your issue of August 29th, a paragraph which professes to give a description of an electrical, or rather electro-magnetic, drilling machine, devised by Mr. Willatt, of Earle's Shipbuilding and Engineering Company (Limited), Hull, but which really describes a modification of the special class of electromagnetic machines for drilling and similar operations which I patented in 1882, and have introduced successfully since then.

You were good enough to publish extensive illustrations of some of my designs in your issue of June 3rd, 1887, and other illustrations have appeared in the *Engineer* and other papers from time to time; so that such publicity has been given to them as would fairly entitle me to believe that no person interested need have been ignorant that such machines had been devised.

I have further ground of complaint against this attempt to appropriate my designs and to take the credit of my invention, in that my friends, Messrs. McWhirter, Ferguson and Co., of Govan, who have manufactured several of my machines, supplied to Earle's Shipbuilding Company, in May last, a photograph and full particulars of one of my drillers, in reply to an inquiry addressed to them by Earle's Company.

I do not believe that the paragraph in your issue of last week is inserted with the sanction of the General Manager or the Board of that Company, and am, indeed, surprised that anyone should lend his name to so barefaced an attempt to appropriate the brains of another man.

My drillers, having electromagnets for attaching themselves to a curved deck, have been doing exactly the work you describe since January last in French shipbuilding works on some Japanese cruisers being built there, and have recently been introduced on the Clyde for similar work. In other forms they—as well as tapping and other machines on my system—are also doing a variety of other work on ships and boilers successfully.

You can understand from this that I am prepared to maintain my claim to this invention.—Yours, &c., F. J. ROWAN.

Regent Chambers, 121, West Regent-street,
Glasgow, September 1, 1890.

[The paragraph to which our correspondent alludes was taken from a local paper. We presume that most of our readers are aware of the inventions of Mr. Rowan, and many of them are no doubt acquainted with the ingenious methods which he has employed in carrying them out. We have no information as to the comparative merits or priority of the patents of the two drilling machines, and cannot therefore judge as to any intention to infringe or as to the "barefaced attempt to appropriate" our correspondent's brains.—ED. *E.*]

ELECTRICAL NOMENCLATURE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Dr. Fleming has raised the question respecting the nomenclature of the various units used in electrical measurements; and, in common with many others, he objects to the unit of self-induction being called either a Secohm or a Quadrant, and at the same time he calls attention to the fact that other units have distinguished physicists as their sponsors. To carry this system of baptism a step further, I venture to suggest that the unit of self-induction be in future designated as the "Flem."—Yours, &c., B. A. M.

British Association, Leeds, September 3, 1890.

TRADE NOTES AND NOTICES.

REMOVAL.—We understand that Messrs. Nalder Bros. and Co. are removing their factory from Westminster to No. 16, Red Lion-street, Clerkenwell, owing to increase of their business. The new premises will allow for considerable extension of their manufacture of voltmeters, ammeters, and other instruments, and the testing department will be on the same premises instead of at a distance as at present.

DISSOLUTION OF PARTNERSHIP.—The partnership has been dissolved which lately existed between Messrs. W. Mackie and Chalmers, electrical engineers, of Turnmill-street, Clerkenwell, E.C.

TENDERS DUE.—Tenders for the Electrical Central Station in Stockholm will be received from September 15th until October 12th, 1890, addressed to the direction of gasworks in Stockholm.

Digitized by Google

MAXIM-WESTON ELECTRIC LIGHT COMPANY (IN LIQUIDATION).—The liquidators of this Company invite tenders for the purchase of all machinery, plant, and stock, in one lot, at the Company's works, Kingsland Green, Dalston, N.E. Tenders, endorsed "Tender for Works," are to be in by September 15th next. Further particulars will be supplied by the Secretary of the Company, 55, Victoria-street, Westminster, S.W.

MESSRS. ERNEST SCOTT AND CO.—This firm have obtained the contract for the complete electric light installation for the new flour mill at Dunston, being built by the Co-Operative Wholesale Society. This mill will be one of the largest in the kingdom, if not the largest, and the electric light plant, which is being put in in duplicate, will consist of two 400-light "Tyne" compound-wound dynamos, and 466 16 candle-power incandescent lamps. The arc light installation will consist of one 9-unit "Tyne" compound-wound dynamo, and ten "Tyne" arc lamps, in strong water-tight lanterns, with reflectors. We hear that Messrs. Ernest Scott and Co. have a considerable quantity of work in hand of all descriptions, including a large contract for the lighting of Messrs. Arthurs and Co.'s works in Glasgow, in which two 400-light "Tyne" dynamos will be used. They are also lighting Messrs. John Bright and Bros.' Mills, at Rochdale, the new works of the *Bolton Evening News*, and the Cold Meat Rooms of the Northern Counties Ice Company.

SHIP LIGHTING.—The contract for lighting the four new steamers for the Manchester, Sheffield, and Lincolnshire Railway Company has been given to Messrs. Paterson and Cooper. Two of these are being built by Earle's Shipbuilding Company, Hull, and two by Swan and Hunter, Newcastle. Messrs. Paterson and Cooper have on hand besides the above the lighting of the ss. "Innamincka," "Garnet," "Tuskar," "Arranmore," "City of Dundee," and H.M. training ship "Empress."

THE WENHAM COMPANY (LIMITED).—This Company have recently carried out several important installations—among others, the Dental Hospital, Leicester-square, and the new theatre and winter gardens at Craig-y-nôs Castle, for Madame Patti-Nicolini—which have given their clients and the insurance companies great satisfaction. The theatre contains in all about 220 lamps, and there are also a number of suspended lamps in the winter gardens.

MESSRS. PAGE AND MILES.—This Company have lately completed an installation for Mr. G. Russell Miller, of Burgess Hill, Sussex, in which they have used an "Infant" dynamo with very satisfactory results. The dynamo is a 200 watt shunt-wound machine, and is driven by a Crossley two-man gas engine. This is principally engaged in charging a set of E.P.S. accumulators, but will run direct or in parallel with the cells if required.

MESSRS. EARL AND PHILP.—The tender of this firm, whose business address is 113, London-wall, E.C., has been accepted for lighting and ventilating the new premises of Mr. I. Kino on Ludgate-hill. The amount of the tender was £375.

ASBESTOS FIREPROOF CURTAINS.—The United Asbestos Company have received a letter from the lessee of the Queen's Theatre, Manchester, recently destroyed by fire, stating that, "Although for a long time the extent of the fire on one side of the curtain was so great that it must have been red hot, it remained intact, and the stage was saved, and the stage stock uninjured." This was the first occasion on which a "Victor" metallic drop curtain has been severely and practically tested, and justifies the claim of the Company as to its fireproof character.

THE AUTHOR'S HAIRLESS PAPER PAD.—We have received, and have almost used up, a very handy block of scribbling paper, sold under this title by The Leadenhall Press. A very light wooden holder to fit it is very convenient when writing in the train or in an arm chair. The back is of thick blotting paper, and each sheet when written can be placed underneath, the ledges on the wooden holder keeping them together.

CRICKET.—WOODHOUSE AND RAWSON UNITED (LIMITED) v. APPLETON, BURBEY AND WILLIAMSON.—A cricket match between elevens representing the above firms was played on Saturday last at Raynes Park, which, after an exciting game, ended in a victory for the former by one run. Scores:—Woodhouse and Rawson United (Limited).—First innings, 133; second innings, 58; total, 191. Appleton, Burbey and Williamson.—First innings, 94; second innings, 96; total, 190.

COMPANIES' MEETINGS & REPORTS.

Brush Electrical Engineering Company (Limited).

First annual report, to be presented to the shareholders at the general meeting of the Company to be held at Cannon-street Hotel, London, on the 8th September, 1890, at 12 o'clock noon:—

The Company was registered on the 10th August, 1889, and the business of the Anglo-American Brush Electric Light Corporation (Limited) was taken over as from the 1st August, 1889, and that of the Falcon Engine and Car Works (Limited) as from the 14th June, 1889, and the accounts made up to the 30th June last are for the periods embraced by these dates. The arrangements for carrying on the business of the Australasian Electric Light and Power Company (Limited) were not completed until much later, and the accompanying accounts do not include any return of business effected by the Australasian branch.

The profit and loss account shows a gross profit of £36,698. 16s., and after deducting all standing charges, maintenance of plant and buildings, and interest on debentures, there remains a balance of £14,235. 6s. 1d. It is proposed to apply £625 to reduction of preliminary expenses, £500 to reduction of provisional orders account, and £3,000 to reduction of property, patents and goodwill account to meet depreciation under these heads. The net balance of £10,426. 19s. 3d. is available for dividends. An interim dividend absorbing £3,808. 6s. 10d. has already been paid upon the Preference shares for the six months from August 10th to February 10th last, and it is proposed to apply £3,505. 4s. 6d. to the payment of a further dividend upon these shares, making up the full preferential dividend at the rate of 6 per cent. per annum from the date of registration of Company to June 30, 1890. The Directors recommend that the balance of £2,796. 14s. 9d. be carried forward to next account.

The temporary interruption to business caused by the amalgamations with other Companies and extensions of works has to some extent adversely affected the profit and loss account; and as several months have necessarily to elapse before the new works at Loughborough could be completed, the advantages of the lower cost of production at the country works were not obtained in regard to a large proportion of the orders executed. In view of all these circumstances, Directors consider the result of the year's working as encouraging.

The Falcon works at Loughborough have been considerably enlarged during the year at an expenditure of about £20,000; and the extension of these works enables the Company to manufacture at a materially reduced cost engines, boilers, cars and electrical machinery of practically every description and size. The Directors are of opinion that this money has been well spent, and they anticipate good results in the future from the erection of these works.

PATENT
SILICIUM BRONZE AND SILICIUM COPPER WIRE.
The best for overhead Telephone and Telegraph Lines,
AND ALL ELECTRICAL PURPOSES.

Hard Drawn High Conductivity Copper Wire.

ROLLED AND DRAWN
PHOSPHOR BRONZE.

PHOSPHOR BRONZE

WIRE AND SHEET MILLS: BAGOT STREET, BIRMINGHAM.

Digitized by Google

It affords the Directors much satisfaction to state that the Bill confirming the Provisional Order for lighting the central division of the City of London has been passed by Parliament. The agreement with the Commissioners of Sewers of the City of London provides that the work for the purpose of public lighting shall be commenced within nine months from the 21st May last, and the Directors are making the necessary preparations for giving effect to this condition.

The Company has also obtained a Provisional Order for Bournemouth, where a central electric light station has already been erected, which promises to yield very satisfactory returns. The Directors have applied to the Board of Trade for Provisional Orders for several other towns in the United Kingdom where the Company has interests to protect.

The Austro-Hungarian businesses have developed in a satisfactory manner, and the Vienna factory shows improving results both as to volume of trade and as to net profit. The necessity for providing additional factory accommodation in Vienna has now arisen, and the Directors are concluding negotiations for the acquisition of some freehold land and buildings adjoining the present works. They have also under consideration proposals for a re-arrangement of the Company's interests in the Vienna business.

The Directors have, with the assistance of Captain Rowan, the late general manager of the Australasian Company, fully examined into the character of the business acquired from that Company, and have made arrangements for the proper development of the Company's valuable patents and organisation in the Colonies.

Messrs. Cooper, Brothers and Co., the auditors, offer themselves for re-election.

The transfer books of the Company will be closed until after the 9th inst.

NEW COMPANIES REGISTERED.

LAMP MANUFACTURING COMPANY (LIMITED).—Registered, with a capital of £16,000, in £1 shares. Object: To carry into effect, with or without modification, an agreement which is already prepared and expressed to be made between Ridsdale's Railway Lamp and Lighting Company (Limited), of the first part; Edward Cecil Moore, the official liquidator of the said Company, of the second part; and Peter E. Chalton, of 18, Saltoun-road, Brixton, as trustee for the Company, of the third part; to carry on business as manufacturers of and dealers in lamps of all kinds.

NEW COMPANIES REGISTERED DURING AUGUST.—The following new electrical and engineering companies were registered during August:—

	Capital.
Atlas Engine Company (Limited), £1 shares	£12,000
Ceres Ironworks (Limited), £10 shares	15,000
Gordon Electric Traction Syndicate (Limited), £10 shares	2,400
Lartigue Railway Construction Company (Limited), £1 shares	125,000
Lamp Manufacturing Company (Limited), £10 and £1 shares	16,000
Mills's Patent Sectional Boiler Company (Limited), £5 shares	100,000
Nickel Steel Syndicate (Limited), £10 shares	75,000
Nonpareil Electrical Syndicate (Limited), £10 shares	6,000
Square Drilling Machine Company (Limited), £1 shares	100,000
Store's Patent Submarine Engineering Company (Limited), £1 shares	6,100
Sheffield Telephone Exchange and Electric Light Company (Limited), £1 shares	100,000
Vaughan-Sherrin Electrical Engineering Company (Limited), £5 shares	25,000

SHEFFIELD TELEPHONE EXCHANGE AMD ELECTRIC LIGHT COMPANY (LIMITED).—Registered by J. B. Roberts, 12, Coleman-street, E.C., with a capital of £100,000, in £10 shares. Objects: To acquire the undertaking of the Sheffield Telephone Exchange and Electric Light Company (Limited) (incorporated September 11, 1888), and to carry on in the United Kingdom or abroad all or any of the businesses of forming, establishing, and conducting telephonic and electric exchanges or centres, and of dealers in and leasing or letting of telephones and telephonic apparatus and wires. The first subscribers are:—John Tasker, Geo. Senior, Geo. Franklin, William Johnson, T. G. Shuttleworth, R. Charles Tasker, and William Tasker. There shall be not less than three nor more than six Directors. The first are John Tasker (Chairman), Joseph Gamble, George Senior, George Franklin, and William Tasker. Qualification, 20 shares. Remuneration, £300, divisible.

CITY NOTES, &c.

BANKERS' AND MERCHANTS' TELEGRAPH COMPANY OF NEW YORK.—The property and franchises of this Company have been recently sold at auction under foreclosure. Colonel Robert G. Ingersoll bid it in for $390,000.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended August 29th amounted to £4,806.

COMPAGNIE NATIONALE D'ELECTRICITE.—The public subscription to the share-capital of this Company, which works the Ferrante system in France, has enabled the company to commence immediate operations both in Paris and in the provinces.

CUBA SUBMARINE TELEGRAPH COMPANY.—The estimated traffic receipts of this Company for the month of August were £2,900, as compared with £2,815 in the corresponding month of last year. The receipts for the month of May, estimated at £3,400, realised £3,409.

DIRECT SPANISH TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of August amounted to £2,075, as compared with £1,624 for the corresponding period last year.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of August, 1890, amounted to £52,606, and to £52,012 in the corresponding period of 1889, an increase of £594.

EASTERN EXTENSION TELEGRAPH COMPANY.—The receipts of this Company for August amounted to £46,526, as against £39,469 in the corresponding period, showing an increase of £7,057.

ELMORE'S PATENT COPPER DEPOSITING COMPANY (LIMITED).—The *Financial News* of September 3rd devotes an article to the subject of the value of the shares of this Company, for which, it appears, that the plant now in process of completion is estimated to yield a profit of £174,720 per annum, sufficient to enable the Company to pay a dividend of 100 per cent. and leave a large surplus. Mr. Elmore himself is credited with the statement that the shares of the Company, although now standing at only £7, will at no very distant period stand at £50 each. If the various reports which are in circulation can be taken as correct, there must be a good time coming for Elmore shares.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this Company are as follows:—Receipts in August, 1890, £25,000; 1st January to 31st August, 1890, £181,000; corresponding months, 1889, £178,200; corresponding months, 1888, £179,200.

TRUSTEES, EXECUTORS, AND SECURITIES INSURANCE CORPORATION (LIMITED).—This Corporation announces that it will pay off the whole of its £200,000 first mortgage four-and-a-half per cent. debentures on March 1, 1891, at the rate of 110 per cent.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The Traffic Receipts of this Company for the month ending 31st August, 1890, amounted to £4,950.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended August 29, 1890, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,772.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the half-month ended August 31st, amounted to £2,420, compared with £2,161 in the corresponding period last year, an increase of £259.

WINFIELDS (LIMITED).—The Directors of this Company in their report just issued announce that, notwithstanding the reduction of the capital of the Company, they are still unable to recommend the payment of any dividend to the shareholders. They propose to raise £25,000 in £100 Debentures, and solicit the co-operation of the shareholders in their efforts to place the Company on a sound footing.

THE NON-CONDUCTOR OF ELECTRICITY.

VULCANISED FIBRE,

PATENTED.

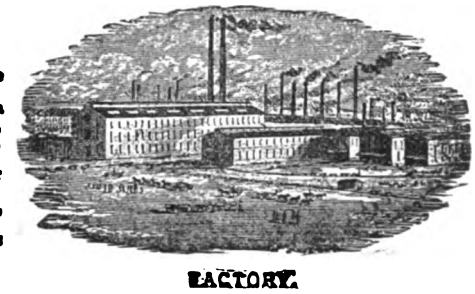
This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 2ft. 6in., varying in thickness from 1-50in. to 1in.



FACTORY.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

MOSSES & MITCHELL, 70, Chiswell-st., London, E.C.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 643.—Vol. XXV. FRIDAY, SEPTEMBER 12, 1890. Price Fourpence.

NOTES.

The most important communication at the Meeting of the British Association this year, so far as electrical science is concerned, was undoubtedly that of Prof. Ewing on "A Molecular Theory of Induced Magnetism," whose contribution to the current number of the *Phil. Mag.* on this subject will be found in another column. Among the congratulations and expressions of admiration which followed the discourse, the assertions that this was the most important discovery of this year and that it ranked with those of Hertz were not due to mere temporary enthusiasm. The illustrations in the author's Paper give a very inadequate idea of the beautiful experiments which it would be almost impossible to describe, and which must be seen to be appreciated. We hope that Prof. Ewing will be induced to repeat them under conditions more worthy of the occasion, and before an audience of ten times the size, at some institution in London. Besides the magnetic theory of Prof. Ewing, the meeting of the British Association at Leeds in 1890 will not be memorable for anything which concerns electrical engineering.

The work of the Sections commenced on Thursday with the Presidential Addresses. In Section A Dr. Glaisher did not attempt the usual, and generally unsatisfactory, task of reviewing the progress of his own subject—pure mathematics, or of that of the Section for the preceding 50 years, or since the British Association last met at Leeds; but delivered an address which surprised even those who know the special branch of mathematics to which he has devoted himself. Ranking as he does as one of the four great pure mathematicians of the day, he gave in his address, of which we give a brief abstract, an excellent account of the relations which mathematics bear to physics. Specialising in a subject which seems to most people to be the extreme sublimity of arithmetic, although he says that the theory has nothing to do with arithmetic in the ordinary sense of the word, his division of the theory of quantity into two branches only, "Algebra, and all the ordinary subjects of pure mathematics," and "the theory of numbers," is not remarkable. It is an excellent thing that mathematics should be so specialised. Some minds are mathematical, and some are not; exactly as some are musical and others find neither pleasure or any interest in melody or harmony. But there are still a number of engineers, and even men of science, who, believing mathematics to be "the ordinary processes of algebra, differential and integral calculus, &c.," imagine that they are not mathematically minded, and therefore avoid those branches in which such operations are required. The day is happily approaching when geometrical methods are being more commonly used; and such persons are beginning to realise that some subjects, at all events, are open to them in which they can surely arrive at solutions of problems without having to translate them first into a language of symbols, thence to be re-translated into common sense.

The discussion which was announced for Friday morning on Electrical Units was very disappointing. Mr. Glazebook read a valuable Paper describing the different methods by which the ohm had been determined, and gave a very complete list of the results, pointing out the relative merits of the various systems, especially with reference to the various degrees of accuracy with which the different quantities could be measured and the form in which they appear in the calculations. It is difficult, for example, to measure the exact mean radius of a coil, and it is therefore desirable that the diameter should not appear as a square, but as its first power. The Paper by Prof. Viriamu Jones was of great interest; but the discussion, except so far as it related to the methods, was very poor. The general question of the use of mercury was raised; and there appeared to be a general opinion among most of those who have been engaged in carrying out the work of making the determinations, that mercury was the proper material of which to make the standard. It was admitted that such a standard was quite unsuitable for engineers, Lord Rayleigh saying that it was useless for factory purposes, a wire being what was really wanted. The fact is that practical men are in the hands of the higher beings who carry out the experiments. The comparison of a wire with the mercury standard is a sufficiently difficult operation, and quite beyond the powers of any ordinary engineer and of most instrument makers.

It was proposed in a very formal manner that the meeting should determine whether the value of 106·3 should be adopted. It was pointed out that since the United States were represented by Prof. Rowland, and France by Prof. Mascart, the question might receive an international sanction. This ambitious idea unfortunately fell through, as Prof. Rowland was unprepared with any figures, and Prof. Mascart had apparently gone to lunch. No one but a Surgeon-Major, whose name we did not catch, raised any objection. Mr. Preece, who justified his reluctance to adopt the value pro-

Digitized by Google

posed four years ago, unhesitatingly accepted the average of the latest determinations, and undertook to recommend the adoption of 106·3 to the Government. At a subsequent meeting of the committee this value was adopted by the British Association.

For the Paper by Mr. Wilson Hartnell, the author substituted a lecture "On the Stringency of Fire Office Rules," illustrating his remarks by experiments. He had provided a number of glow lamps and switched them on gradually, with a single No. 20 wire in circuit, until 50 amperes were passing. The wire then began to burn. The same current was then passed through a No. 16 wire, raising it to about 90 degrees. We are able to state upon the highest authority that the point of the author's arguments was altogether missed; and, therefore, without further comment, we refer our readers to the Paper, which will be reproduced in our columns.

Among the examples of the want of organisation was the reading in Section G, on Monday, of the Paper by Mr. Newman Laurence, and Dr. Harries, on the physiological effects of currents, another being down for reading by Mr. Swinburne in Section A, on the same subject. This is by no means a rare occurrence, and is an instance of the careless way in which the business is arranged. The discussion on the former did not bring to light any useful information.

An artificial retina sensitive to light in the same way as the average human eye is certainly a great desideratum in photometry; and, according to M. Lion, this may be obtained by the use of a moist film of iodide of nitrogen. A new photometer, based on the employment of this substance, was described in the Notes column of our last issue, and since the longer the film is subjected to the action of the light rays the greater is the quantity of nitrogen disengaged, the sensibility of the instrument must continually increase with the time of exposure. This characteristic forms a decided advantage which the instrument possesses over others; but its significance is much diminished by the fact that it appears to take a considerable time before sufficient nitrogen is disengaged to take a reliable reading. In spite of the fact that the chemical action of light is caused chiefly by the non-luminous or ultra-violet rays, it appears that with this substance the luminous rays are most effective, and that, just as with the human eye, the yellow green rays have the greatest influence. Considering the well-known fact that human eyes differ considerably among themselves, and that partly in consequence of this photometric measurements are subject to many errors, it would appear that the film of iodide of nitrogen can be regarded as an artificial retina, measuring illumination equally well, whatever its colour. If a substance of this nature can be found which may be left to itself without danger, and from whose indications reliable readings may be obtained without the need of waiting some minutes, its applications to photometry would be numerous and important; and with this view it seems desirable that the action of light on complicated chemical compounds should be studied further than has hitherto been the case.

For some time past there have been reports of a very unsatisfactory character with regard to the performances of the electric light at Bath, but we were inclined to attribute them in a large measure to local exaggeration of those minor mishaps which seem to be the inevitable concomitants of electric lighting stations in this country when they first come into operation. The letter of Mr. Charles Powell, which will be found in our correspondence columns, shows, however, that things at Bath are not as they should be, and that the breakdowns are due to causes well within human control. In A.D. 1890, "experimental lighting" should be as extinct as the dodo.

In our correspondence columns this week will be found two interesting communications from Prof. Elihu Thomson with regard to some recent editorial comments of ours upon his new meter and new alternator.

Telegrams for South America.—We are informed that the cable from Buenaventura to Santa Elena has been repaired.

Platinum.—It is reported that platinum has been discovered in some ores from the Las Yedras Mines in the State of Sinaloa.

Teplitz.—The Town Council has decided not to renew their contract with the Gas Works, but to build an electric light station.

Woolwich.—The Woolwich Local Board has decided to support the proposed Order of the Woolwich District Electric Lighting Company.

Derby.—At the last meeting of the Town Council an Electric Lighting Committee was appointed to take into immediate consideration the question of carrying out the provisions of the Electric Lighting Order just granted to the Corporation.

Zurich.—The Zurich municipality intend, says *Industries*, to arrange with the Oerlikon Works for the street and private lighting of the town. The installation will be for 10,000 lamps of 16 c.p. Brockie-Pell lamps will be used for the arc lighting.

The Zanzibar—Dar-es-Salaam Cable.—The Eastern Telegraph Company's ss. "Amber" completed on 10th instant the laying of cables from Zanzibar to the German stations at Bagamoyo and Dar-Es-Salaam under agreement with the German Government.

Ayr.—On the recommendation of the Committee, the Town Council has agreed to appoint Messrs. Muir, Mavor, and Coulson to report as to the best system of electric lighting for Ayr, and to give plans and full statistics as to the cost of erection and maintenance of works.

Glasgow.—At the last meeting of the Town Council it was decided that a remit should be made to the Gas Committee to consider, under such professional guidance as they might think necessary, the whole subject of carrying into effect the powers contained in the Corporation Electric Lighting Order.

Electric Light in the Hofburg.—The Emperor of Austria has decided that the electric light shall be introduced into his palace in Vienna, the Hofburg, where till now wax lights have generally been employed for the purpose of illumination. About 8,000 incandescent lamps will be required to light the building throughout.

Bristol.—The Sub-Committee appointed to visit various towns to inspect the methods adopted for supplying electricity for lighting purposes have recommended that the Corporation shall take the electric lighting into its own hands, and suggest that some 70 1,000 candle-power arc lamps shall be erected in the main streets.

Tempered Copper.—Amongst the electrical exhibits at the Cape May meeting of the National Electric Light Association were some tempered copper castings. Samples were shown of

Digitized by Google

commutator segments, dynamo brushes, rolled copper for brushes, spring rolled copper, journal bearings, and copper castings of various kinds.

The Australasian Cable Rates.—*The Times* states that the New Zealand Government has declined to bear a share of the subsidies and guarantees required by the cable companies in connection with the proposed reduction of the telegraph rates between Australia and Great Britain, owing to the refusal of the Imperial Government to bear any portion of the responsibility.

Electrical Litigation.—The Victor Popp Company, says the *Bulletin International de l'Electricité*, used to number amongst its customers the Café Chauvet. Owing to the unsatisfactory character of the supply, however, the proprietor recently decided to give up the use of the electric light, and has now brought an action against the Popp Company for the purpose of obliging it to place his fittings in their original condition.

A Diminutive Electric Light and Power Station.—Collias, near Nimes, a village of 465 inhabitants, has just been lighted by electricity. The motive power for the 1,600-light dynamo is derived from a small waterfall. The streets are lighted by 25 lamps of 16 candle-power each. Besides lighting the village, the current is employed during the day in putting in motion the pumps for supplying certain parts of the village with water.

Personal.—We are informed that Major-General Webber's Paper on "Electrical Distribution," which he had purposed reading before Section G last Monday, was withdrawn owing to the Committee having felt that the subject was too comprehensive to permit of its being adequately discussed in the time available. Major-General Webber intends to bring his Paper before the Institution of Electrical Engineers at an early date.

Dundee.—At the last monthly meeting of the Dundee Gas Commission, Mr. Henry Robertson stated that with a steadily increasing consumption of gas the Board were apt to remain quiescent in regard to electric lighting, but he hoped the Board would not delay in providing the community with the light of the future. A letter was then read from the Electric Installation and Maintenance Company tendering its services for the construction and maintenance of electric works in Dundee.

Morse Signalling at Night.—On Monday night last experiments were conducted in the Solent with a new electric signalling lamp, under the superintendency of Captain Gallwey, of the Hecla. The Mastiff, Blazer, Seahorse, and a torpedo boat were stationed at fixed distances apart, stretching from Bembridge Ledge to the shore, and after dark a number of flashing signals were exchanged with the object of determining the range at which the Morse code could be distinguished and read.

Wanton Destruction of Telegraph Insulators.—At the Manchester Police Court on Monday, five youths were each fined 40s. and costs for destroying telegraph insulators. For some time the habit of smashing insulators has been growing amongst the lads in the suburbs of Manchester, with the result that since January over 400 have been broken in one district. One of the witnesses stated that in his district alone the cost of repairs by the damage to insulators was close on £1,000 per year.

The British Association Meeting.—The *Yorkshire Evening Post* of Wednesday contains a humorous illustrated description of what the Editor terms "The Farewell to the Philosophers." Some grotesque caricatures from the pen of Mr. Harry Furniss are given; included in the list being Sir Douglas Galton, Sir Frederick Abel, Sir William Thomson, Lord Rayleigh, Sir Henry Roscoe, Sir Frederick Bramwell, Prof. Glaisher, &c. Humorous text accompanies the illustrations, and this is followed by some poetry on the work of the Association.

Magnetic Brass.—We have recently had an opportunity of examining sheet-brass compass cases, which exhibited distinct traces of magnetism. In some the polarity was weak and somewhat irregular and ill-defined, but in one in our possession the poles are strong and well defined, and this phenomenon is doubtless due to the presence of iron particles within the brass, although we should add that the cases in question were supplied by a good maker. It would be interesting to know whether instrument makers and others have often met with this "magnetic brass."

Fareham.—An experimental run of the electric light was made on Friday night over a portion of the system by the Fareham Electric Light Company. The main streets, from the railway station to Wallington Hill, a distance of about a mile and a quarter, are to be lighted by 21 arc lamps of 1,200 candle-power, and the side streets are to be illuminated by about 85 incandescent lamps, each of 20 candle-power. The Company's contract with the Local Board, who have engaged to pay £500 per annum for the lighting of the town, came into effect on Monday.

Edinburgh Exhibition.—The East of Scotland Engineering Association recently held a special session at the Exhibition. Amongst the Papers read was one on the "Protection of Buildings from Lightning," by Mr. A. R. Bennett, Vice-President of the Association, in which the effects of several recent storms in Scotland on buildings and telegraph wires were described; and one descriptive of the telephonic exhibits, by Mr. C. G. Wright. The remaining Papers dealt with the mechanical exhibits, the one by Prof. Elliot on the Locomotive Annex being specially noteworthy.

The Seely Flexible Wired Moulding.—The Seely "flexible wired moulding" is of rubber, and in this moulding the wire is imbedded. The moulding corresponds to ordinary wooden moulding, and answers exactly the same conditions, as well as having a number of advantages of its own. It can be placed on ornamental ceilings and walls without defacing them, and will take any decorative finish required. It can be handled in rolls of several yards, cut to any needed length, and carried right to the spot, with the consequent avoidance of carting, and the cutting, sawing, &c.

A Sign of Progress.—One of the most characteristic signs of the progress which is being made by electricity is, says *La Lumière Electrique*, to be seen in the rapidly increasing size of the dynamo units adopted at central lighting stations. At the Electrical Exhibition of 1881 the most powerful dynamo was an Edison machine giving 800 amperes and 110 volts (120 horse-power). At the present moment the Berlin central stations have 500 horse-power dynamos running, and at Deptford a 3,000 horse-power alternator is at work and two 10,000 horse-power machines are building.

The Water Power of the United States.—"An official calculation upon the best data obtainable brings out the extraordinary fact," says the *Electrical Engineer* of New York, "that the rivers and streams of the United States, averaged throughout the year, show over 200,000,000 horse-power." The returns of the 1880 census showed that there were in use in the United States no fewer than 55,404 water-wheels, developing a total of 1,225,379 horse-power, or 36 per cent. of the total power employed for industrial purposes. In 1880, therefore, only ·6 per cent. of the total available water-power of the United States was utilised.

Georgetown (Demerara).—The Telephone Exchange—to which there are already 200 subscribers—was inaugurated on August 1st. All business places are required to pay an annual rental of $24, and private residences a subscription of half the amount, one month's notice being required of intended discontinuance. At present 27 of the Government Office are on the list of renters, as well as the Town Hall, Waterworks, and three other Municipal Offices, 95 business firms, including the Railway, Gas Company, and Ice depôts, and 73 private residences. The whole of the arrangements are in charge of Mr. S. Vyle, the Government Electrician.

Tasmanian Telegraphic Statistics.—The last report of the Tasmanian Telegraph Department shows a steady increase in business. The number of messages increased in 1889 from 70,453 in the previous year to 77,408, and the revenue from £4,801. 17s. 4d. to £5,378. 3s. 3d. The lines during the year were extended 47 miles, and five new offices were opened. The miles of poles on December 31, 1889, numbered 1,283, miles of wire 1,889, stations in circuit 120, persons employed

Digitized by Google

184. During the year 43,087 free messages were transmitted, valued at £4,530. 3s. The total number of messages passing through the Hobart office during the year was 79,163. The rental received from telephones during the year was £3,108. 14s. 5d., as compared with £2,640. 18s. in the previous year.

The Gassner Dry Cell.—In a letter to the *English Mechanic* Mr. G. E. Bonney gives some particulars relating to an experiment which he carried out to test the durability and recuperative capabilities of the Gassner dry cell. The cell employed was of the flat square type, measuring $6\frac{1}{4} \times 3\frac{1}{4} \times 1\frac{1}{4}$in. The cell was connected up to a 2in. bell and run on it day by day, stopping only at night. The recuperative effect of a night's rest on the cell was most marked. When 118 hours' work had been got out of the cell it was determined to recharge it. To effect this it is only necessary to connect the positive pole of a two-celled Bunsen battery to the negative pole of the Gassner cell, and send a current through for a few hours, to thoroughly renew its vigour.

The Lemp Transformer for Heavy Currents.—When transformers are designed to produce very large currents, as in electric welding operations, the question of winding the secondary becomes a difficult one. In the Lemp transformer the secondary is a solid mass of copper, having a groove in its side, in which lies the primary coil. By this arrangement the secondary can be made as a single casting and the primary wound over it, or, in some cases, wound on a bobbin and slipped over it. The secondary thus consists of a single turn of a great cross section and consequently enormous carrying power, while the construction of the transformer is rendered exceedingly simple. Transformers of this type have been made at the works of the Thomson Electric Welding Company, and have proved very convenient and efficient.

The Frankfort Exhibition.—Messrs. Siemens and Halske are putting down continuous and alternating current plant on a very extensive scale at the Exhibition, as well as a huge battery of accumulators. Two tramways, one worked by accumulators, the other by an overhead conductor, will convey passengers to the Schillerplatz. Inside the Exhibition a tramway with underground conductor will also be shown. For running various workshops Messrs. Siemens and Halske are transmitting power by electricity from a source four kilometres distant at the Palmengarten. The deposition of copper and the commercial production of ozone are to be shown in the metallurgical and chemical sections. In the telegraphic section will be a tape-printing machine, which, it is said, has not yet come into extensive application in Germany.

University College, Nottingham.—The classes about to commence at this College in electrical and mechanical engineering, for both day and evening students, will practically cover the same ground as those at Finsbury, and will prepare evening students for the City and Guilds technological examinations, and for the Government and Whitworth Exhibitions. The College is provided with a three-light Brush and 300-light Ferranti dynamo, with Siemens's exciter, &c., driven by a Roby steam-engine. In the new dynamo-room the newest type of Atkinson Cycle gas engine, specially fitted for tests, &c., drives a Phœnix dynamo that can be joined up in various ways. For the mechanical course, a well-provided mechanical engineering laboratory is being arranged. The new technical schools, to be erected at a cost of £15,000, for the engineering department, besides being the headquarters of the various courses in engineering proper, are intended to support the local industries, lace and hosiery, and meet the local needs.

Electric Lighting at Reichenhall, Bavaria.—The motive power for the Reichenhall central station is obtained from a stream, the quantity of water available being about 4,000 to 4,500 litres (140 to 157 cubic feet) per second, with a fall of 2·6cm. (8·8ft.). Jonval constant-speed turbines, running at 34 revolutions a minute, are employed, and drive Kapp alternators through intermediate shafting. The alternators have an output of 2,000 volts and 30 amperes at 600 revolutions. The mains, which are of 6mm. copper wire, run overhead on masts 50ft. high, Johnson and Phillips' insulators being used. The circuit runs through the town of Reichenhall to the cloister of St. Zeno, about two miles away, and thence to the Kirchberg and other distant localities. At present 10 Kapp transformers, having a total output of 43,000 watts, are installed. The transformers are provided with three terminals to enable the consumers to run either 50 or 100 volt lamps. Some 900 incandescent and 118 arc lamps have already been connected to the mains.

Barnsley.—At a meeting of the Town Council, on Tuesday, the minutes of the Park and Lighting Committee were discussed. The committee recommended that the Town Clerk should be directed to apply to the Local Government Board for their sanction to borrow the sum of £23,000, required for electric lighting purposes. The committee also recommended that Mr. Bromley Holmes be appointed electrical engineer during the construction of the electric lighting plant, and also for three months after its completion. Mr. J. H. Bailey moved that the clause with respect to the appointment of Mr. Bromley Holmes be adjourned to next month; and he raised the question whether they had, in the Westinghouse Company, whose tender the Council had decided to accept, the best system that could be got. He moved that the minute referred to be adjourned, and that the Thomson-Houston Company be allowed to send in an amended tender. A long discussion ensued, and ultimately the minutes were confirmed, subject to the last clause being adjourned one month. Mr. Bailey then gave notice that he would at the next meeting propose that the resolution of the Council accepting the Westinghouse tender be rescinded.

A Mascart Dynamometer.—In a recent number of the *Comptes Rendus*, M. Mascart describes a direct-reading transmission dynamometer with photographic recording-apparatus devised by him. The following abstract of his description is taken from the Foreign Abstracts of the Institution of Civil Engineers. On the shaft of the prime mover are mounted two pulleys, one fast the other loose. The latter is connected to the former by springs, the deformation of which is indicated by a pointer playing over a scale on one of the pulleys. The scale is empirically graduated. When the movement is slow, the position of the pointer can be determined by inspection; but for quick-running shafts, M. Mascart increases the time during which the pointer is visible, by adding to it a lens so placed that the pointer is in its focus. The pointer and corresponding mark on the scale remain then visible during the time that the shaft requires to revolve through an angle equal to the focal angle of the lens. The image of the pointer can be photographed on a slip of sensitised paper set in movement by the shaft. M. Mascart states that the dynamometer described has been fitted to a 10-HP. steam-engine at the Central Meteorological Bureau.

The Safety of Electricity.—The vague and irresponsible statements which have for a long time past been circulated, more particularly by the daily press, have had the effect, says The *Electrical Engineer* of New York, of instilling into the minds of the uninformed the notion that the *employés* of electric-light stations were subject to greater risks from accidents than those engaged in any other occupation, powder mills and dynamite factories not excepted. All attempts to counteract this feeling of distrust have heretofore been futile; and it is, therefore, a matter for congratulation that the electrical fraternity is now enabled to go before the public with a statement of the exact facts, in the shape of statistics gathered by an Insurance Company, whose desire to get at the correct figures cannot be called in question. The result of the investigation undertaken by the Employers' Liability Assurance Corporation, as set forth in Prof. Morton's Paper, read at Cape May, shows that out of 91 accidents reported in central stations only 15 were assignable to the effects of the current, the remaining ones being such as are constantly occurring in power-using establishments.

Telegraphic Statistics.—According to the New York *Tribune* there are in use now throughout the world 2,500,000 miles of land telegraph wires. Of the sum total of lines, those of the United States constitute a little more than 30 per cent. Sixty-one per cent. of the telegraph lines of the world are owned and operated by Governments, and leaving the United States out of consideration, about 88 per cent. In North America the

Digitized by Google

body of the message only is charged for; in other countries the address or signature, or both, are tollable. In the United States the toll ranges from 25c. to $1 for ten words, according to the distance; in the Argentine Republic it is 40c. for ten words, and 20c. for each additional ten words; in Denmark and in Sweden and Norway, 13·4c. for ten words, and 1·34c. for each additional word; in Ecuador, 20c. for ten words; in Egypt, 49·6 for ten words; in Germany, 1·4c. per word, the minimum being 14c. per message; in the United Kingdom, 6d. for twelve words; in the Cape Colonies, 1s. for ten words, and 6d. for each additional five words or part thereof; in Italy, 20c. for fifteen words, and 1c. for each additional word; in Japan, 4c. per word, including the address and signature; in Portugal, 5c. for the first word, and 1c. for each additional word; in Switzerland, 1½c. per word; in Turkey 2c. to 4c. per word. In New Zealand messages are classified as urgent, ordinary, and delayed, the rates being respectively 2s., 1s., and 6d. for ten words, with ½d. for each additional word.

Electrolysis of Animal Tissues.—A Paper on this subject by Mr. G. N. Stewart is being published in a volume of memoirs from the physiological laboratory of the Owens College, Manchester. The first part of the research was directed to answering two questions:—Is the conduction in animal tissues entirely or chiefly electrolytic? What are the electrolytes? It is shown that by far the greatest part of the conduction at any rate is electrolytic, and that the best conductors are undoubtedly the inorganic constituents of the tissues. The proteids are exceedingly bad conductors. It is shown that the proteids are affected not by primary electrolysis, but by the products of electrolysis of the salts. In solutions of coagulable proteids alkali-albumen is formed at the cathode, and acid-albumen at the anode, some of the proteid being coagulated at the latter. Great changes were found in the microscopic appearance of the fibres of isolated tissues, suggesting the action of a dilute acid. At the cathode the fibres were more homogeneous than before. There was no indication in the electrolysis of blood that hæmoglobin acts the part of an ion. At the anode the reaction becomes acid, and acid-hæmatin is formed, which remains partly in solution and is partly thrown down, the solution becoming less deeply coloured. When the current is strong, or long continued, the hæmatin suffers further change and is decolorised, apparently by the oxygen or chlorine set free. The proteids of the serum and corpuscles are partly coagulated at the positive pole.

The Gibbs System of Train Lighting and Heating.—In some of the express trains running on the lines of the Chicago, Milwaukee, and St. Paul Railway Company, the Gibbs system of lighting and heating has been in successful operation for nearly two years. An independent "light and heat tender," in other words a central light, heat and power station on wheels, is attached to the train. This special car follows immediately behind the locomotive tender, it is 34ft. long by 9ft. in width, and is encased in ¼in. plate steel. Including full equipment, the car weighs about 29 tons. The interior is divided into two compartments, separated from each other by steel doors. The forward section contains a tubular steel boiler of the locomotive type, with water leg around fire-box. The rear section contains a No. 4 Edison compound-wound dynamo belted direct to a standard Westinghouse engine of 15 horse-power, the distance between the centres of shafting being 7ft. 6in. The weight of engine and dynamo is counterbalanced by a steel tank placed on the opposite side of the section, and holding 270 gallons of water in reserve for use in the event of an accident or the absence of the locomotive tender, from which the water required in the boiler is constantly pumped. Experience has shown that when the thermometer falls to 10°F. above zero, it requires 100lb. of water per car hour to properly heat the train, and 70lb. of water per car hour of the temperature is only 5° below freezing point. In addition about 58lb. of water are required per indicated horse-power hour in the operation of the dynamo. An idea of the efficiency of the system may be drawn from the results of a recent test, which show that for 48,000 watt-hours supplied in the lamps, 68 horse-power hours were supplied to the dynamo. The commercial efficiency of the system is therefore about 94 per cent.

Street Lighting of New York.—With reference to the high prices asked by the electrical supply companies for street lighting of New York, the *New York World* learns that every subway connection to an arc light costs the company $100 (£20. 18s.), and the subway rental amounts to from 5½ to 11 cents (2¼d. to 5d.) a night for each lamp. One circuit averages nearly 11 cents rental for each lamp. In this circuit there are six and four fifths miles of cable, the actual cost of which was $182.50 (£38) for each lamp. This, added to the cost of connections, lamps, and other expenses, brings the total preliminary outlay up to $322 (£67) per lamp. As the city will only make contracts for one year this expenditure may all be a dead loss. The relative cost of dynamo stations, machinery, &c., is about $400 (£83. 10s.) for each lamp. Interest and taxes on this total preliminary outlay of $722 (£150) per lamp will amount to 10 per cent., or $72.20 a year. The actual cost for coal, labour, &c., to generate the current amounts to an average of 26 cents nightly for each lamp. A cable will not last over ten years, if so long. Adding 10 per cent. of the cost of the cables for the actual running expenses, and interest and taxes on capital invested, brings the actual expense per lamp up to $223.18 (£46. 10s.) a year. At 35 cents (1s. 6d.) per night for each city lamp the companies would receive $127.75 (£26. 10s. about) a year, or $95.43 (£20) less than the actual cost, and in the estimate of cost officers' salaries and some other necessary expenses are not included. The New York companies this year offered to light the lamps for the same as last year up to January 1st and for 43 cents (1s. 9d.) after that. The reason given for this is that there was only about $70,000 (£14,600) left for street lighting. A few years ago the city paid 45 cents a night for each lamp, and found that price cheaper than hiring extra policemen.

Electrical Gear for Quick-Firing Guns.—The Forges et Chantiers de la Mediterranée are making great use of electrical power, not only in their Toulon shops, but for working the Canet quick-firing gun. For training in elevation, a small electric motor is placed on a bracket bolted to the rear of the left-hand frame of the carriage and forming an extension of it; the armature runs on a horizontal shaft. On this is mounted a bevel wheel that gives motion to suitable gearing, and to a spindle that actuates the elevating gear. For training horizontally, a second small motor is employed. In both cases a clutch is interposed in such a manner that, by shifting a lever, the electrical arrangement can be thrown out and the ordinary hand gear substituted. The motor that supplies the energy for training in elevation weighs 61·6lb; that for training in direction, 72·6lb. The difference of potential adopted is 70 volts, which is the standard in use in the French Navy for electric lighting. At the Paris Exhibition, where an electrically-equipped Canet quick-firing gun was exhibited, recourse was had to accumulators, Commelin-Desmazures cells being employed. These accumulators, it will be remembered, consist of copper and zinc plates placed in an alkaline bath; the positive plate is formed of porous copper, and the negative of a metallic cloth made of tinned iron wire. The bath consists of a concentrated solution of zincate of potash. During the charge the porous copper is transformed into a sub-oxide of copper, and the zinc is deposited on the iron gauze, the potash remaining free in the solution. During the discharge the zinc is restored to the potash solution; the sub-oxide of copper is reduced, and is restored to its original condition of porous copper. The plates so arranged do not require any preliminary formation. At the Exhibition the installation used for furnishing power to work the gun consisted of 45 cells, each of which gave about ·75 of a volt. Especially interesting in this arrangement is the facility given for training both in direction and elevation at the same time, as it is obvious that the work of laying the gun can be carried out far more promptly, and the rapidity of fire can be thus largely increased. It is evident, says *Engineering*, to whom we are indebted for the above particulars, that if electrical power can be relied upon, and the disadvantages attending its use overcome, that it presents great advantages as regards first cost and ease of maintenance and control, as compared with water power. It seems, indeed, most probable that the departure exhibited by M. Canet last year will have larger consequences than he imagined at the time when he designed the apparatus for electrically raising, lowering, and turning his 15-centimetre quick-firing gun.

ON ALTERNATE CURRENTS IN PARALLEL CONDUCTORS OF HOMOGENEOUS OR HETEROGENEOUS SUBSTANCE.*

BY SIR WILLIAM THOMSON, F.R.S.

This Paper consists of a description of some of the results of a full mathematical investigation of the subject, which I hope to communicate to the *Philosophical Magazine* for an early number :—

1. Two or more straight parallel conductors, supposed for simplicity to be infinitely long, have alternating currents maintained in them by an alternate-current dynamo or other electromotive agent applied to one set of their ends at so great a distance from the portion investigated that in it the currents are not sensibly deviated from parallel straight lines. The other sets of ends may, indifferently in respect to our present problem, be either all connected together without resistance, or through resistances, or through electro-motive agents. All that we are concerned with at present is, that the conductors we consider form closed circuits, or one closed circuit, and that therefore the total quantities of electricity per unit of time at any instant traversing the normal sections in opposite directions are equal.

2. We suppose the period of the alternation to be very great in comparison with the time taken by light to traverse a distance equal to the greatest diameter of cross-section of our whole group of conductors. This supposition is implied in the previous assumptions of parallel rectilinearity of the electric stream lines, and of equality of the quantities of electricity traversing, in opposite directions, the several areas of a normal section.

3. We farther suppose that the length of our conductors and their effective ohmic resistances are so moderate† that the quantities of electricity deposited on and removed from their boundaries to supply the electrostatic forces along the conductors required for producing the alternations of the currents, are negligible in comparison with the total quantity flowing in either direction in the half-period. This supposition excludes important practical problems of telegraphy and telephony, the problem of long submarine cables, for instance ; but it includes the problem of electric lighting by alternating currents transmitted at high tension through considerable distances ; as, for example, from Deptford to London.

4. The general investigation includes as readily any number of separate circuits of parallel conductors as a single circuit, but, for simplicity in describing results, I suppose our system of conductors to be so joined at their ends as to constitute a single simple circuit of two parallel conductors.‡ It may be either two parallel conductors or one conductor, one of which may or may not surround the other, as shown in Figs. 1 and 2, representing cross-sections. Each conductor may be single as in Figs. 1 and 2, or either may be multiple parallels.

5. We suppose each conductor to be homogeneous in substance, and in cross-section from end to end, but not necessarily homogeneous in different parts of the cross-section. Thus the two conductors, or the different parts of either, may be of different metals, or either conductor or any part of either conductor may consist of two metals (as iron and copper, or iron and lead) laid parallel and soldered together.

6. We shall call A and A′ the cross-sectional areas or groups of areas of the two conductors respectively of the other. All the different portions of A are connected metallically at their two ends, and are thus all of them at one potential at one end and another potential at the other end ; and similarly for A′. The homogeneousness of the material and of the cross-sections along the length of the conductors and the uniformity of the total currents assumed in § 3, implies that all the different parts of A in one cross-sectional plane are at one potential, even though A consist of mutually isolated parts, or A′ consist of isolated parts. If, as in Figs. 1 and 2, all the parts of A are in mutual metallic connection, and all the parts of A′ are in mutual metallic connection, this would entail uniformity of potential through A, and uniformity of potential through A′, even without the limitation of our subject laid down in § 3.

7. The following are some of the most noteworthy results of the full mathematical treatment of the subject.

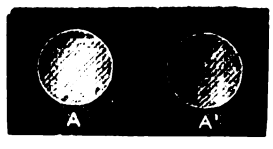

Fig. 1.

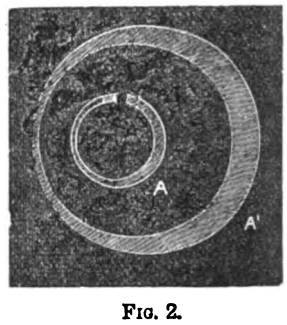

Fig. 2.

I. When the period of alternation is large in comparison with 400 times the square of the greatest thickness or diameter of any of the conductors, multiplied by its magnetic permeability, and divided by its electric resistivity, the current intensity is distributed through each conductor inversely as the electric resistivity ; the phase of alternation of the current is the same as the phase of the electro-motive force ; and the current across every infinitesimal area of the cross-section is calculated, according to the electro-motive force at each instant, by simple application of Ohm's law.

II. When the period is very small in comparison with 400 times the square of the smallest thickness, or diameter of any of the conductors, multiplied by its magnetic permeability and divided by its electric resistivity, the current is confined to an exceedingly thin surface-stratum of the conductors. The thickness of this stratum is directly as the square root of the quotient of resistivity, divided by magnetic permeability, of the substance in different parts of the surface. The total quantity of the current per unit breadth of the surface is independent of the material, and, except in such cases as those referred to at the end of II. below, varies in each cross-section in simple proportion to the electric surface density of the static electrification induced by the electro-motive force applied between the extremities for maintaining the current. The distribution of this electric density is similar in all cross-sections, but its absolute magnitude at corresponding points of the cross-section varies along the length of the conductor in simple proportion to the difference of electric potential between A and A′, and is zero at one end, in the particular case in which the conductors are connected through zero resistance at one end, while the electromotive force is applied by an alternate current dynamo at the other end. On the other hand, the surface distribution of electric current is uniform throughout the whole length of the conductors, and it is only its distribution in different parts of the cross-section that varies as the electric density.

* Author's abstract of a Paper read before the British Association, in Section A, Leeds, September, 1890.

† The circumstances in which this condition is fulfilled may be usefully illustrated by considering the important practical cases of submarine cables, and of metallic circuits of two parallel wires insulated at a distance anything less than a few hundred times their diameter. For all these cases the numeric expressing the electro-static capacity of either conductor per unit of its length (the other supposed for the moment to be at zero potential) is between 2 and 0·1, and for our present rough comparison may be regarded as moderate in comparison with unity. On this supposition the condition of the text requires for fulfilment that the mean proportional between the velocity which expresses in electro-magnetic measure the resistance of one of the conductors and the velocity of a body travelling the length of the conductor, in a time equal to half the period of alternation, shall be exceedingly small in comparison with the velocity of light.

‡ The case of a single circuit made up of parallel conductors, so joined at their ends that to travel once round it we must go and come two or three or more times along separate conductors, joined by their ends in series, so as to make one circuit, is specially considered in my Paper on "Anti-Effective Copper in Parallel or in Coiled Conductors for Alternating Currents," to be communicated presently to Section A.

Digitized by Google

The proportionality of surface intensity of the current to electric density, asserted above, fails clearly in any case in which the circumstances are such that the distance we must travel along the surface to find a sensible difference in electric density is not very great in comparison with the thickness of the current-stratum. Such a case is represented in Fig. 3, which is drawn to scale for alternate currents of period $\frac{1}{80}$th of a second in round rods of copper of six centimetres diameter. The spaces between the outer circular boundaries and the inner fine circles indicate what I have called the mhoic thickness,* being 714 of a centimetre for copper of resistivity 1611 square centimetres per second. The full solution for such a case as that represented in Fig. 3 belongs to the large class of cases intermediate between I. and II., and could only be arrived at by a kind of transcendent mathematics not hitherto worked. But without working it out, it is easy to see how the time-maximum intensity of the current will diminish inwards from the surface, and will be, at any point of either of the inner fine circles, about one-half or one-third of what it is at the nearest point of the boundary surface; and that at points in the surface, distant from B B′ by one-half or one or two times the mhoic thickness, the current intensity will be much smaller than it is at B B′.

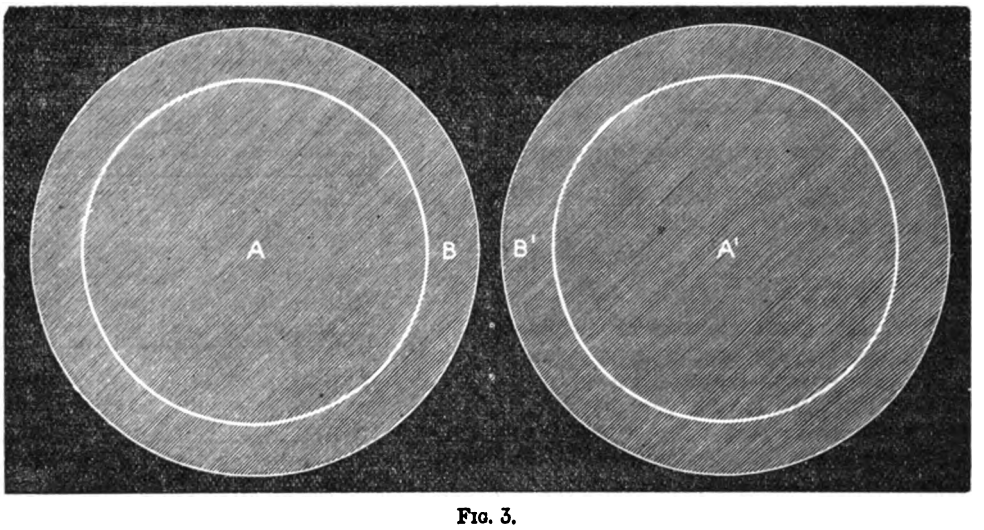

Fig. 3.

III. In Case I. the heat generated per unit of time, per unit of volume, in different parts of the conductors, is inversely as the electric resistivity of the substance, and directly as the square of the total strength of current, at any instant. In Case II. the time-average of the heat generated per unit of time, per unit of area of the current stratum, is as the time-average of the square of the quantity of current per unit breadth, multiplied by the square root of the product of the electric resistivity into the magnetic permeability.

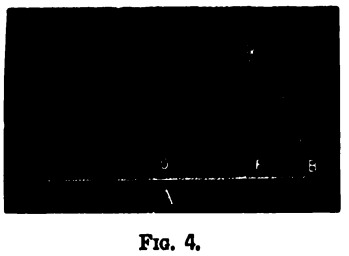

Fig. 4.

IV. Example of III: Let the conductor A be a thin flat bar, as shown in the diagram (Fig. 4), A′ being a tube surrounding A, or another flat bar like A, or a conductor of any form whatever, provided only that its shortest distance from A is a considerable multiple of the breadth of A. The thickness of A must be sufficiently great to satisfy the condition of II., and its breadth must be a large multiple of its thickness. (For copper carrying alternating currents of frequency 80 periods per second, these conditions will be practically fulfilled by a flat bar of 4cms. thickness and 30 or 40cms. breadth.) The current in it is chiefly confined to two strata extending to small distances inwards from its two sides. (For copper and frequency 80 periods per second, the time-maximum of intensity of the current at the surface will be about ϵ^2, or 7·4, times what it is at a distance 1·43cms. in from the surface.) The quantity of current per unit breadth, or, as we may call it for brevity, the surface-density of the current in each stratum, is determined by the well-known solution of the problem of finding the surface-electric-density of an electrified ellipsoid of conductive material undisturbed by any other electrified body. The case we have to consider is that of an ellipsoid, whose longest diameter is infinite, medium diameter the breadth of our flat conductor, and least diameter infinitely small. In this case the electric density varies inversely as $\sqrt{(O B^2 - O P^2)}$. The graphic construction in the drawing shows $P Q = \sqrt{(O B^2 - O P^2)}$, and we conclude that the time-maximum of the surface-density of the current varies inversely as P Q. The infinity, which in the electric problem we find for electric density of the ideal conductor, is obviated for the electric current problem by the proper consideration of the rectangular corners or the rounded edge (as the case may be) of our copper bar, which, though exceedingly interesting, is not included in the present communication. Suffice it to say that there will be no infinities, even if the corners be true mathematical angles.

V. Example of Cases I. and II.: Let A consist of three circular wires, C, L, and I, of copper, lead, and iron respectively. In Case I. the quantities of the whole current they will carry and the quantities of heat generated per unit of time in them will be inversely as their resistivities. In Case II., if the centres of the three circular cross-sections form an equilateral triangle, the quantities of heat generated in them will be directly as the square roots of the resistivities for C and L, and for I. would be as the square root of the product of the resistivity into the magnetic permeability, if the magnetic permeability were constant and the viscous or frictional resistance to change of magnetism nothing for the iron in the actual circumstances. This last supposition is probably true approximately with a permeability of $\frac{1}{80}$ for iron steel, according to Lord Rayleigh, if the current is so small that the greatest magnetising force acting on the iron is less than ·1 C.-G.-S.

VI. The dependence of the total quantity carried on extent of surface, according to the electrostatic problem described in II., justifies Snow Harris, and proves that those who condemned him out of Ohm's law were wrong, in respect to his advising tubes or broad plates for lightning conductors; but does not justify him in bringing them down in the interior of a ship (even through the powder magazine) instead of across the deck and down its sides, or from the masts

* "Collected Papers," Vol. III., Art. CII, § 35.

Digitized by Google

along the rigging and down the sides to the water. The non-dependence of the total quantities of current on the material, whether iron or non-magnetic metals, seems quite in accordance with Dr. Oliver Lodge's experiments and doctrines regarding "alternative path" and lightning conductors. The case of alternate currents is, of course, not exactly that of lightning discharges; but from it, by Fourier's methods, we infer the main conclusions of II. and V., whether the discharges be oscillatory or non-oscillatory, provided only that it be as sudden as we have reason to believe lightning discharges are.

DISCUSSION.

Prof. HENRY A. ROWLAND, Ph.D., said that he had considered this question of parallel conductors himself, and he believed that he gave the theorem with regard to the distribution in the case of perfect conductors. In that case the distribution of current over the conductors was exactly the same as it would have been if they had been charged with electricity at rest. There was some theorem with regard to the capacity, &c.; but that was a special case of such a nature as to get away from the velocity of light. That was a much more limited problem than that given here; but it guided them with regard to the distribution of currents, because in the case of perfect conductors the distribution of current was exactly the same as the distribution of the density in the case of conductive breadth, so that it would make the conductivity a little less than that, and they were guided somewhat by that theory. But he did not know of any solution in the case where the conductors were not perfect. Sir William Thomson's conclusions were somewhat different to the case that he had mentioned.

Prof. OLIVER LODGE, F.R.S., said the experiments bore out the statement that more heat was developed in iron than in copper by the same alternate current passing through it.

ON ANTI-EFFECTIVE COPPER IN PARALLEL CONDUCTORS OR IN COILED CONDUCTORS FOR ALTERNATE CURRENTS.*

BY SIR WILLIAM THOMSON, F.R.S.

1. It is known that by making the conductors of a circuit too thick we do not get the advantage of the whole conductivity of the metal—copper, let us say—for alternate currents. When the conductor is too thick, we have in part of it comparatively ineffective copper present; but, so far as I know, it has generally been supposed that the thicker the conductor the greater will be its whole effective conductance, and that thickening it too much can never do worse than add comparatively ineffective copper to that which is most effective in conveying the current. It might, however, be expected that we could get a positive augmentation of the effective ohmic resistance, because we know that the presence of copper in the neighbourhood of a circuit carrying alternate currents causes a virtual increase of the apparent ohmic resistance of the circuit in virtue of the heat generated by the currents induced in it. May it not be that anti-effective influence such as is thus produced by copper not forming part of the circuit can be produced by copper actually in the circuit, if the conductor be too thick? Examining the question mathematically, I find that it must be answered in the affirmative, and that great augmentation of the effective ohmic resistance is actually produced if the conductor be too thick; especially in coils consisting of several layers of wire laid over one another in series around a cylindric or flat core, as in various forms of transformer.

2. Fig. 1 may be imagined to represent the secondary coil of a transformer consisting of solid square copper wire in three layers. For simplicity we suppose the axial length to be infinitely great, and straight; but the uniformity which this involves and a close practical application to its simplicity is realised in that excellent form of transformer which consists of a toroidal iron core completely covered by primary and secondary wires laid on toroidal surfaces. To simplify the mathematical work, I suppose the whole thickness of the three layers to be small in comparison with the greatest radius of curvature of the circular or flat cylindric surface on which the wire is wound, but if it is not so the solution is easily obtained, for the case of circular cylinders, in terms of the Fourier-Bessel functions. It is of no consequence for our present question what there be inside of coil No. 3, and, if we please, we may imagine there to be nothing but air; the drawing, however, indicates an iron core and space which might be occupied by the primary coil, if a transformer is the subject; or our coil A A A A may be the primary coil of a transformer with secondary coil and core inside it, and the alternate current maintained in it by an external electro-motive agent acting in an arc between its ends outside. Our present results are applicable to all these varieties of cases indifferently, all that is essential being that the total quantity of current be given at each instant, and be uniform throughout the whole length of the coiled conductor.

3. This last condition is secured by perfectness of insulation between all contiguous turns of the coil, unless we were considering so enormously long a coil that the quantity of electricity required for the essential changes of static electrification would be sensible as constituting drafts from, or contributions to, the current in the coil. The consideration of static electrification, involved in the maintenance of alternate currents through a coil such as that represented in Fig. 1, is exceedingly curious and interesting; but we do not enter on it at present at all, as in all practical cases the quantities concerned are quite infinitesimal in comparison with the whole quantity flowing in one direction or the other in the half period.

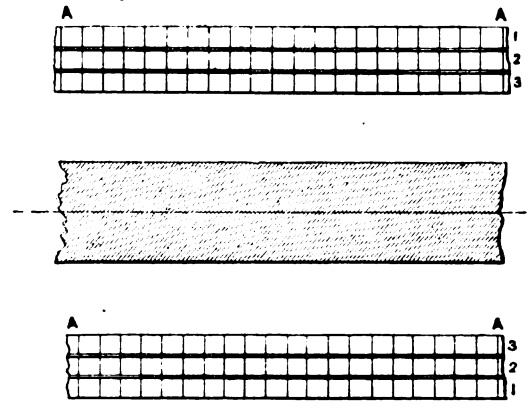

FIG. 1

4. In the drawing, the section of the wires is represented as square; but this is not essential, and in practice a flat rectangular ribbon would, no doubt for some dimensions of coils, be preferable. I assume the thickness of the insulation between the successive squares or rectangles in each layer to be infinitely small in comparison with the breadth of the rectangle; but the thickness of the insulation between successive layers, which is a matter of indifference to my calculations, may be anything; and would, in practice, naturally be, as shown in the diagram, considerably greater than the thickness of the insulation between the contiguous portions of the coil in each layer.

5. The full mathematical work, which I hope to communicate to the *Philosophical Magazine* for publication in an early number, includes an investigation of the self-induction of the coil with or without anything in its interior (such as core or primary wire of a transformer); but at present I merely give results, so far as effective ohmic resistance, or generation of heat in the interior of the wire of the coil A A A A itself, is concerned, which, as said above, is independent of everything in the interior, and of the mode in which the alternating current is produced, provided only that the total amount of electricity crossing the section of the wire per unit of time be given at each instant.

6. As a preliminary to facilitate the expression of these results, it is convenient first to give a general statement of the solution of the problem of laminar diffusion of a simple harmonic variation, applied to the case of electric currents in a homogeneous conductor. Let the periodically varying magnetic

* Paper read before the British Association in Section A, Leeds, September, 1890.

Digitized by Google

force in the air or other insulating material in the neighbourhood of so small a portion, S, of the surface of a conductor that we may regard it as plane, be given. Resolve this magnetic force into two components; one, perpendicular to S, which we may neglect, as it has no influence in connection with the currents we are to consider; the other, parallel to S, which we shall call the effective component and denote by Y. Through any point O, of S, draw three rectangular lines O X, O Y, O Z, of which O Y and O Z are in S, and O X is parallel to the direction of the effective magnetic force component Y. Let now the value of Y at time t be

$$Y = N + M \cos \frac{2\pi t}{T},$$

where N and M denote constants, and T the period of the alternation. The varying magnetic force Y, to whatever cause it may be due, gives rise to currents parallel to O Z in the conductor, expressed by the following formula for γ, the current intensity at distance X from the plane S, provided T be small enough to fulfil the condition stated below:—

$$\gamma = \frac{M}{\lambda\sqrt{2}} \epsilon^{-\frac{2\pi x}{\lambda}} \cdot \cos\left(\frac{2\pi t}{T} - \frac{2\pi x}{\lambda} + \frac{1}{4}\pi\right);$$

where λ denotes what we may call the wave-length of the disturbance, and is given in terms of T, the period of the disturbance, and ρ and Π the resistivity and magnetic permeability of the substance, by the following formula:—

$$\lambda = \sqrt{\frac{T\rho}{\Pi}}.$$

For copper we have $\Pi = 1$, and $\rho = 1611$ square centimetres per second; and thus for 80 periods per second $\lambda = 4{\cdot}49$, or, say, $4\frac{1}{2}$ centimetres. In order that the formula for γ may be approximately true it is necessary, in the first place, that λ be small in comparison with the distance we must travel in any direction in the surface of S before finding any deviation of it from the tangent plane through O comparable with λ. Secondly, for a very good approximation, λ should be so small that we may be able to travel inwards in any direction from O, through a space equal to at least twice λ, without coming to any other part of the bounding surface of the conductor. If, for example, the surface be a flat plate, this condition requires that the thickness be more than twice λ. But (because $\epsilon^{-\pi}$ is less than $\frac{1}{23}$) the formula gives a very fair approximation, requiring for a half the thickness of the plate inwards from S no greater correction than about 4 per cent., even if the thickness of our plate be no greater than λ. When the thickness of the plate is less than 2 λ, we may consider waves of electric current as travelling inwards from its two sides, and being both sensible at the middle of the plate; and a complete solution of the problem is readily found by the method of images. But a direct analytical investigation, by which the proper conditions of relation to varying magnetic force on the two sides of the plate are fulfilled is the most convenient way of fully solving the problem, and it is thus that the results given below have been obtained.

7. The smallness of the insulating space between the successive turns in each layer of our coil A A A A, and the equality of the whole current through them all, prevent any surface disturbance from being produced at the contiguous faces, and allow the problem to be treated as if, instead of a row of squares or rectangles, we had a continuous plate forming each stratum. The smallness of the thickness of this plate in comparison with the radius of the cylindric surface to which it is bent, allows, as said above, the mathematical treatment for an infinite plate bounded by two parallel planes to be used without practical error. I have thus found an expression for the intensity of the current at any point in the metal of any one of the layers of a coil of one, two, three or more layers; and have deduced from it an expression for the quantity of heat generated per unit of time, at any instant, per unit breadth in any one of the layers. I need not at present quote the former expression; the latter is as follows:—With q to denote the dynamical value of the time-average of the heat generated per unit of time at different instants of the period, per unit breadth and unit length in layer No. i, from the outside of the coil, c^2 the time-average of the square of the total current per unit breadth, and a the thickness of the layer,

$$q = \frac{2\pi\rho}{\lambda} \Theta c^2,$$

where $$\Theta = \frac{\epsilon^{2\theta} + 2\sin 2\theta - \epsilon^{-2\theta}}{\epsilon^{2\theta} - 2\cos 2\theta + \epsilon^{-2\theta}} + 2i(i-1)\frac{\epsilon^{\theta} - 2\sin\theta - \epsilon^{-\theta}}{\epsilon^{\theta} + 2\cos\theta + \epsilon^{-\theta}},$$

and $$\theta = \frac{2\pi a}{\lambda}.$$

8. The numerical results shown in the table have been calculated, and the accompanying graphic representation (Fig. 2) drawn for me, by Mr. Magnus Maclean.

Table of Values of Θ.

$\frac{16\theta}{\pi}$	$i=1$	$i=2$	$i=3$	$i=4$
1	5·113	5·118	5·127	5·141
2	2·553	2·592	2·669	2·786
4	1·316	1·634	2·270	3·224
6	·9854	1·997	4·019	7·053
8	·9173	2·993	7·143	13·37
10	·9452	4·062	10·30	19·65
12	·9822	4·899	12·73	24·48
14	1·000	5·276	13·83	26·66
16	1·002	5·362	14·08	27·16
∞		5·000	13·00	25·00

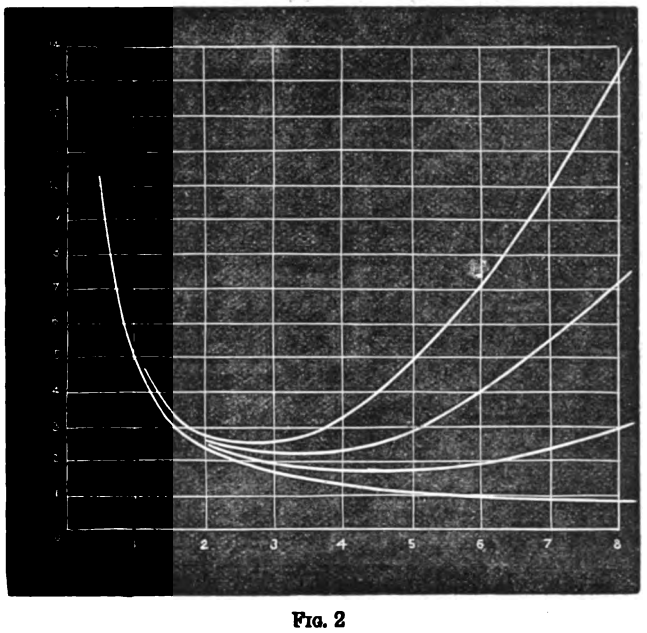

FIG. 2

8. We see from the table and curves that each curve has a minimum distance from the line of abscissas, and that each comes to a horizontal asymptote, parallel to the line of abscissas, for $\theta = \infty$. By looking at the formula we see that there is, in fact, an infinite succession of minimums and maximums in the expression for Θ; but it is only the first minimum and following maximum that occur within the range of variation of Θ, which we regard as sensible. In the case of $i = 1$ the formula gives $\theta = \frac{1}{2}\pi$ for the first minimum. The curves show for the cases of $i = 2, 3, 4$, respectively the first minimum at $\frac{16\theta}{\pi} = 4\frac{1}{2}$, $3\frac{1}{2}$, and 2·6, respectively. The thickness which corresponds to $\theta = \pi$ is the half wave length of the electric disturbance, which, as we have seen, is for copper 2·244 centimetres when the frequency of the alternations is 80 periods per second; and for this case, therefore, the thicknesses that give minimum generation of heat in the first, second, third, and fourth layers are respectively 11·22, 6·31, 4·91, and 3·65 millimetres. Anything more of continuous copper than these thicknesses in any of the layers would be not merely ineffective

Digitized by Google

or comparatively ineffective, but would be positively anti-effective. Even with so small a thickness as 2·8 millimetres, for copper and frequency 80, line 2 of the table (corresponding to a sixteenth of the wave length) shows, in the first, second, third, and fourth layers, losses of 0·3 per cent., 2 per cent., 5 per cent., and 10 per cent. in excess of that due to the true ohmic resistance of the copper were it all effective. When the size chosen for the transformer and the amount of output required of it are such that a thickness of 2½ millimetres in the direction perpendicular to the layers is insufficient, a remedy is to be had by using braided wire, or twisted strand, with slight insulation of varnish or whitewash, crushed or rolled into rectangular or square form of the desired thickness and breadth. A very slight resistance between the different wires thus crushed together would suffice to cause the current to run nearly enough full bore to do away with any sensible loss from the cause which forms the subject of this communication.

ON AN ILLUSTRATION OF CONTACT ELECTRICITY PRESENTED BY THE MULTICELLULAR ELECTROMETER.*

BY SIR W. THOMSON, F.R.S.

The contact electricity of dry metals had been formerly discussed at great length; but the action was now admitted. The presence of brass and aluminium in an electrostatic instrument brings out a feature of contact electricity in the multicellular electrometer, which (see *The Electrician*, November 8, 1889, p. 6), consists of a number of cells and a number of needles, the needles attached to a stem which was suspended by a fine platino-iridium wire. If both cells and needles had been made of brass, or if both had been of polished aluminium, the difference due to contact electricity would not have been present.

Any difference between the substances will give the difference in question. When a difference of potential of 100 volts was maintained, the needles being +, and the cells −, the reading was 100·2. With the needles −, and the cells +, the reading was 99·8. No effect of this kind was visible in the early instruments; or at all events it was hardly visible, and never amounted to more than $\frac{1}{10}$ of a volt. Mr. Rennie, of the Board of Trade Standardising Laboratory, had found in a new instrument a difference of a quarter of a volt. That might be expected; the original instruments were not made up of polished metal parts, but of bits which were frequently handled and lay about in the laboratory; the condition of the surfaces was not, therefore, such as would give the results; but in well-polished instruments it was very noticeable. He had that morning received a letter from Mr. Rennie, who had made observations nearly every day for a month, and had found an error of ± ·5 to ·6 volt, halving that gave an effect of ·25 to ·3. There appeared to be a decrease in the error, probably due to the polish toning down.

DISCUSSION.

Prof. FITZGERALD said that he had given a warning in the Proceedings of the Royal Society of Dublin that errors from this cause might arise with instruments in which different materials were used. He alluded particularly to the effect produced with a guard-ring electrometer, in which the guard-ring was made of brass, and the disc was made of aluminium. The contact electricity would in this case give rise to a disturbing force which would introduce errors in delicate experiments. In instruments of this character care should be taken to use similar metals in the construction of those parts which could produce error. It was essential in guard-ring instruments that the discs should be of similar metal to the attracted disc.

Dr. FLEMING said that in the multicellular voltmeter which he possessed there was a slight difference in the readings of the voltmeter, according as the needle was positive or negative. Supposing 100 volts were put upon the instrument, then, if the needle were positive, the reading would be slightly greater than 100 volts; if negative, perhaps slightly less. He had been experimenting with a kind of unicellular electrostatic voltmeter. One side of the contact was made very rough, and the other was made very smooth. His experiments, so far as they had gone at present, seemed to indicate a very curious effect, namely, that the attraction between two surfaces, one of which was very rough and the other smooth, and which were kept at a certain definite constant difference of potential, would differ according as the surfaces were positively or negatively electrified; and that a considerable difference in the roughness of the two surfaces might make a very slight difference in the attraction between the surfaces when they were kept at a constant difference of potential. He had not fully completed his experiments.

Sir WM. THOMSON, in reply to Dr. Fleming, said that what he himself called the contact difference between the two surfaces had been anticipated in the very beginning of the trials of the instrument he exhibited, and some experiments were made showing that the contact difference of metals does tell upon the force of attraction between a movable piece of metal and a fixed piece of metal under electrification. The question put by Dr. Fleming had been the subject of a communication to Section A. In the case of aluminium and brass he should expect to find a sensible amount of difference between the reading with the connections one way, and the reading with the connections reversed, because of the contact difference between the two metals. The whole of the experiments in contact electricity with two surfaces of the same metal show a contact difference according to the degree of oxidation; for instance, bright copper opposed to copper oxidised by heat differed as much as a quarter of a volt. There was a slight correction to be made according as the needle and the casing of the instrument was positive or the other way. A difference of ·2 or ·25 volt had to be subtracted from the reading in the one case, or added to it in the other; but that was not a correction which gave any trouble in practice, because they knew it was in the instrument, and it would no doubt be exceedingly constant in the instrument. It was just possible, however, that it might gradually diminish in consequence of the very slow tarnishing of the two surfaces. The differences between rough surfaces and smooth surfaces were very interesting, and were most probably due to the difference of oxidation of the different parts of the rough surface.

* Abstract of Paper read before the British Association, in Section A, Leeds, September, 1890.

CONTRIBUTIONS TO THE MOLECULAR THEORY OF INDUCED MAGNETISM.*

BY J. A. EWING, F.R.S.

As the facts of induced magnetism become better known, increasing interest attaches to molecular theories, and increasing difficulty attends the theories that are current. Weber's fundamental conception that the molecules of iron or nickel, or cobalt, are always magnets, and that the process of magnetising consists in turning them from many directions towards one direction, has been strongly confirmed by the now well-established fact that there is a true saturation value, a finite limit to the intensity of magnetism, which may be reached or very closely approached by using a strong magnetic force †. Without going further back, to inquire (with Ampère) how the molecules come to be magnets, we may take this conception as the natural starting-point of a theory. But when we go on to examine the conditions of constraint on the part of the rotatable molecules which have been suggested to make the theory square with what is known about permeability, about residual magnetism, and other effects of magnetic hysteresis, about the effects of stress, of temperature, of mechanical vibration and so forth, we find a mass of arbitrary assumptions which still leave the subject bristling with difficulties. Many of the phenomena suggest, for instance, the idea that there is a quasi-frictional resistance which opposes the turning of the molecular magnets; this notion lends itself well to account for the most obvious effects of magnetic hysteresis and the reduction of hysteresis by vibration. On the other hand, it conflicts with the fact that even the feeblest magnetic force induces some magnetism. My object in this Paper is to refer to another (and not at all arbitrary) condition of constraint which not only suffices to explain all the phenomena of hysteresis without any notion of friction, but seems to have in it abundant capability to account for every complexity of magnetic quality.

In describing Weber's theory, Maxwell points out that, if each molecular magnet were perfectly free to turn, the slightest magnetic force would suffice to bring the molecules into complete parallelism, and thus to produce magnetic saturation. He continues:—"This, however, is not the case. The molecules do not turn with their axes parallel to the force, and

* Paper read before the Royal Society, June 19, 1890.

Digitized by Google

this is either because each molecule is acted on by a force tending to preserve it in its original direction, or because an equivalent effect is produced by the mutual action of the entire system of molecules. Weber adopts the former of these suppositions as the simplest.* Weber supposes a directing force to act in the original direction of the molecules axis which continues to act as a restoring force in that direction after the molecule is disturbed. This assumed constraint is quite arbitrary; moreover, if it were the only constraint, there would be no residual magnetism when the deflecting force was withdrawn. Accordingly, Maxwell modifies Weber's theory by introducing the further assumption that when the angle of deflection exceeds a certain limit the molecule begins to take permanent set. The development of this, however, does not agree well with the facts. The alternative which is offered in the sentence I have quoted from Maxwell was not followed up by him, and seems to have been very generally overlooked, notwithstanding its obvious freedom from arbitrary assumption. Several writers, notably, Wiedemann† and Hughes‡, have recognised the inter-molecular magnetic forces by suggesting that the molecules, when unacted on by any magnetising force from outside, may form closed rings or chains, "so as to satisfy their mutual attraction by the shortest path."§ But Wiedemann expressly postulates a frictional resistance to rotation, which will prevent this arrangement from being more than approximately attained, and which may be more or less overcome by vibration ‖.

I lately commented on the fact that soft iron and other magnetic metals (notably nickel under particular conditions of strain¶) show a remarkably close approach to instability at certain stages in the magnetising or demagnetising process**. When the magnetic force reaches a particular value, the rate of change of magnetism with respect to change of force may become enormous. Referring to this in a Paper which has just been published ††, Mr. A. E. Kennelly has reverted to the idea of chains of magnetic molecules, held together by the inter-molecular magnetic forces, and contends that when such a chain is ruptured by applying a sufficiently strong external magnetic force it will fall to pieces throughout, and the molecular magnets which compose the chain will take their alignment suddenly. He accordingly sketches what he calls a "chain-theory" of magnetisation and an adaptation of the theory of Hughes, in which, however, he postulates an elastic resistance to the rotation of the molecules in addition to the constraint afforded by their mutual magnetic forces. Mr. Kennelly's remarks are highly interesting and suggestive; but I do not think (for reasons which will appear immediately) that the notion of closed magnetic chains can be maintained as a general account of the molecular structure of unmagnetised iron.

I have experimented on the subject by making a model molecular structure consisting of a large number of short steel bar-magnets, strongly magnetised, each pivot like a compass-needle upon a sharp vertical centre and balanced to swing horizontally. We cannot readily imitate in a model the two degrees of rotational freedom possessed by the axes of actual molecular magnets, but a group of magnets swinging in one plane gives a sufficiently good general idea of the nature of the equilibrium which is brought about by inter-molecular forces, and the manner in which that equilibrium is disturbed when an external force is applied. The model is very easily made. Each magnet is a piece of steel wire about 1-10th of an inch in diameter and 2in. long (Fig. 1) bent in the middle to bring the centre of gravity below the point of support. The hole, or rather recess, for the pivot is made by a centre punch: the pivot itself is a sewing-needle fixed upright in a small base-plate which is punched out of a sheet of lead. The bars swing with but little friction, and their pole-strength is sufficient to make the mutual forces quite mask the earth's directive force when they are set moderately near one another. The group is arranged on a board on which lines are drawn to facilitate regularity in grouping when that is wanted, and the board slips into a large frame or open-sided flat box wound round the top, bottom, and two sides, with a coil through which an adjustable current may be passed to expose the group to a nearly homogeneous external magnetic force. The coil is wound in a single very open layer, through which a sufficiently good view of the group inside is obtained. A liquid rheostat with a sliding terminal is used

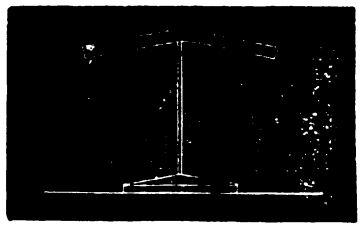

Fig. 1.

to secure continuity in varying the magnetic force. It is scarcely necessary to add that the magnetic force which is applied to the group is too weak to have any material effect on the magnetism of individual bars. It alters their alignment only, just as a magnetic force alters the alignment of Weber's molecular magnets.

When a number of these magnets are grouped either in a regular pattern or at random, and are left after disturbance to come to rest free from external magnetic force, they of course assume a form which has no resultant magnetic moment, provided the number be sufficiently great; but it is apparent that they do not arrange themselves in closed chains. Any such configuration would in general be unstable. Many stable configurations admit of being formed, and if the magnets are again disturbed and left to settle, the chances are much against any one configuration immediately repeating itself. One general characteristic of these configurations is that they contain *lines* consisting of two, three, or more magnets, each member of a line being strongly controlled by its next neighbours in that line, but little influenced by neighbours which lie off the line on either side. Thus, if there are two magnets simply, they form (as might be anticipated) a highly stable pair. With three magnets, two form a line along one side of the triangle joining the fixed centres, and the third lies parallel, or nearly so, facing oppositely. Four magnets will usually form two lines with directions which lie nearly along two sides of the quadrilateral; but diagonally opposite magnets may pair, leaving the others unattached. Suppose them set at the corners of a rectangle with unequal sides, they may lie in any of these forms (Fig. 1A),

Fig. 1A

if the inequality in distance be not too great. All these configurations are stable, and the condition of least energy, while making the first of them the most probable, does not prevent the occasional formation of the others. In a long line, the same condition leads in general to the formation of a continuous section; but it is by no means uncommon to find a line broken into two or more sections. Seven magnets grouped so that the centres of six form a regular hexagon, with one in the middle, have a great variety of possible stable configurations, of which these are examples (Fig. 2).

Experimental study of the forms which may be assumed by groups, and of the vibrations which may be transmitted through groups, is interesting, but to pursue it would be beside my present purpose. In all cases, the configuration assumed

by a group is such that there is stability for small displacements, but different positions of the group may be stable in different degrees, and if members of the group be turned through a sufficiently great angle, they become unstable, and fall into a new position of stability, bringing about a partial reconstruction of the lines that characterise the group. Special interest attaches to square patterns, from the fact that iron and nickel (probably cobalt also) crystallise in the cubic system. In a square pattern of many members, we find, in general, lines running parallel with all sides of the square when the group settles without directive force after a disturbance.

Let the group, or collection of groups, be subjected to an external magnetic force, H, gradually increasing from zero. The first effect is to produce a *stable* deflexion of all members except those which lie exactly along or opposite to the direction of H. This results in giving a small resultant moment to the

Fig. 2.

group (assuming that there was none to begin with), which increases at a uniform or very nearly uniform rate as H increases. This corresponds to the first stage in the magnetisation of iron or other magnetic metal (*a*, Fig. 3). The initial susceptibility is a small finite quantity, and it is sensibly uniform for very small values of H.

Suppose that, without going beyond this stage, we remove H; the molecular magnets, not having been deflected beyond the limit of stability, simply return to their initial places, and there is no residual magnetism. This, again, agrees with the fact that no residual magnetism is produced by very feeble magnetising forces. Up to this point there has been no magnetic hysteresis. But let the value of H be increased until any part of the group becomes unstable, and hysteresis immediately comes into play. At the same time, there begins to be a marked augmentation of susceptibility—that is to say, a marked increase in the rate at which resultant moment is acquired. It is not difficult to arrange groups in which the state of instability is reached with one and the same value of H throughout

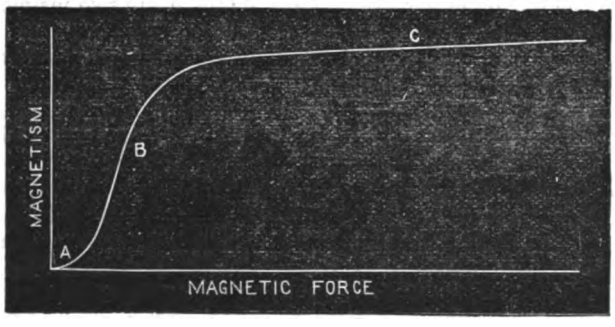

Fig. 3.

the group. But, in general, we shall have different elementary magnets, or different lines of them, reaching instability with different values of H. The range of H, however, which suffices to bring about instability throughout the whole, or nearly the whole, of the members in most groups is not large; we, therefore, find in the action of the model a close analogy to the second stage (*b*, Fig. 3) of the process of magnetisation, in which the magnetism rises more or less suddenly, as well as to the first stage (*a*).

During the second stage (*b*), the magnetic elements fall for the most part into lines which agree more or less exactly with the direction of H. If, at the end of this stage, we remove H, we find that a very large proportion of the moment which the group has acquired remains; in other words, there is a great deal of residual magnetism. To take an instance, suppose we have a group lying initially as in Fig. 4, and apply a magnetic force, H, in the direction sketched, the first stage (*a*) deflects all the molecular magnets slightly, without making any of them become unstable; the second stage (*b*) brings the molecules into the general direction shown in Fig. 5, or rather that is the direction they assume when H is removed, and the residual magnetism contributed by the group is then the sum of their moments resolved along H. When H is acting, the components along H are slightly greater, for the molecules are then (stably) deflected through a small angle towards the line of H.

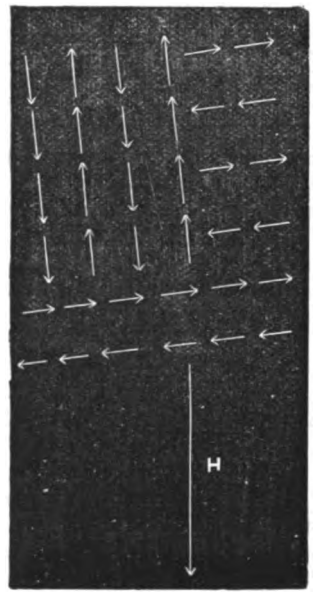

Fig. 4.

Let H be further increased—we now have the third stage (*c*, Fig. 3), which consists in the closer approach to saturation that is caused by the molecules being more nearly pulled into exact line with H (Fig. 6). Whether there will be instability during the deflexion of them from the lines of Fig. 5 will depend on the closeness of the pol s, and on the inclination of the lines of Fig. 5 to the direction of H (see below). In some groups saturation will be complete with a finite value

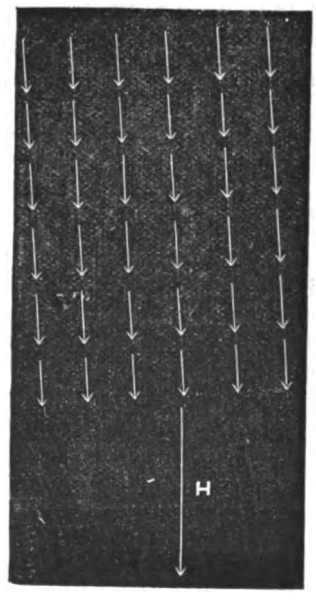

Fig. 5

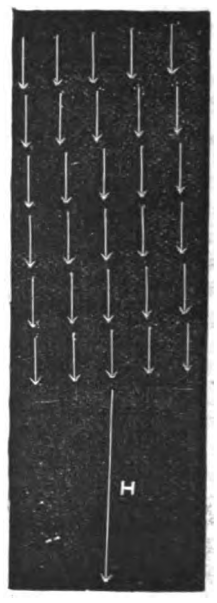

Fig. 6

of H; in others, it will only be closely approximated to. In magnetising any actual specimen of iron, we have, of course, to deal with a multitude of groups, the lines to which lie at very various inclinations to H. If we remove the force H at a point in stage *c*, we find very little, if any, more residual magnetism than was found at the end of stage *b*. The ratio of residual to induced magnetism is a maximum about the end

Digitized by Google

of stage *b*, and diminishes as stage *c* proceeds. This, again, agrees completely with the observed facts.

There is *some* hysteresis during the removal (whether complete or partial) and reapplication of magnetic force, because (provided we have enough groups to deal with) there will be some lines of elements which pass to and fro through a condition of instability during the removal and reapplication of the force. For certain inclinations of the line, the movements are not reversible.

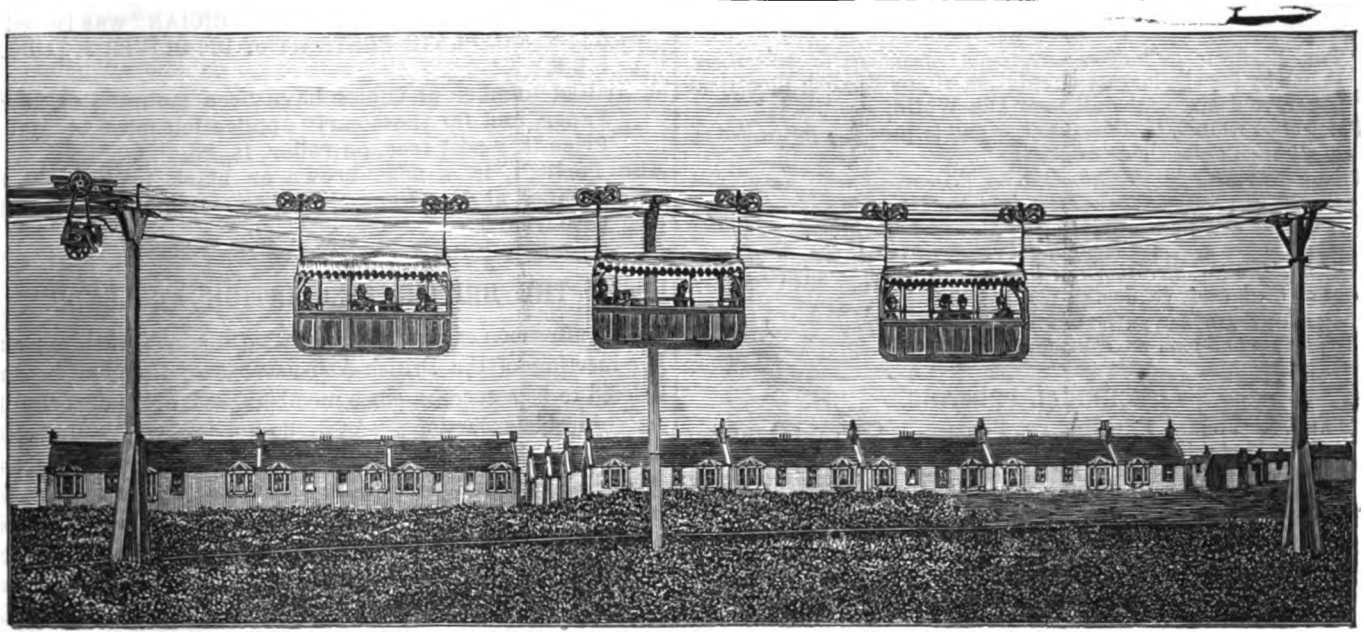
Suppose, next, that having applied and removed a strong force H, leaving strong residual polarity, we begin slowly to reverse H. At first the effects are slight; presently, however, instability begins, and as the force is increased within a narrow range, we find the molecules all upset. This is followed by a stage of nearly elastic deflexion as saturation is approached. Thus the well-known general characteristics of cyclic processes are all reproduced in the model (see Fig. 8).

Again, a small repeated cyclic change of H superposed upon a constant value of H produces small changes of aggregate polarity, which are reversible if the change of H is very small. This, as Lord Rayleigh has shown,* is what happens in a magnetic metal, and the susceptibility with respect to small cyclic changes is small in the model, just as it is in the actual solid.

(To be continued.)

THE TELPHER LINE AT THE EDINBURGH EXHIBITION.

The Telpher line put up at the Edinburgh Exhibition by the Electrical Engineering Corporation shows the most recent improvements, and is arranged so as to carry passengers as well as demonstrate the advantages of the system for this transport of goods.



The Telpher Line at the Edinburgh Exhibition.

The Edinburgh line consists of over a quarter mile of track, the flexible portion of it being constructed in spans of 50 ft. and the rigid ends in spans of 15 ft. The stand ropes on which the locomotive and carriages travel are of crucible steel and 1½in. in diameter. These are tightened, so that with a full load on the line there is a sag of about 2 ft. 4½ in. on the spans covered by the train. The arms supporting the stand rope are arranged so that they move in either direction, allowing the sag in the rope to follow the train as it moves along, thus not putting any undue strain upon the posts themselves. The stand rope at its junction with the rigid rail passes from a special descent junction saddle so arranged that the train rises from the rope on to the rigid rail without any jerk or other unsatisfactory movement. From the junction saddle the stand rope passes direct to a structure termed the abutment post; this is fastened to the substantial anchorages in the ground by flexible steel ropes 5in. in circumference. The strain upon the ends of the stand rope with a fully-load train is about five tons, and the strain upon the anchorages about eight tons. The current is conducted along a conductor which is not attached to the insulators on which it rests at any point, but merely rests upon them. From the locomotive a rigid arm projects underneath the conductor, but above the insulators, and slides along under the conductor, lifting it off the insulators as the arm passes them, allowing it to rest on them again after it has passed. This method of collection is recommended in the proposed "Waller-Man-ville" system of electrical traction, described in *The Electrician* of May 9, 1890.

The train, as will be seen from the illustration, is a very practicable one; the cars, which with the plant and the rest of the equipment were made at the works of the Electrical Engineering Corporation at West Drayton, are built much in the fashion of railway carriages, each car having two compartments and holding four persons, and each compartment being entered from a door with a railway latch. The whole of the car is suspended by iron hangers from two bogie trucks, the bodies of which latter consist of mitis iron castings resting on the axles of the wheels at each end. The hanger does not depend directly from the body of the bogie truck, but rests upon two vertical springs contained in boxes on each side of the body.

The locomotive consists of what is termed by the Corporation a swinging tub, and the motor drives a small countershaft, to one end of which is attached an electrical governor to maintain a set speed; the other end of the countershaft has upon it a chain wheel, which drives directly upon a larger chain wheel contained on the upper frame. The motor is suspended from the upper frame by a hanger, so arranged as to allow the whole to swing, the swinging movement thus allowed not interfering with the motion of the chain, as it is a movement radially to the centre of the large chain-wheel on the upper frame. The upper frame contains, in addition to the large chain-wheel, two driving wheels with malleable cast-iron tyres to grip the rope, each attached to a chain-wheel driven from the shaft supporting the large central chain-wheel.

This new method of cheap transport has, it is needless to say, attracted considerable attention at the Edinburgh Exhibition; and, in view of the many instances where telpherage might be advantageously employed, the Electrical Engineering Corporation has shown great enterprise in bringing the system so prominently before the public.

The Electrician.

Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing, and Printing Offices:
SALISBURY COURT, FLEET ST., LONDON, E.C.
Telephone No. 2714. Telegrams: "ELECTRICIAN NEWSPAPER, LONDON."

All Letters relating to Advertisements and other business communications should be addressed to the Publisher. "THE ELECTRICIAN," *Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN," *and be crossed* "*Coutts and Co.*" *All other letters to be addressed to the Editor.*

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

SUBSCRIPTION RATES.

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

	3 months.	6 months.	12 months.
	s. d.	s. d.	s. d.
For the United Kingdom	5 0	10 0	19 6
For Foreign Parts and Colonies:—			
Within Postal Union	6 6	12 6	24 0
Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 5 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1890 Edition consists of about 850 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

Orders for the 1890 issue should be forwarded AT ONCE *to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.*

ELECTRICAL BOOKS AND PUBLICATIONS.

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" ***Printing and Publishing Company, who are proprietors of the well known*** "ELECTRICIAN" ***Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.***

OUR SUPPLEMENT.

With the last Number of "THE ELECTRICIAN" was issued a fine STEEL PLATE PORTRAIT of Dr. OLIVER J. LODGE, F.R.S.

A limited number of Copies have been mounted on India Paper, and for these early application must be made. Price 1s.; post free, on roller, 1s. 2d.

The Portrait, in a neat brown or black frame, will be supplied at 4s. 6d., post free, 5s. If mounted, 5s. 6d., post free, 6s.

THE BRITISH ASSOCIATION AT LEEDS.

The afternoon of Saturday was very fine in Yorkshire; and the meeting of the British Association may therefore be considered to be a success, since members had every opportunity for enjoyable excursions. As we do not pretend to appreciate the Association in its present form, we shall not attempt to generalise pleasantly on the "advancement of science," for which it is supposed to be founded. We shall endeavour to avoi being cynical; but if remarks have to be made on the subject, they may as well be candid, especially as they are aimed at no individuals. The most remarkable feature about the annual meetings of the British Association is that although it is admittedly a gathering of a large proportion of the leading scientific men of the day, hardly any results, so far as the "advancement of science" is concerned, are to be found, except in the contents of the Papers which are brought by some of them to the Sections.

The Presidential Addresses too often afford examples of a deplorable waste of the time and energies of an able man. Addresses of this kind are, perhaps, a necessary evil, but they are occasionally atoned for by brilliant exceptions. They differ in no marked respect from the inaugural addresses of the presidents of the scientific societies. The Institution of Electrical Engineers has on more than one occasion found a leader who not only writes his best on his own subject, but invites discussion on his address. Prof. HUGHES and Dr.

Digitized by Google

HOPKINSON are examples of such. They, by the way, are among those who are conspicuous by their absence from the meetings of the British Association. Sometimes a man like TYNDALL will set up a landmark in literature by a memorable essay, which is not marred by a list of poets, divines, and other ornaments of the past history of the locality, or by hearsay history of subjects which lie outside his own work. The address to Section A to which we have alluded in another column was of a modest but useful type. Those who write Papers for Societies know well how much they learn in getting up a subject, however familiar it may be to them; and when a man endeavours to give, not a sketch of his own subject, but an account of some phase of it, discussing its aspect from some particular standpoint, and indicating how it is related to some other branch of knowledge, he benefits both himself and his audience far more than if he attempted to expound or to popularise his own specialities. The addresses of Dr. GLAISHER and of Prof. MARSHALL were of this commendable type.

We have referred to the singular limitation of the results of the meeting to the contents of the Papers. As far as the holding of the meeting is concerned, the Papers might have been sent in to the Secretaries without going through the form of presentation to an audience, except in the rare cases where experiments are made. The results which one might expect from the gathering of so many able minds are those which should arise from debate and discussion upon the subjects presented to them. The length of the discussions, or the standing of the men who take part in them, at the sectional meetings of the British Association is no indication whatever of the importance of the communications. When the programme containing the list of Papers for the day is issued nominally at 8 a.m. on the morning on which they are to be read, but which is practically in the hands of those members who apply for them at, say, half-past nine or ten, those who speak have to do so on the spur of the moment, and their utterances are, as a rule, of far less value than at the meeting of the scientific societies. The length of the discussion is, therefore, not infrequently inversely as the scientific worth of the Paper. The valuable results of the discussions at meetings of the Institutions of the Civil and Electrical Engineers are mainly due to the custom of printing the papers and distributing them to members before the meetings. The effect of this is that the debates are often more important than the Papers themselves. It was evident on Friday last that if some of the members had been prepared for Prof. EWING'S remarkable magnetic theory, or rather for his explanation of the model which exhibits and combines several of the features of older hypotheses with new suggestions and developments, and if a reasonable discussion had thus been possible, the theory of magnetism might have made so marked a stride that the Leeds meeting of 1890 would have been a notable landmark in the history of the subject. As it was, several members had wearied of the atmosphere of the meeting house, or had been compelled to go out for lunch; others returned only in time for the latter part, and many had been fasting since the morning. These conditions, which are repeated at every meeting, are conducive neither to appreciation of the subject, prolonged discussion, or to physical comfort.

In short, by the British Association meetings as at present arranged, the minimum of scientific progress is effected by the maximum expenditure of energy. The meetings already fail to attract many leading men; and unless there is some change of method it is very probable that many of those who at present attend will grudge the sacrifice of a week of their holidays, and will leave the Association in the hands of a small well-meaning clique and a few advertisers and bores. The fact is not to be disguised that these meetings are holiday affairs, and that men who will submit to the regulations of scientific societies in their winter session do not care to treat matters quite so seriously at a summer gathering. Is it not time that these meetings should be managed so as to attain more satisfactory results? Why should not the Sectional Committees be of more manageable dimensions and their work more concentrated? Let the number of Papers to be read in each Section be rigorously limited, and printed well before the meeting. It is possible that a higher grade of Papers would then be contributed, their originality might possibly be more marked, and the discussions on them more to the point. Moreover, if some such arrangement were instituted there would be some *kudos* attached to the reading of a Paper before the British Association—a quality which is at present conspicuous by its absence. Formal debates on matters of general scientific interest should become a regular feature of the meetings. There can be no better opportunity for them than at these annual gatherings, where it might be expected that something of the old broad scientific spirit would be infused into the discussions by the presence of so many varieties of the scientific species. Reforms somewhat on these lines should be speedily undertaken, unless the British Association is to go the way of all institutions which fail to adapt themselves to the times.

THE BRITISH ASSOCIATION AT LEEDS.

RÉSUMÉ OF PROCEEDINGS.

WEDNESDAY, SEPT. 3.—Presidential Address of Sir Frederick Abel.

THURSDAY, SEPT. 4.—The meeting of Section A opened with an address by Dr. Glaisher on the relation of pure mathematics to physics. A report of the Committee on "Electro-optics" was brought up, but it was merely an intimation that no regular work had yet been done. Mr. Swinburne then read a Paper on the details of the construction and use of vacuum pumps; and Mr. Shenstone described some joints and taps for the same purpose. Profs. Barr and Stroud showed photographic apparatus very cleverly contrived to facilitate the making of lantern slides for educational and lecture work. M. du Bois described the measurement of the refractive index of various metals. Thin films of platinum, nickel, iron, and cobalt, were deposited on glass, and these films were thickened locally by electro-deposition. The thickening was painted with stripes of black paint, leaving bands showing the thickest and thinnest parts and a graded part. The latter was practically a wedge or prism of a very small angle, and this was used to determine the refractive index, the thickest part being thin enough to transmit light. Sir W. Thomson described the effect of using aluminium for the needles and brass for the cells of the multicellular voltmeter. (For description of this instrument, see *The Electrician*, November 8, 1889.) Different metals being used, the contact electricity was found to be sufficient to give rise to an error. The present instruments are (we are informed) being made with aluminium cells. Lord Rayleigh followed with some accounts of defective colour vision; and Mr. W. N. Shaw read a Paper on ventilation, a subject which he has recently studied with apparatus made on the apparently unlikely principle of the Wheatstone bridge. While this was being read, the report of the Committee "On the Silent Discharge of Electricity," was read in Section B. This merely stated that the work had not yet been begun. In Section G (Mechanical Science) a description was given of the Victoria Torpedo, of which we recently gave a short account. (See *The Electrician*, August 8, p. 370.)

Digitized by Google

FRIDAY, SEPT. 5.—A discussion on Electrical Units was announced to be opened by a Paper by Mr. Glazebrook and another by Prof. J. Viviamu Jones. The former was important historically, and showed that the mean value of the best determination of the ohm was 106·3, this being the length in centimetre of a column of mercury one millimetre square, at 0 centigrade. Prof. V. Jones's Paper was interesting on account of its mechanical details; but the discussion was very disappointing, no general debate on electrical units being attempted. Sir W. Thomson read two Papers on the mutual action of alternate current in conductors; and Prof. Ewing contributed the most valuable and important communication of the meeting in describing his molecular theory of induced magnetism. Five other Papers were postponed.

SATURDAY, SEPT. 6.—Sir W. Thomson described a method of determining in absolute measure the susceptibility of diamagnetic or feebly magnetic bodies; and a report and discussion on electrolysis, together with Papers by Mr. Shaw and Prof. Ostwald, followed.

MONDAY, SEPT. 8.—Sir William Thomson described his meter, an instrument which is admittedly in an early stage, and the multi-cellular voltmeter (*The Electrician*, November 8, 1889); he also described an engine-room voltmeter (*The Electrician*, August 8, 1890), an ampere gauge, and a new form of volta-pile, useful in standardising work. Mr. Kapp read a Paper on the Lineff system of electric traction, which gave rise to little that was useful in the discussion. A Paper on the physiological effects of alternate and continuous currents, by Mr. Lawrence and Dr. Harries, was then read, the discussion turning to details of the electric execution. Mr. Wilson Hartnell attacked the fire insurance offices for undue severity in their rules; Mr. Barbour Starkey concluded with a Paper on his well-known system of addingcarbonate of soda, and on experiments with sawdust and plaster of Paris. In the discussion, it was pointed out that sulphate, not carbonate, should be used.

At the meeting of the general committee held in the Council Chamber at the Town Hall, the place for the 1892 meeting was selected, and officers appointed for next year's meeting at Cardiff. The Secretary read a communication from the Lord Provost of Edinburgh inviting the Association to hold its meeting in 1892 in that city. Sir William Thomson formally moved that the meeting of the Association in 1892 be held in Edinburgh. The motion was seconded by Prof. Fitzgerald, and on being submitted to the meeting was carried unanimously. Lord Rayleigh proposed that Dr. William Huggins should be appointed president of the Cardiff meeting. Dr. Glaisher seconded the resolution, which was adopted. After some discussion as to the most suitable time, it was decided that the Cardiff meeting should commence August 19th.

TUESDAY, SEPT. 9.—No less than 14 Papers were got through in Section A on this day. Prof. Mascart began with a discourse in French on the optical phenomena of coloured and achromatic fringes observed in minerals. Lord Rayleigh exhibited photographs of water jets taken by the light of a discharge of a Leyden jar. Mr. Glazebrook took a report on electrical standards, together with Papers on resistance coils; an air condenser of Dr. Muirhead's design; the specific resistance of copper; and a comparison of platinum with mercury thermometers. Mr. Preece described the great superiority of French over English steel for making permanent magnets, and discussed whether this was due to the material or to the tempering. Mr. O'Shea described the effects of oxidation of manganese steel in increasing its magnetic properties; and Mr. Swinburne followed with an account of magnetic tests of iron. He also read a brief note on the compensation of alternate current instruments. Prof. Fitzgerald read a short but abstruse Paper on theoretical stability with magnetic forces. Dr. Oliver Lodge read and commented on a Paper by Mr. Trowbridge on electrical oscillations, and another by himself on the electrostatic forces between conductors carrying currents.

WEDNESDAY, SEPT. 10.—Prof. Fitzgerald read a Paper on the "J." of Maxwell's equations in relation to Hertz's discoveries. Prof. Barrett presented the report of the Committee on "Molecular Phenomena attending the Magnetisation of Iron," and gave a *résumé* of the recent work of Hopkinson, Osmond, and others on recalescence of iron and steel, and their allotropic states. Prof. Fitzgerald discussed the thermodynamical aspect of the subject. A Paper by Mr. Swinburne on the resistance of the human body under direct and alternating pressures was taken as read. Mr. F. H. Varley exhibited and described a photometer; and after a brief description of some spectrum photographs by Mr. Gibbs, the meeting terminated.

The President of the Section, in closing the meeting, observed that he had attended nineteen meetings of the British Association, and at none of them had he heard so many valuable Papers, and such interesting discussions. Sir William Thomson said that the meeting could not separate without according their thanks to Dr. Glaisher for the sympathetic manner in which he had presided, although the subjects of the majority of the Papers lay outside the pure mathematics in which he had so distinguished himself.

At one o'clock the last meeting of the General Committee was held in the Council Chamber of the Town Hall. The chair was taken by Sir F. Abel. Mr. Vernon Harcourt (general secretary) reported the numbers of tickets sold at this meeting, which were as follows:—Old life members, 259; new life members, 21; old annual members, 368; new annual members, 92; associates, 680; ladies, 334; foreign members, 21—total, 1,775. The total receipts were £1,776. Among the grants recommended by the Committee of Recommendations were the following:—Professor Carey Foster—electrical standards, £100; Professor Fitzgerald—electrolysis, £5; Professor O. J. Lodge—discharge of electricity from points, £10.

THE MEETING OF THE BRITISH ASSOCIATION.

The following is a complete list of the electrical Papers read, reports presented, and instruments exhibited at the recent meeting of the British Association:—

SECTION A.

PROFS. BARR and W. STROUD.—"On the Use of the Lantern in Class-room Work."

PROF. J. A. EWING, F.R.S.—"On the Molecular Theory of Induced Magnetism."

PROF. G. F. FITZGERALD, F.R.S.—"On an Episode in the Life of J. (Hertz's Solution of Maxwell's Equations)."

PROF. G. F. FITZGERALD, F.R.S.—"On Kinetic Stability with Magnetic Forces."

R. T. GLAZEBROOK, F.R.S.—"On Recent Determinations of the Absolute Resistance of Mercury."

PROF. J. VIRIAMU JONES.—"On Suggestions towards a Determination of the Ohm."

PROF. O. LODGE, F.R.S.—"On Electrostatic Forces between Conductors carrying Currents."

PROF. E. MASCART.—"Sur les Perturbations Magnetiques en France."

L. T. O'SHEA.—"On the Effect of Oxidation on the Magnetic Properties of Manganese Steel."

PROF. W. OSTWALD.—"On the Action of Semipermeable Membranes in Electrolysis."

W. H. PREECE, F.R.S.—"On the Character of Steel used for Permanent Magnets."

A. W. RÜCKER, F.R.S., AND T. E. THORPE, F.R.S.—"On Regional Magnetic Disturbances in the United Kingdom."

W. N. SHAW.—"Report on the State of our Knowledge of Electrolysis and Electro-Chemistry."

W. A. SHENSTONE.—"Some new Vacuum Joints and Taps."

J. SWINBURNE.—"On the Resistance of the Human Body under Direct and Alternating Pressures."

J. SWINBURNE AND W. F. BOURNE.—"Testing Iron."

J. SWINBURNE.—"The Compensation of Alternate-Current Instruments."

Digitized by Google

J. SWINBURNE.—"Notes on High Vacua."

SIR W. THOMSON, F.R.S.—"On an Illustration of Contact Electricity presented by the Multicellular Electrometer."

SIR W. THOMSON, F.R.S.—"On a Method of Determining in Absolute Measure the Magnetic Susceptibility of Diamagnetic and Feebly Magnetic Solids."

SIR W. THOMSON, F.R.S.—"On Alternate Currents in Parallel Conductors of Homogeneous or Heterogeneous Substances."

SIR W. THOMSON, F.R.S.—"On Anti-Effective Copper in Parallel or in Coiled Conductors for Alternate Currents."

F. T. TROUTON.—"Experiments to Determine Wave-Velocity in Dielectrics."

J. TROWBRIDGE.—"On Electrical Oscillations."

F. H. VARLEY.—"On a new Direct-reading Photometer."

Report of the Committee on Electrical Standards, with the four following Papers:—

T. C. FITZPATRICK.—"On the Specific Resistance of Copper."

R. T. GLAZEBROOK, F.R.S.—"On Variations in some Standard Resistance Coils."

R. T. GLAZEBROOK, F.R.S., AND A. MUIRHEAD.—"On some Standard Air Condensers."

E. H. GRIFFITHS.—"A Comparison of a Platinum Thermometer with some Mercury Thermometers."

Report of the Committee on Molecular Phenomena attending the Magnetisation of Iron.

Report of the Committee on Electro-Optics.

Report of the Committee on Electrolysis.

SECTION B.

Report of the Committee on the Silent Discharge of Electricity.

SECTION G.

W. J. S. BARBOUR-STARKEY.—Secondary Batteries.

WILSON HARTNELL.—"Electric Lighting and Fire Insurance Rules."

F. HIGGINS.—The Column Printing Telegraph.

GISBERT KAPP.—"The Lineff System of Electric Traction."

H. N. LAWRENCE and DR. HARRIES.—"Alternato *v.* Continuous Currents in relation to the Human Body."

G. R. MURPHY.—The Victoria Torpedo.

W. H. PREECE.—"On the Form of Submarine Cables for Long-Distance Telephony."

SIR W. THOMSON, F.R.S.—"On a New Electric Meter. The Multicellular Voltmeter. An Engine-Room Voltmeter. An Ampere Gauge. A new form of Voltapile, useful in Standardising Operations."

THE LINEFF ELECTRIC TRAMWAY.*

BY GISBERT KAPP, M.I.E.E.

Engineers and tramway managers, not less than the travelling public, are agreed as to the desirability of replacing animal by some sort of mechanical traction; and electrical engineers in particular are convinced that of all methods of applying mechanical power that involving the use of electromotors is the most convenient for the ordinary type of tramline. On lines with exceptionally steep gradients the cable has the advantage over the steam locomotive and electromotor that the weight of the car to be hauled up the grade is a minimum; but on lines which are not too steep to be worked by steam or horses this advantage is on long lines more than counter-balanced by the waste of power involved in keeping the cable itself in motion; and it is in these cases which form the majority that the electromotor has the most promising field of application. It may be asked how it comes that with all these circumstances in its favour, electric traction on tramways has made in this country so little progress. We have cheap coal, good steam-engines, excellent dynamos, and thoroughly reliable and efficient electromotors. The transmission of power from the motor spindle to the axle of the car, although not so easy a problem as it might perhaps appear at first sight, does not present any insuperable difficulties, and has, in fact, been very satisfactorily solved by more than one engineer. The application of electricity to traction should therefore be an easy matter. Yet progress is slow. The explanation appears to be that although the generation of the electric current taken by itself is easy enough, and the conversion of this current into mechanical power taken by itself is easy enough, the connecting link between the two processes, namely, the conveyance of the current from the dynamo at the tramway depôt to the car on the line, is a matter of some difficulty, and as yet we have no system of conveyance which may be considered as satisfactory in every respect. It is in this direction that inventors should work. There is very little need for improved dynamos, motors, switches, or other gear; all these appliances, though not absolutely perfect, are quite good enough for practical work. There is, however, great need for improved methods of conveying the electric current to the car in a manner which shall at once be economical, certain, free from danger to persons and animals, offer no obstruction to the general traffic in the streets, and be acceptable on æsthetic grounds. All these conditions except the first are fulfilled in those systems where a storage battery is used for conveying the current from the dynamo at the depôt to the motor on the car; but unfortunately the first condition is too important to be neglected, since the fundamental reason for substituting mechanical for horse traction is not a humanitarian or scientific one, but the aim to save a penny or two per car mile, and thus increase the financial prosperity of the company. I do not say that such a saving may not be effected by the use of battery cars; but I say that up to the present we have no practical proof that such cars are more economical to work than horse cars; and I maintain that whatever saving may result from the adoption of batteries, a greater saving under the same circumstances must result from direct working; that is, working under some system of conveying the current direct from the dynamo to the motor by means of a conductor. On the other hand, there may be reasons for preferring the storage car, notwithstanding its lower efficiency; but I do not propose to enter into this subject, as it can only be satisfactorily discussed with reference to the local conditions in each particular case. My object is to bring before you a new system of direct supply for tram-cars, which has recently come under my notice, and which seems to fulfil all the conditions stated above.

When we have to convey current to the car by means of a conductor, this conductor must run along the line either above or below ground. In the former case it may be a wire suspended along poles, or a rail resting on insulating supports close to the ground, or it may be formed by the tram-rails themselves. All these arrangements have been tried, but it is needless to say that they are inadmissible for urban and suburban lines in this country. With such lines the first condition must necessarily be to place the conductor underground. As usually carried out this system involves the adoption of a slot in the road through which passes a slipper or contact-shoe attached to the car, and which establishes electrical connection between the conductor underground and the motor on the car. The system is, as experience shows, practically workable; though the slot, which must admit dirt and moisture into the underground channel and may to a certain extent inconvenience other traffic, is a disadvantage. This disadvantage may perhaps not be very great considered from a purely technical point of view, but such as it is it has to be taken into account. If we consider the question from the point of view which will naturally be taken by the local authorities and the public whom they represent, we shall come to the conclusion that the slot is a great disadvantage to the general traffic, and that its abolition is highly desirable. How to abolish the slot and yet retain electrical connection between the underground conductor and the motor on the car is the problem which has been solved in the system of electric tramway I am about to describe.

The conductor consists of bare copper strip or cable, and of iron strip. The latter is galvanised so as to protect it from rusting. It lies on the copper conductor, and both are enclosed in a sealed channel formed of asphalte. The copper conductor rests upon the bottom of a trough made of a succession of glazed tiles, and the cover to this trough is formed by the lower flanges of iron rails arranged in short sections so as to be insulated from each other. The head of one rail reaches up to the surface of the road; the head of the other is cut off, and this rail is, therefore, completely buried in the asphalte. The surface rail, which may be arranged alongside one of the ordinary tram rails, or in the centre of the track, is in electric and magnetic contact with an electromagnet carried under the car. This magnet runs upon the surface rail on wheels, which form its north and south poles. The distance of the wheels is greater than the length of a section of insulated rail, so that successive sections become oppositely magnetised. This causes the iron strip immediately below the magnetised region to be attracted upwards and thus come into contact for a length of several feet with the under side of the two sectional rails. At the same time the iron strip to both sides of this region remains in contact with the copper conductor, and forms thus an electrical connecting link between the copper conductor and a few sections of insulated rail under the car. The current passes from the surface rail through the body of the electro-magnet (which is insulated from the body of

* Paper read before the British Association in Section G, Leeds, September, 1890.

Digitized by Google

the car) into the motor, and finally into the ordinary tram rails and earth in the usual manner. The electro magnet is energised by a shunt current obtained from the main conductor, but to provide for the possibility of dropping the strip from some unforeseen cause there is placed on the electro-magnet a third thick wire coil, which can at all times be energised by two storage cells carried on the car, and thus the strip can be picked up and the main circuit again established if it should have been accidentally interrupted. I may, however, at once state that during some tests which I made on an experimental line of this kind, and which lasted over several days, there has been no need for the picking-up battery, as the current was never lost. I shall say a few words about the results of these tests presently; but before entering upon the practical results I would draw your attention to a question of both practical and theoretical importance—namely, the way in which Mr. Lineff makes use of magnetic lines of force to effect the attraction of the iron strip. It might, perhaps, be thought that the most direct and therefore the best way of utilising the lines of force would be by one single line of sectional rail through which there would be longitudinal magnetic flux corresponding with the fore and aft position of the poles and attraction of the strip at every gap between two sections. Experiment has, however, shown that this apparently direct way is by no means the best way, and that far more satisfactory results can be obtained by arranging a more roundabout course for the lines of force. This is attained by the employment of the subsidiary or buried rail, the gaps in which do not exactly correspond with those in the main or surface rail, but are shifted forward by a certain amount. In consequence of this arrangement, the buried rail acts as a kind of magnetic bridge (*see* Fig. 1) to successive portions of the surface

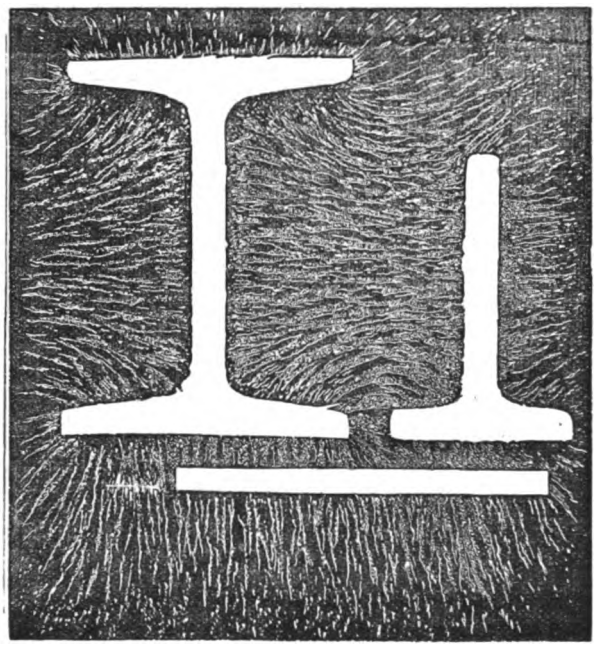

Fig. 1.—Lineff System Magnetic Circuit.

rail, and this action takes place in two ways, one direct and the other indirect. The direct way is longitudinal, and does not affect the strip at all. The indirect way is both longitudinal and transverse, the latter passing several times through the strip. The buried rail is a rather imperfect bridge to the lines of force traversing it longitudinally, because its magnetic resistance in that direction is great, but this rail forms a very efficient bridge for lines passing through it transversely, owing to its lower magnetic resistance in that direction, which includes the strip. This flow of magnetic force transversely is, therefore, that which effects the attraction of the strip, and may be represented as a series of magnetic stitches passing to and fro between the two sets of rails and the strip.

This action will be understood by reference to the diagrams 2 to 4, which represent the magnetic condition of the rails for three positions of the electro-magnet. A represents the surface rail, and B the buried rail. The energy provided to attract the strip is only 180 watts, or equivalent to that consumed by three glow lamps; and this I have found sufficient under all circumstances. Fig. 6 is a cross-section, Fig. 5 a plan, and Fig. 7 a longitudinal section of the line and electro-magnet.

The experiments to which I have referred were undertaken to see whether the whole system is practically workable. The first question which presented itself was whether the wave in the strip running along at the speed of the car was likely to induce subsidiary waves either in front or behind the car, whereby exposed sections of the surface rail might become charged and be a danger to ordinary traffic. To investigate this matter a pilot brush was fitted to the car at different distances from its centre, and connected with an electric bell. The pilot brush was so placed as to slide over the surface rail, and if on a charged section the bell would sound. It was found that the charged region was at all speeds considerably shorter than the length of an ordinary car. Contact tests were also made over the whole line at greater distances from the car than the pilot brush could reach, and in no case have I found an exposed section of rail charged. There was, further, the danger that with a dry and dirty line the collection of current might be accompanied by sparking, which would frighten horses; but this difficulty was overcome by fitting wire brushes to the pole-shoes of the electro-magnet.

An important point in all conductor systems of electric tramway is the energy spent in collecting the current. With the overhead wire system this is very small and practically inappreciable. With an underground system it is naturally larger. In the first system elaborated by Mr. Lineff, the flexible underground shoe with its trailing rope required from 20 to 48lb. for its propulsion. In the series system the "arrow" rubbing through the "spring jacks" must necessarily also require the application of considerable force; but I have no figures on this point. In the new Lineff system the electro-magnet rolls on the surface rail, and the propelling energy is consequently small. I am informed by Mr. Lineff that he has succeeded in reducing it to 210 watts with the magnet energised. The whole power spent in collection of current is therefore about half a horse power.

The insulation resistance of the conductor was tested both by the bridge method (48 Leclanché cells, Post Office pattern bridge, and mirror galvanometer), and by passing the leakage current through a voltmeter, and the two methods gave fairly accordant results. The highest reading I recorded by the voltmeter test, when the full pressure of 230 volts was on the conductor, was 5,400 ohms, and the lowest 3,550 ohms. From these figures it appears that the average insulation is 186 ohms per mile.

To ascertain the surface leakage I also applied the voltmeter test, and found the following insulation resistances of three charged sections of magnetic rail. With the line clear and moist, 4,183 ohms; with the line very wet and covered with mud and horse droppings, 980 ohms. Taking 2,000 ohms as an average, the loss of power at 300 volts by surface leakage per car amounts to 45 watts.

The mechanical strength of the line was tested by running a steam roller over it in various directions, under which treatment the line suffered no damage whatever.

DISCUSSION.

Major-General WEBBER said the Lineff system met in a remarkable way and to a very large extent a want which they had all been feeling for some time, that is to say, some means of connecting the motor which actuates the car with an underground conductor. In the absence of information as to the voltage or the pressure which actuated the motor, he failed to see that they did securely prevent the strip remaining in contact after the passage of the car. He also felt some doubt as to the insulation of the conductor shown in the diagram on the blackboard.

Mr. W. H. PREECE said that under Mr. Kapp's guidance he had inspected the working of the Lineff system near Chiswick, and could corroborate every word in the Paper. His fears for the practical success of the system were principally that there might be a failure of the contact between the flexible strip and the rail, but that was virtually got over by having a very broad strip and long length in contact, and also by the fact that the flexible iron conductor was galvanised and therefore always clean; moreover, the galvanisation on the surface had precisely the same effect as the insertion of pieces of paper on the pull-pieces of electro-magnets, that is, that as the energising power ceases the armature drops off; so here as soon as the current ceases the flexible strip will fall to the bottom of the trough. There was no doubt that of all the systems yet produced, this one had the air of practicability about it; but it would be quite impossible to give a definite opinion upon it until it has received the test of actual practice.

Prof. EWING referred to the correspondence between the Lineff system and the system originally introduced by Profs. Ayrton and Perry, of having a thoroughly well-insulated conductor underground, which was to be connected when the car passed with successive sections of a not so well insulated conductor serving as a surface conductor. This was done by Mr. Lineff in a very much more satisfactory way than by the mechanical methods of connection proposed by Profs. Ayrton and Perry.

Major-General WEBBER said they might dismiss the question of insulated returns from their minds. He had reason to believe that before very long almost all the telephone systems in the country would be served by metallic returns and not by earth returns; and in such a case it would not be necessary for the telephone companies to insist upon such clauses.

Mr. KAPP, in reply, said that with regard to the telephone question, the three-wire system offered a very simple way of greatly minimising the disturbance. He did not believe the telephone would suffer very much from the comparatively low currents of tram lines. The strip did *not* remain in contact. His own fear had been that there would be enough residual magnetism to keep the strip up · and another fear had been that

Digitized by Google

the main wave under the car might perhaps produce a subsidiary wave, rising up, say, 100 yards behind the car and making contact. But he could not produce such contact, although he had tried in many ways, such as starting the car at full speed and suddenly stopping it. The residual magnetism did not prolong the contact. In his experiments the voltage was 230 volts, but as far as he could judge at present, the line was perfectly safe for 300 volts. With reference to the insulation, the diagrams showed the line as actually built, but Mr. Lineff had since improved the general arrangements, by which he now expected to get a very much higher insulation. There was absolutely no noise with this system. Mechanical cleaning brushes were used; they were put on at an angle something like the cow-catchers on locomotives. Mr. Lineff told him that the cost of his plant, in addition to the ordinary tram line, was £2,000 per mile, which was a little heavier than an overhead conductor.

DR. GLAISHER'S PRESIDENTIAL ADDRESS IN SECTION A.*

No one who is called upon to preside over this Section can fail to be struck by the range of subjects comprehended within its scope. The field assigned to us extends from the most exact of all knowledge, the sciences of number, quantity, and position, to branches of inquiry in which the progress has been so slight that they still consist of little more than collections of observed facts. This breadth of area has obvious disadvantages, but it is not without some compensating advantages. In these days, when science is so much subdivided, it is well that students of subjects even so diverse as those with which we have to deal should occasionally meet on common ground, and have the opportunity of learning from each other's lips the kind of work in which they are engaged. Wide as is our range, we should remember also how closely knit together in various ways are the more important of our subjects; and in the case of mathematics, astronomy, and physics, besides their actual and historical alliance, a mathematician may be permitted to feel that a special bond of union is created by the mathematical processes and language which are essential for their investigation and expression. It is, I am afraid, unfortunate for my audience, that my own subject should be at one extreme, not only of those dealt with by our Section, but even of the still greater range covered by the Association. I will endeavour, however, in my remarks to confine myself to a few general considerations relating to pure mathematics which I hope will not be considered out of place on this occasion.

By pure mathematics, I do not mean the ordinary processes of algebra, differential and integral calculus, &c., which every worker in the so-called mathematical sciences should have at his command. I refer to the abstract sciences which do not rest upon experiment in the ordinary sense of the term, their fundamental principles being derived from observations so simple as to be more or less axiomatic. To this class belong the theories of magnitude and position, the former including all that relates to quantity, whether discrete or continuous, and the latter including all branches of geometry. Nor would I willingly undervalue the interest of those branches of mathematics which we owe to the mathematical necessities of physical inquiry. But it always appears to me that there is a certain perfection, and also a certain luxuriance and exuberance in the pure sciences which have resulted from the unaided, and I might almost say, inspired genius of the greatest mathematicians, which is conspicuously absent from most of the investigations which have had their origin in the attempt to forge the weapons required for research in the less abstract sciences. We do not find the easy flow or homogeneity of form which is characteristic of a mathematical theory properly so called. In such a theory, as—for example—the theory of double periodicity (elliptic functions) the subject develops itself naturally as it proceeds; one group of results leads spontaneously to another; new and unexpected prospects open of themselves; ideas the most novel and striking, which penetrate the mind with a charm of their own, spring directly out of the subject itself. We are surprised by the wonderful connections with other subjects, which unexpectedly start into existence, and by the widely different methods of arriving at the same truths; in fact, as our knowledge progresses, we continually find that results which seemed to lie far away in the interior of the subject—so remote and concealed that, at first sight, we might think that no other path except the one actually pursued could have reached them—are actually close to its edge when approached from another side or viewed from another standpoint. We notice, too, that any great theory gives rise to its own special analysis or algebra, frequently connecting together into one whole what were hitherto merely isolated and apparently independent analytical results and affording a reason for their existence, and also—what is often even more interesting—a reason for the non-occurrence of others, which analogy might have led us to expect. I do not pretend that there are not many branches of mathematics which partake of both these characters, nor do I suppose that the description I have given of a mathematical theory is at all peculiar to pure mathematics. Much of it is common to all scientific research in a fruitful field, though possibly we may not find elsewhere such profusion of ideas or perfection of form.

I have been tempted to speak at such length on the objects and aims of the mathematician by the feeling that they are not infrequently misunderstood by the workers in the less abstract sciences. I do not think that mathematical formulæ or processes, merely as such, are much more interesting to the pure than to the applied mathematician. The one studies number, quantity, and position, the other deals with matter and motion; and in both cases the investigations are carried on by means of the same symbolic language.

The order in which the subjects which form an ordinary mathematical course are presented to the student is regulated by the fact that portions of the elements of the pure sciences are required for the explanation and development of any exact science; for example, a knowledge of the elements of trigonometry, analytical geometry, and differential and integral calculus, must necessarily precede any adequate treatment of mechanics, light, or electricity. The majority of students, after mastering a sufficient amount of pure mathematics to enable them to pass on to the physical subjects, continue to devote their attention to the latter, and never know more of the nature of the pure sciences than they can derive from the processes and methods which they learned at the very outset of their mathematical studies. Most of the mathematical text-books in use at Cambridge are so admirably adapted to the purposes for which they are intended that it seems ungracious to make an adverse criticism of a general kind. But I cannot help feeling regret that their writers have had so much in view the immediate application of the principles of the pure subjects to the treatment of physical problems. In the case of the differential and integral calculus, for example, there seems an increasing tendency to introduce into the bookwork and examples propositions which really belong to the physical subjects. This is an important tribute to the growth and influence of physical mathematics in this country, and a zealous physicist might even consider it satisfactory that the student should not be required to encumber himself with knowledge which was not directly applicable to the theory of matter. But from the mathematician's point of view it is unfortunate; for, while shortening by very little the path of the student, it cannot fail to give an incomplete, if not erroneous, idea of the relations of the pure to the applied sciences. How can he help feeling that the former are merely ancillary to the latter when he finds that the mathematical problems which arise naturally in physical investigations have been already dealt with out of their place in the treatises which should have been devoted solely to the sciences of quantity and position?

Passing to the consideration of pure mathematics itself, that is to say, of the abstract sciences, which can only be conquered and explored by mathematical methods, it is difficult not to feel somewhat appalled by the enormous development they have received in the last fifty years. The mass of investigation, which is annually added to the literature of the subject, is so great that it is fast becoming bewildering from its mere magnitude. To those who believe, if any such there are, that mathematics exist for the sake of its applications to the concrete sciences, it must indeed seem that it has long since run wild, and expanded itself into a thousand useless extravagances. Even the mathematician must sometimes ask himself the questions—not unfrequently put to him by his friends—"To what is it all tending? What will be the result of it all? Will there be anyend?" The last question is readily answered. There certainly can be no end; so wide and so various are the subjects of research, so interesting and fascinating the results, so wonderful the fields of research laid open at each succeeding advance—no matter in what direction—that we may be sure that, while the love of learning and knowledge continue to exist in the human mind, there can be no relaxation of our efforts to penetrate still further into the mysterious worlds of abstract truth which lie so temptingly spread before the investigator. This wonderful suggestiveness is itself one of the marks of a true theory, one of the signs by which we know that we are investigating the actual, existing truths of nature, and that our symbols and formulæ are expressing facts quite independent of themselves, though decipherable only by their means.

Instead of attempting to consider the general question of what may be expected to result from the progress of mathematical science, we may restrict ourselves to asking whether the great extension of the bounds of the subject which is taking place in our time, will materially add to its powers as a weapon of research in the concrete subjects. For my own part I do not think that the bearing of the modern developments of mathematics upon the physical sciences is likely to be very direct or immediate. It would indeed be rash to assert that there is any branch of mathematics so abstract or so recondite, that it might not at any moment find an application in some concrete subject; still it seems to me that if the extension of the pure sciences could only be justified by the value of their applications, it is very doubtful whether a satisfactory plea for any further developments could be sustained. There is a general resemblance of style running through much of the analysis required in the physical sciences, but there is no such resemblance in the case of the pure sciences or between the pure and the physical sciences. It appears likely, therefore, that in the future, the mathematical obstacles which present themselves in physical research will have to be overcome, as heretofore, by means of investigations undertaken for the purpose, and that analysis will continue to be enriched by conceptions and results and even by whole subjects (such as spherical harmonies), which will be entirely due to the concrete sciences. Of course, it will sometimes happen that a differential equation or an integral has already been considered in connection with some other theory, or a whole body of analysis or geometry will suddenly be found to admit of a physical interpretation; but, after all, even the pure sciences themselves exert but an indirect effect upon the perfection of mathematical formulæ and processes, and we must be prepared to find that in general the requirements of physics have to be met by special analytical researches. Having now endeavoured to consider the proposed question impartially, and from a cold and rational standpoint, I cannot refrain from adding that, in spite of all I have said, I believe that every mathematician must cherish in his heart the conviction that at any moment some special analysis, devised in connection with a branch of pure mathematics, may bear wonderful fruit in one of the applied sciences, giving short and complete solutions of problems which could hitherto be treated only by prolix and cumbrous methods.

It would seem at first sight as if the rapid expansion of the region of mathematics must be a source of danger to its future progress. Not only does the area widen, but the subjects of study increase rapidly in number, and the work of the mathematician tends to become more and more specialised. It is, of course, merely a brilliant exaggeration to say that no mathematician is able to understand the work of any other mathematician, but it is certainly true that it is daily becoming more and more difficult for a mathematician to keep himself acquainted, even in a general way, with the progress of any of the branches of mathematics except those which form the field of his own labours. It rests with the worker in mathematics not only to explore new truths, but to devise the language by which they may be discovered and expressed; and the genius of a great mathematician displays itself no less in the notation he invents for deciphering his subject than in the results attained. There are some theories in which the notation seems to arise so simply and naturally out of the subject itself, that it is difficult to realise that it could have required any creative power to produce it; but it may well have happened that in these

* Abstract of Address delivered before British Association at Leeds, September, 1890.

Digitized by Google

very cases it was the discovery of the appropriate notation which gave the subject its first real start, and rendered it amenable to effective treatment. When the principles that underlie a theory have been well grasped, the proper notation almost necessarily suggests itself, if it has not been already discovered; but some sort of provisional notation is required in the early stages of a theory in order to make any progress at all, and the mathematician who first gains a real insight into the nature of a subject is almost sure to be the first to seize upon the right notation.

Quite distinct from the theoretical question of the manner in which mathematics will rescue itself from the perils to which it is exposed by its own prolific nature is the practical problem of finding means of rendering available for the student the results which have been already accumulated, and making it possible for a learner to obtain some idea of the present state of the various departments of mathematics. This is a problem which is common to all rapidly moving branches of science, although the difficulties are increased in the case of mathematics by its wide extent and the comparative smallness of the audience addressed. The great mass of mathematical literature will be always contained in journals and transactions, but there is no reason why it should not be rendered far more useful and accessible than at present by means of treatises or higher text-books. The whole science suffers from want of avenues of approach, and many beautiful branches of mathematics are regarded as difficult and technical merely because they are not easily accessible. Ten years ago I should have said that even a bad treatise was better than none at all. I do not say that now—the number of excellent text-books of an elementary kind that are published in this country makes it all the more to be regretted that we have so few that are intended for the more advanced student. As an example of the higher kind of text-book, the want of which is so badly felt in many subjects, I may mention the second part of Prof. Chrystal's Algebra published last year, which in a small compass gives a great mass of valuable and fundamental knowledge that has hitherto been beyond the reach of an ordinary student, though in reality lying so close at hand.

Although it may not be possible to contemplate the actual position of pure mathematics in this country with any great amount of enthusiasm, we may yet feel some satisfaction in reflecting that there is more cause for congratulation at present than there has been at any time in the last hundred and fifty years, and that we are far removed from the state of affairs which existed before the days of Cayley and Sylvester. Unfortunately, we cannot point with pride to any distinct school of the pure sciences corresponding to the Cambridge school of mathematical physics, and I am afraid that the old saying that we have generals without armies is as true as ever. For this there is no immediate remedy; a school must grow up gradually of itself, as the study of mathematical physics has grown up at Cambridge. I certainly should not wish, even if it were possible, to obtain more recruits for the pure sciences at the expense of the applied, nor do I desire to see the system of instruction which has found favour in this country so modified that pure mathematics could be carried on by narrow specialists. I should be sorry, for example, that a student, after learning algebra and differential calculus, should pass directly to the theory of curves, and devote himself to research in this field without ever having acquired a general knowledge of other branches of mathematics or of any of its applications. If the student were brought by the shortest possible route to the frontier of one of the subjects, where a fruitful field of research was pointed out to him, there is no doubt that the amount of mathematical literature produced might be greatly increased, but I am sure that the advantage to science would not be proportional to this increased amount. I am convinced that no one should devote himself to the abstract sciences unless he feels strongly drawn to them by his tastes.

Before leaving this part of my subject I should like to say a few words upon the subject of accuracy of form in the presentation of mathematical results. In other branches of science, where quick publication seems to be so much desired, there may possibly be some excuse for giving to the world slovenly or ill-digested work, but there is no such excuse in mathematics. The form ought to be as perfect as the substance and the demonstrations as rigorous as those of Euclid. The mathematician has to deal with the most exact facts of nature, and he should spare no effort to render his interpretation worthy of his subject, and to give to his work its highest degree of perfection. "*Pauca sed matura*" was Gauss's motto. I do not presume to assert that the interest taken in the pure sciences can be regarded as an index of the energy and power of a nation, but it is certain that mathematical research flourishes only in a vigorous community. The search after abstract truth for its own sake, without the smallest thought of practical application or return in any form, and the yearning desire to explore the unknown, are signs of the vitality of a people, which are among the first to disappear when decay begins.

THE ELECTRO-MAGNET.[1]

BY PROF. SILVANUS P. THOMPSON, D.SC., B.A., M.I.E.E.

Introductory.

Amongst the great inventions which have originated in the lecture room in which we are met are two of special interest to electricians—the application of gutta percha to the purpose of submarine telegraph cables, and the electro-magnet. This latter invention was first publicly described, from the very platform on which I stand, on May 23, 1825, by William Sturgeon, whose Paper is to be found in the volume of the *Transactions* of the Society of Arts for that year. For this invention we may rightfully claim the very highest place. Electrical engineering—the latest and most vigorous offshoot of applied science—embraces many branches. The dynamo for generating electric currents, the motor for transforming their energy back into work, the arc lamp, the electric bell, the telephone, the recent electro-magnetic machinery for coal mining, for the separation of ore, and many other electro-mechanical contrivances come within the purview of the electrical engineer. In every one of these, and in many more of the useful applications of electricity, the central organ is an electro-magnet. By means of this simple and familiar contrivance—an iron core surrounded by a copper wire coil—mechanical actions are produced at will, at a distance, under control, by the agency of electric currents. These mechanical actions are known to vary with the mass, form, and quality of the iron core, the quantity and disposition of the copper wire wound upon it, the quantity of electric current circulating around it, the form, quality, and distance of the iron armature upon which it acts. But the laws which govern the mechanical action in relation to these various matters are by no means well known, and, indeed, several of them have long been a matter of dispute. Gradually, however, that which has been vague and indeterminate becomes clear and precise. The laws of the steady circulation of electric currents, at one time altogether obscure, were cleared up by the discovery of the famous law of Ohm. Their extension to the case of rapidly-interrupted currents, such as are used in telegraphic working, was discovered by Helmholtz; whilst to Maxwell is due their further extension to alternating, or, as they are sometimes called, undulatory currents. All this was purely electric work. But the law of the electro-magnet was still undiscovered; the magnetic part of the problem was still buried in obscurity. The only exact reasoning about magnetism dealt with problems of another kind; it was couched in language of a misleading character; for the practical problems connected with the electro-magnet it was worse than useless. The doctrine of two magnetic fluids distributed over the end surfaces of magnets, under the sanction of the great names of Coulomb, of Poisson, and of Laplace, had unfortunately become recognised as an accepted part of science, along with the law of inverse squares. How greatly the progress of electro-magnetic science has been impeded and retarded by the weight of these great names it is impossible now to gauge. We now know that for all purposes, save only those whose value lies in the domain of abstract mathematics, the doctrine of the two magnetic fluids is false and misleading. We know that magnetism, so far from residing on the end or surface of the magnet, is a property resident throughout the mass; that the internal not the external magnetisation is the important fact to be considered; that the so-called free magnetism on the surface is, as it were, an accidental phenomenon; that the magnet is really most highly magnetised at those parts where there is least surface magnetisation; finally, that the doctrine of surface distribution of fluids is absolutely incompetent to afford a basis of calculation such as is required by the electrical engineer. He requires rules to enable him not only to predict the lifting power of a given electro-magnet, but also to guide him in designing and constructing electro-magnets of special forms suitable for the various cases that arise in his practice. He wants in one place a strong electro-magnet to hold on to its armature like a limpet to its native rock; in another case he desires a magnet having a very long range of attraction, and wants a rule to guide him to the best design; in another he wants a special form having the most rapid action attainable; in yet another he must sacrifice everything else to attain maximum action with minimum weight. Toward the solution of such practical problems as these the old theory of magnetism offered not the slightest aid. Its array of mathematical symbols was a mockery. It was as though an engineer asking for rules to enable him to design the cylinder and piston of an engine were confronted with receipts how to estimate the cost of painting it.

Gradually, however, new light dawned. It became customary, in spite of the mathematicians, to regard the magnetism of a magnet as something that traverses or circulates around a definite path, flowing more freely through such substances as iron than through other relatively non-magnetic materials. Analogies between the flow of electricity in an electrically-conducting circuit, and the passage of magnetic lines of force through circuits possessing magnetic conductivity, forced themselves upon the minds of experimenters, and compelled a mode of thought quite other than the previously accepted. So far back as 1821, Cumming[2] experimented on magnetic conductivity. The idea of a magnetic circuit was more or less familiar to Ritchie,[3] Sturgeon,[4] Dove,[5] Dub,[6] and De La Rive,[7]

the last-named of whom explicitly uses the phrase, "a closed magnetic circuit." Joule[8] found the maximum power of an electro-magnet to be proportional to "the least sectional area of the entire magnetic circuit," and he considered the resistance to induction as proportional to the length of the magnetic circuit. Indeed, there are to be found scattered in Joule's writings on the subject of magnetism, some five or six sentences, which, if collected together, constitute a very full statement of the whole matter. Faraday[9] considered that he had proved that each magnetic line of force constitutes a closed curve; that the path of these closed curves depended on the magnetic conductivity of the masses disposed in proximity; that the lines of magnetic force were strictly analogous to the lines of electric flow in an electric circuit. He spoke of a magnet surrounded by air being like unto a voltaic battery immersed in water or other electrolyte. He even saw the existence of a power, analogous to that of electro-motive force in electric circuits, though the name, "magneto-motive force," is of more recent origin. The notion of magnetic conductivity is to be found in Maxwell's great treatise (Vol. II., p. 51), but it is only briefly mentioned. Rowland,[10] in 1873, expressly adopted the reasoning and language of Faraday's method in the working out of some new results on magnetic permeability, and pointed out that the flow of magnetic lines of force through a bar could be subjected to exact calculation; the elementary law, he says, "is similar to the law of Ohm." According to Rowland, the "magnetising force of helix" was to be divided by the "resistance to the lines of force;" a calculation for magnetic circuits which every electrician will recognise as precisely as Ohm's law for electric circuits. He applied the calculations to determine the permeability of certain specimens of iron, steel, and nickel. In 1882[11] and again in 1883, Mr. R. H. Bosanquet[12] brought out at greater length a similar argument, employing the extremely apt term "Magneto-motive Force," to connote the force tending to drive the magnetic lines of induction through the "magnetic resistance" of the circuit. In these Papers the calculations are reduced to a system, and deal not only with the specific properties of iron, but with problems arising out of the shape of the iron. Bosanquet shows how to calculate the several resistances of the separate parts of the circuit, and then add them together to obtain the total resistance of the magnetic circuit.

Prior to this, however, the principle of the magnetic circuit had been seized upon by Lord Elphinstone and Mr. Vincent, who proposed to apply it in the construction of the dynamo-electric machines. On two occasions[13] they communicated to the Royal Society the results of experiments to show that the same exciting current would evoke a larger amount of magnetism in a given iron structure, if that iron structure formed a closed magnetic circuit, than if it were otherwise disposed.

In recent years the notion of the magnetic circuit has been vigorously taken up by the designers of dynamo-machines, who indeed base the calculation of their designs upon this all-important principle. Having this, they need no laws of inverse squares of distances, no magnetic moments, none of the elaborate expressions for surface distribution of magnetism, none of the ancient paraphernalia of the last century. The simple law of the magnetic circuit and a knowledge of the properties of iron is practically all they need. About four years ago, much was done by Mr. Gisbert Kapp[14] and by Drs. J. and E. Hopkinson[15] in the application of these considerations to the design of dynamo machines, which previously had been a matter of empirical practice. To this end the formulæ of Prof. Forbes[16] for calculating magnetic leakage, and the researches of Profs. Ayrton and Perry[17] on magnetic shunts, contributed a not unimportant share. As the result of the advances made at that time, the subject of dynamo design was reduced to an exact science.

It is the aim and object of the present course of lectures to show how the same considerations which have been applied with such great success to the subject of the designing of dynamo-electric machines may be applied to the study of the electro-magnet. The theory and practice of the design and construction of electro-magnets will thus be placed, once for all, upon a rational basis. Definite rules will be laid down for the guidance of the constructor, directing him as to the proper dimensions and form of iron to be chosen, and as to the proper size and amount of copper wire to be wound upon it in order to produce any desired result.

First, however, a historical account of the invention will be given, followed by a number of general considerations respecting the uses and forms of electro-magnets. These will be followed by a discussion of the magnetic properties of iron and steel and other materials; some account being added of the methods used for determining the magnetic permeability of various brands of iron at different degrees of saturation. Tabular information is given as to the results found by different observers. In connection with the magnetic properties of iron the phenomenon of magnetic hysteresis is also described and discussed. The principle of the magnetic circuit is then discussed with numerical examples, and a number of experimental data respecting the performance of electro-magnets are adduced, in particular those bearing upon the tractive power of electro-magnets. The law of traction between an electro-magnet and its armature is then laid down, followed by the rules for predetermining the iron cores and copper coils required to give any prescribed tractive force. The rules for calculating the winding of the copper coils are explained, and the limiting relation between the magnetising power of the coil and the heating effect of the current in it is explained. Then comes the extension of the calculation of the magnetic circuit to those cases where there is an air gap between the poles of the magnet and the armature; and where, in consequence, there is leakage of the magnetic lines from pole to pole. After this comes a detailed discussion of the special varieties of form that must be given to electro-magnets in order to adapt them to special services. Those which are designed for maximum traction, for quickest action, for longest range, for greatest economy when used in continuous daily service, for working in series with constant current, for use in parallel at constant pressure, and those for use with alternate currents, are separately considered.

Lastly, some account is given of the various forms of electro-magnetic mechanism which have arisen in connection with the invention of the electro-magnet. The plunger and coil is specially considered as constituting a species of electro-magnet adapted for a long range of motion. Modes of mechanically securing long range for electro-magnets, and of equalising their pull over the range of motion of the armature, are also described. The analogies between sundry electro-mechanical movements and the corresponding pieces of ordinary mechanism are traced out. The course is concluded by a consideration of the various modes of preventing or minimising the sparks which occur in the circuits in which electro-magnets are used.

Historical Sketch.

The effect which an electric current, flowing in a wire, can exercise upon a neighbouring compass needle was discovered by Oersted in 1820.[18] This first announcement of the possession of magnetic properties by an electric current was followed speedily by the researches of Ampere,[19] Arago,[20] Davy,[21] and by the devices of several other experimenters, including De la Rive's[22] floating battery and coil, Schweigger's[23] multiplier, Cumming's[24] galvanometer, Faraday's[25] apparatus for rotation of a permanent magnet, Marsh's[26] vibrating pendulum, and Barlow's[27] rotating star-wheel. But it was not until 1825 that the electro-magnet was invented. Davy had, indeed, in 1821 surrounded with temporary coils of wire the steel needles upon which he was experimenting, and had shown that the flow of electricity around the coil could confer magnetic power upon the steel needles. But from this experiment it was a grand step forward to the discovery that a core of soft iron, surrounded by its own appropriate coil of copper, could be made to act not only as a powerful magnet, but as a magnet whose power could be turned on or off at will, could be augmented to any desired degree, and could be set into action and controlled from a practically unlimited distance.

The electro-magnet, in the form which can first claim recognition for these qualities, was devised by William Sturgeon,[28] and is de-

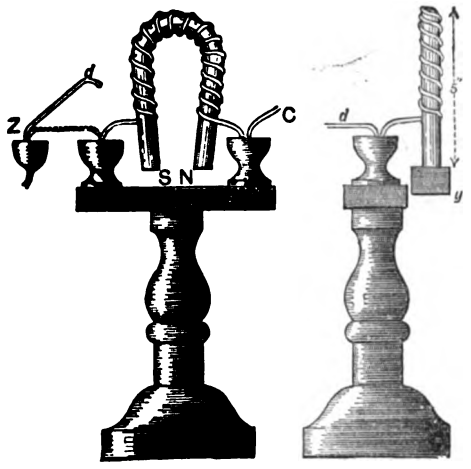
[28] William Sturgeon, the inventor of the electro-magnet, was born at Whittington, in Lancashire, in 1783. Apprenticed as a boy to the trade of a shoemaker, at the age of nineteen he joined the Westmoreland Militia, and two years later enlisted into the Royal Artillery, thus gaining the chance of learning something of science, and having leisure in which to

Digitized by Google

scribed by him in the Paper which he contributed to the *Proceedings* of the Society of Arts in 1825, accompanying a set of improved apparatus for electro-magnetic experiments.[29] Amongst this set of apparatus are two electro-magnets, one of the horseshoe shape (Figs. 1 and 2) and one a straight bar (Fig. 3). It will be seen that the former figures represent an electro-magnet consisting of a bent iron rod about one foot long and half an inch in diameter, varnished over and then coiled with a single left-handed spiral of stout uncovered copper wire of 18 turns. This coil was found appropriate to the particular battery which Sturgeon preferred, namely, a single cell containing a spirally enrolled pair of zinc and copper plates of large area (about 130 square inches) immersed in acid; which cell, having small internal resistance, would yield a large quantity of current when connected to a circuit of small resistance. The ends of the copper wire were brought out sideways and bent down so as to dip into two deep connecting cups, marked Z and C, fixed upon a wooden stand. These cups, which were of wood, served as supports to hold up the electro-magnet, and having mercury in them, served



FIGS. 1 and 2.—Sturgeon's First Electro-magnet.

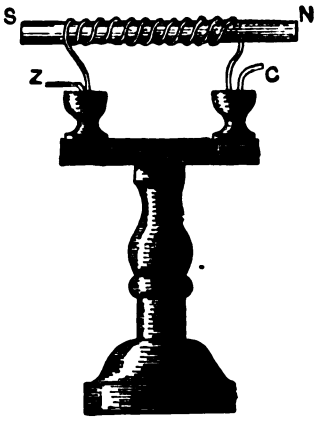


FIG. 3.—Sturgeon's Straight-Bar Electro-magnet.

also to make good electrical connection. In Fig. 2 the magnet is seen sideways, supporting a bar of iron, *y*. The circuit was completed to the battery through a connecting wire, *d*, which could be lifted out of the cup Z, so breaking circuit when desired, and allowing the weight to drop. Sturgeon added in his explanatory remarks that the poles N. and S. of the magnet will be reversed if you wrap the copper wire about the rod as a right-handed screw, instead of a left-handed one, or, more simply, by reversing the connections with the battery, by causing the wire that dips into the Z cup to dip into the C cup, and *vice versâ*. This electro-magnet was capable of supporting 9lb. when thus excited.

Fig. 3 shows another arrangement to fit on the same stand. This arrangement communicates magnetism to hardened steel bars, as soon as they are put in, and renders soft iron within it magnetic during the time of action; it only differs from Figs. 1 and 2 in being straight, and thereby allows the steel or iron bars to slide in and out.

For this piece of apparatus and other adjuncts accompanying it, all of which are described in the Society's "Transactions" for 1825, Sturgeon was awarded the Society's silver medal and a premium of 30gs. for his labours. The apparatus was deposited in the museum of the Society, which therefore might be supposed to be the proud possessor of the first electro-magnet ever constructed. Alas for the vanity of human affairs! The Society's museum of apparatus has long been dispersed, this priceless relic having been either made over to the now defunct Patent-office Museum, or knocked down under the hammer of the auctioneer for a few paltry halfpence.

Sturgeon's first electro-magnet, the core of which was only about 7oz., was able to sustain a load of 9lb., or about 20 times its own weight. At the time it was considered a truly remarkable performance. Its single layer of stout copper wire was well adapted to the battery employed, a single cell of Sturgeon's own particular construction having a surface of 130 square inches, and therefore of small internal resistance. Subsequently, in the hands of Joule, the same electro-magnet sustained a load of 50lb., or about 114 times its own weight. Writing in 1832 about his apparatus of 1825, Sturgeon used the following magniloquent language:—

"When first I showed that the magnetic energies of a galvanic conducting wire are more conspicuously exhibited by exercising them on soft iron than on hard steel, my experiments were limited to small masses—generally to a few inches of rod iron about half an inch in diameter. Some of these pieces were employed while straight, and others were bent into the form of a horse-shoe magnet, each piece being encompassed by a spiral conductor of copper wire. The magnetic energies developed by these simple arrangements are of a very distinguished and exalted character, as is conspicuously manifested by the suspension of a considerable weight at the poles during the period of excitation by the electric influence.

"An unparalleled transiliency of magnetic action is also displayed in soft iron by an instantaneous transition from a state of total inactivity to that of vigorous polarity, and also by a simultaneous reciprocity of polarity in the extremities of the bar—versatilities in this branch of physics for the display of which soft iron is pre-eminently qualified, and which by the agency of electricity become demonstrable with the celerity of thought, and illustrated by experiments the most splendid in magnetics. It is, moreover, abundantly manifested by ample experiments, that galvanic electricity exercises a superlative degree of excitation on the latent magnetism of soft iron, and calls for its recondite powers with astonishing promptitude, to an intensity of action far surpassing anything which can be accomplished by any known application of the most vigorous permanent magnet, or by any other mode of experimenting hitherto discovered. It has been observed, however, by experimenting on different pieces selected from various sources, that, notwithstanding the greatest care be observed in preparing them of a uniform figure and dimensions, there appears a considerable difference in the susceptibility which they individually possess of developing the magnet powers, much of which depends upon the manner of treatment at the forge, as well as upon the natural character of the iron itself.[30]

"The superlative intensity of electro-magnets and the facility and promptitude with which their energies can be brought into play, are qualifications admirably adapted for their introduction into a variety of arrangements in which powerful magnets so essentially operate, and perform a distinguished part in the production of electro-magnetic rotations; whilst the versatilities of polarity of which they are susceptible are eminently calculated to give a pleasing diversity in the exhibition of that highly interesting class

pursue his absorbing passion for chemical and physical experiments. He was forty-two years of age when he made his great, though at the time unrecognised, invention. At the date of his researches in electro-magnetism he was resident at 8, Artillery-place, Woolwich, at which place he was the associate of Marsh, and was intimate with Barlow, Christie, and Gregory, who interested themselves in his work. In 1835 he presented a Paper to the Royal Society containing descriptions, *inter alia*, of a magneto-electric machine with longitudinally-wound armature, and with a commutator consisting of half discs of metal. For some reason this Paper was not admitted to the *Philosophical Transactions*. He afterwards printed it in full, without alteration, in his volume of "Scientific Researches," published by subscription in 1850. From 1836 to 1843 he conducted the *Annals of Electricity*. He had now removed to Manchester, where he lectured on electricity at the Royal Victoria Gallery. He died at Prestwich, near Manchester, in 1850. There is a tablet to his memory in the church at Kirkby Lonsdale, from which town the village of Whittington is distant about two miles. A portrait of Sturgeon in oils, and said to be an excellent likeness, is believed to be still in existence; but all inquiries as to its whereabouts have proved unavailing. At the present moment, so far as I am aware, the scientific world is absolutely without a portrait of the inventor of the electro-magnet.

[29] *Trans.* Society of Arts, 1825, XLIII., p. 38.

[30] "I have made a number of experiments on small pieces, from the result of which it appears that much hammering is highly detrimental to the development of magnetism in soft iron, whether the exciting cause be galvanic or any other. And although good annealing is always essential, and facilitates to a considerable extent the display of polarity, that process is very far from restoring to the iron that degree of susceptibility which it frequently loses by the operation of the hammer. Cylindric rod iron of small dimensions may very easily be bent into the required form, without any hammering whatever; and I have found that small electro-magnets made in this way display the magnetic powers in a very exalted degree."

Digitized by Google

of phenomena, and lead to the production of others inimitable by any other means."[31]

Sturgeon's further work during the next three years is best described in his own words :—

"It does not appear that any very extensive experiments were attempted to improve the lifting power of electro-magnets, from the time that my experiments were published in the 'Transactions of the Society of Arts, &c.,' for 1825, till the latter part of 1828. Mr. Watkins, philosophical instrument maker, Charing-cross, had, however, made them of much larger size than any which I had employed, but I am not aware to what extent he pursued the experiment.

"In the year 1828, Prof. Moll, of Utrecht, being on a visit to London, purchased of Mr. Watkins an electro-magnet weighing about 5lb.—at that time I believe the largest which had been made. It was of round iron, and about 1in. in diameter, and furnished with a single copper wire twisted round it 83 times. When this magnet was excited by a large galvanic surface, it supported about 75lb. Prof. Moll afterwards prepared another electro-magnet, which, when bent, was 12½in. high, 2½in. in diameter, and weighed about 26lb. ; prepared like the former with a single spiral conducting wire. With an acting galvanic surface of 11 square feet, this magnet would support 154lb., but would not lift an anvil which weighed 200lb.

"The largest electro-magnet which I have yet [1832] exhibited in my lectures weighs about 16lb. It is formed of a small bar of soft iron, 1½in. across each side ; the cross piece, which joins the poles, is from the same rod of iron, and about 3¾in. long. Twenty separate strands of copper wire, each strand about 50ft. in length, are coiled round the iron, one above another, from pole to pole, and separated from each other by intervening cases of silk ; the first coil is only the thickness of one ply of silk from the iron ; the

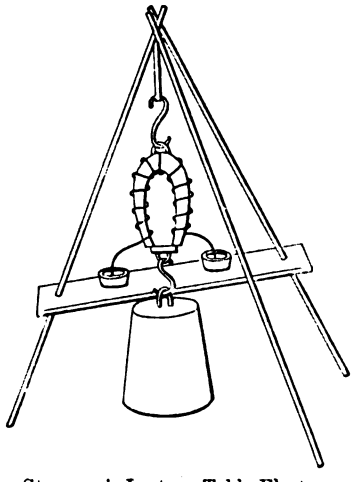

Fig. 4.—Sturgeon's Lecture Table Electro-magnet.

twentieth, or outermost, about half-an-inch from it. By this means, the wires are completely insulated from each other without the trouble of covering them with thread or varnish. The ends of wire project about 2ft. for the convenience of connection. With one of my small cylindrical batteries, exposing about 150 square inches of total surface, this electro-magnet supports 400lb. I have tried it with a larger battery, but its energies do not seem to be so materially exalted as might have been expected by increasing the extent of galvanic surface. Much depends upon a proper acid solution ; good nitric or nitrous acid, with about six or eight times its quantity of water, answers very well. With a new battery of the above dimensions and a strong solution of salt and water, at a temperature of 190° F., the electro-magnet supported between 70lb. and 80lb., when the first 17 coils only were in the circuit. With the three exterior coils alone in the circuit, it would just support the lifter, or cross-piece. When the temperature of the solution was between 40deg. and 50deg., the magnetic force excited was comparatively very feeble. With the innermost coil alone, and a strong acid solution, this electro-magnet supports about 100lb. ; with the four outermost wires about 250lb. It improves in power with every additional coil until about the twelfth but not perceptibly any further ; therefore, the remaining eight coils appear to be useless, although the last three, independently of the innermost seventeen, and at the distance of half-an-inch from the iron, produce in it a lifting power of 75lb.

"Mr. Marsh has fitted up a bar of iron much larger than mine, with a similar distribution of the conducting wires to that devised and so successfully employed by Prof. Henry. Mr. Marsh's electro-magnet will support about 560lb. when excited by a galvanic battery similar to mine. These two, I believe, are the most powerful electro-magnets yet produced in this country.

"A small electro-magnet, which I also employ on the lecture table, and the manner of its suspension, is represented by Fig. 4, Plate VI. The magnet is of cylindric rod iron, and weighs 4oz. ; its poles are about a quarter of an inch asunder. It is furnished with six coils of wire, in the same manner as the large electro-magnet before described, and will support upwards of 50lb.

"I find a triangular gin very convenient for the suspension of the magnet in these experiments. A stage, A A, of thin board, supporting two wooden dishes, C and Z, is fastened, at a proper height, to two of the legs of the gin. Mercury is placed in these vessels, and the dependent amalgamated extremities of the conducting wires dip into it—one into each portion.

"The vessels are sufficiently wide to admit of considerable motion of the wires in the mercury without interrupting the contact, which is sometimes occasioned by the swinging of the magnet and attached weight. The circuit is completed by other wires, which connect the battery with these two portions of mercury. When the weight is supported as in the figure, if an interruption be made by removing either of the connecting wires, the weight instantaneously drops on the table. The large magnet I suspend in the same way on a larger gin ; the weights which it supports are placed one after another on a square board, suspended by means of a cord at each corner from a hook in the cross piece, which joins the poles of the magnet.

"With a new battery, and a solution of salt and water, at a temperature of 190°F., the small electro-magnet (Fig. 3) supports 16lb."

In 1840, after Sturgeon had removed to Manchester, where he assumed the management of the "Victoria Gallery of Practical Science," he continued his work, and in the seventh memoir in his series of researches, he wrote as follows :—

"The electro-magnet belonging to this Institution is made of a cylindrical bar of soft iron, bent into the form of a horse-shoe magnet, having the two branches parallel to each other, and at the distance of 4 5in. The diameter of the iron is 2 75in. ; it is 18in. long when bent. It is surrounded by 14 coils of copper wire, seven on each branch. The wire which constitutes the coils is $\frac{1}{12}$th of an inch diameter, and in each coil there are about 70ft. of wire. They are united in the usual way with branch wires, for the purpose of conducting the currents from the battery. The magnet was made by Mr. Nesbit. . . . The greatest weight sustained by the magnet in these experiments is 12¼cwt., or 1,386lb., which was accomplished by 16 pairs of plates, in four groups of four pairs in series each. The lifting power by 19 pairs in series was considerably less than by 10 pairs in series ; and but very little greater than that given by one cell or one pair only. This is somewhat remarkable, and shows how easily we may be led to waste the magnetic powers of batteries by an injudicious arrangement of its elements."[32]

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *August* 29, 1890.

The Board of Electrical Control.—Matters electrical are somewhat at a standstill just at present. The Board of Electrical Control has settled down to business again, and its meetings are enlivened by the usual obstruction policy of Mayor Grant. At the last meeting it was found that one of the electric light companies had been laying conduits, for which a permit is required, for several blocks, under the guise of subsidiary docks, for which no permit is required, and the Mayor thereupon waxed wrathful.

Meeting of the American Association for the Advancement of Science.—The meeting of the American Association for the Advancement of Science, at Indianapolis, just completed, did not bring out any Papers of commanding importance. They were, as usual, rather theoretical than practical in character, and only one of them had a very marked theoretical interest ; that was a preliminary report on experiments made to determine the effect of a magnetic field on the velocity of light. The results obtained were, however, negative, but the experiments will be tried again with a more powerful field, and it is to be hoped that something definite will be learned.

Digitized by Google

Municipal Opinions on Electric Traction.—An interesting series of questions was recently distributed to the mayors of a considerable number of American cities by one of the Boston daily papers. It bore on the electric street-car system in extensive use throughout this country, and was intended to bring out a clear and frank expression of public opinion concerning their merits. Twenty-seven replies were published a few days since, and in every case the officials addressed were unanimous in declaring the electric street-cars to be a success, to be free from any marked degree of danger, and to have done excellent work in developing outlying districts, and saving valuable time for residents of the suburbs. Public apprehension of the dangers of overhead wires seems to be very ill-founded, and is rapidly dying out. Of course, there is in certain localities a feeling that a storage or conduit system would be more agreeable; but even the large cities are very ready to take electric traction as it is, feeling that it is an enormous benefit to the public, and, like other improvements, should be taken advantage of without waiting for ideal conditions. It is a very singular fact that a number of horses have been killed by the current used on these street-car lines, generally from telephone or telegraph wires breaking and falling across the bare conductor, and thence hanging down over the street. Nevertheless, not a single person has been killed or seriously injured, although the number of shocks reported is considerable. It seems to be definitely established that the 500 volt current now in use cannot, under any ordinary conditions, do serious injury to a human being, while it is apparently pretty clear that horses are considerably more susceptible to shock. Nevertheless, it is found, even in so large a city as Boston, the overhead wires do not produce any considerable amount of apprehension, much less danger.

The Double Carbon Arc Lamp Litigation.—The Brush Company is still pursuing its patent suits vigorously. The double carbon arc lamp patent is the particular subject of legal warfare, and the Brush Company has been uniformly successful in defending it, having obtained several permanent injunctions and other temporary ones. Its suit with the Sperry Company on this issue resulted only in a temporary injunction, and the action is still going on; but in this case the Sperry Company almost immediately retaliated by bringing out what is called a triple carbon lamp, consisting of two parallel round positive carbons of the ordinary type, held rigidly parallel in the same holder, and a single oval negative carbon. The arc, of course, shifts from carbon to carbon perhaps every half hour, but inasmuch as the points of both positive carbons are intensely heated the effect of this shifting is so far modified that very little disturbance to the light is produced. The new form of lamp has a very long life of carbon and gives a uniform and excellent light.

CORRESPONDENCE.

PROF. ELIHU THOMSON'S OSCILLATING METER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your reference to my oscillating meter in your issue of August 15th there are some things which are a little misapprehended, and which I take this occasion to correct.

I would say that the oscillating body is mounted on knife edges, and is balanced so accurately that the meter may be thrown out of level without disturbing the position of the oscillating portion. In regard to the sparking on shifting the current from one fine wire coil to the other, I can state that I find very little difficulty on that score on account of the very high resistance given to the coils, and the very small current which traverses them. I use an amalgamated wire dipping into small mercury cups. There are no dash-pots in the meter, as you seem to infer. I suppose you have mistaken the mercury cups for dash-pots. The switching from one to the other is accomplished quickly by a small overbalanced lever, or, better yet, by a lever carrying an iron mass moving in a magnetic field, adjusted to cause it to move quickly from side to side, as impelled by the main oscillating body. The magnetic effect in this case permits large changes in the level of the meter to be made without affecting the throw.

You are quite right in saying that the arangement is rather a reciprocating electric motor than an electric clock. I would here say, further, that the meter has been chiefly tested on alternating currents, and that its registry is closely proportional to the load in current and not affected by the square of the current. The most remarkable feature of this meter, as it has been worked, is the extremely small energy which it can be made to run by—an amount so small, indeed, that it is entirely negligible. In one of the meters constructed, it is under five watts, with a load of 40 lamps, each consuming about 50 watts, and yet the meter was sensitive to one lamp. Another merit of the meter is that, with the requisite machinery, it can, without doubt, be made very cheaply.—Yours, &c.,

ELIHU THOMSON.

Lynn, Mass., August 27, 1890.

PROF. ELIHU THOMSON'S NEW ALTERNATING MACHINE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have noticed in your issue of August 15th a description of a dynamo machine designed by myself, printed alongside one of a machine designed by Mr. Mordey, and upon which you make certain editorial comments.

In the first place I must begin by stating that the description of my machine which you have copied is one based upon the United States Patent specification as it appeared, and that I am not in any way responsible for any comments which may have been made upon the machine as there described. If this be borne in mind you will see that the case will clear itself up somewhat. It happens to be the custom with American papers to take patent specifications as they issue and make descriptions from them, calling attention to matters found therein which in the Editor's judgment may be proper for the information of the readers. It was in this way that my electric welding inventions were first noticed under my name a number of months before I had written and published anything in connection with the matter.

Now, in regard to forms of dynamo machine, I think it can be truly said that innumerable suggestions have been made either publicly or privately covering the widest possible modifications of this important structure. To determine the question of originality in these cases it would be necessary to bring together in a sort of general concourse all inventors and designers of such machinery and compare the dates of their inventions and designs, hundreds of which I know to exist without publication. Some of the suggested forms have subsequently taken important positions in the art, frequently being reinvented or redesigned by the same or by other parties working upon this general subject. So far as I am personally concerned, I wish it to be understood that I desire to claim nothing to which I would not be justly entitled, and I should prefer to err in claiming less. I have the greatest respect for Mr. Mordey and others who have done exceedingly valuable work in the electric field; but I cannot agree with you at all in the opinion put forward in your editorial notes that the machine designed by me is a good deal behind that of the English one which you publish with it. On the contrary, the case is much the other way, and if both machines were built and run my opinion on the subject would be found to be correct. I need scarcely state that my opportunities for gaining experience in this and kindred matters have been, to say the least, considerable.

The direction of the lamination in the Mordey machine is undoubtedly at right angles to the direction which the dividing surfaces should properly take; and the fact that the iron carrying the armature coils is constantly under the influence of the magnetising field coil, and, therefore, tends to change its magnetism but little, is against working at high inductions. I need scarcely point out that the construction is a somewhat difficult one, the published figures, however, not showing the complete machine, but only its electrical elements.

In regard to the feature which is claimed for the English design, *i.e.*, that "no back volts are set up in the field coil," I

Digitized by Google

would simply say that I have built a numbe of machines of the type you describe under my name, and found no evidence of any back electro-motive force in the field coils. In fact, if there were any back electro-motive force, it would also be accompanied by a forward electro-motive power due to the changes of magnetism in the field, and these effects would compensate each other. I would also call attention to the fact that while the figures you have published show the armature bobbins wound on projections, I have operated a machine perfectly well with bobbins without projections, in which case the induced bobbins, or what corresponds to the armature bobbins, were supported in the interior of a simple laminated ring. You will therefore see that the design may include a magnetic circuit, to which but few objections may be raised.

I am not ready to publish tests of any machines of the type referred to, as such tests are not completed. I may say, however, that I found that I could obtain an output of 75,000 watts from a machine weighing (including a heavy bedplate) 8,950lb., with indications of an efficiency not inferior to that of the best direct current machines. There is a remarkable absence of heating, showing the magnetic losses to be very small.

As a matter of interest in connection with this machine, I would add that a smaller machine has been constructed, from which it is easy to obtain a rate of alternations of over 5,000 per second or a periodicity of 2,500, to be used for experimental purposes. The machine gives 1,000 volts between its terminals. A curious fact is that arcs produced by rates of alternations so high as this are not so liable to extinction as those in which slower alternations are employed, and they are accompanied by a very high and a rather powerful musical note, the pitch of which, of course, corresponds with the periodicity. It is probable that the machine, in addition to other uses, will be employed to determine the physiological effect of such high rates of alternations.—Yours, &c., ELIHU THOMSON.

Lynn, Mass., August 27, 1890.

TESTS OF SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of September 5th appears a translated account of some tests of secondary cells as constructed by various Continental makers. The results obtained are extremely interesting, but their value is considerably discounted by the fact that one of the most important details of such tests, viz.—the rates at which the respective cells were charged and discharged, are not given; and it is impossible, therefore, to estimate from the particulars published the comparative utility and efficiency of the various types.

I would like also to point out that tests of secondary cells made for the purpose of proving the utility of various forms are utterly worthless, unless the cells have been subjected to daily charges and discharges for a period of at least six months. —Yours, &c., FRANK KING.

London, E.C., Sept. 8, 1890.

[If our correspondent will again look at the translation in question he will see that the value of the charging and discharging current is given in every case except one, viz., that of the Tudor accumulators. We quite agree with the remarks contained in the last paragraph, and the publication of the results of the first six months' working of the Chelsea Electricity Supply Company's batteries would be invaluable. ED. *E.*]

MR. PREECE'S PAPER ON "THE SANITARY ASPECTS OF ELECTRIC LIGHTING."

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—I have just had brought to my notice the report of the above Paper in your issue of the 29th, in which Mr. Preece is represented to have stated that the "efficiency of a '*high-pressure*' system of distribution which he calls '*the direct current battery is 50 per cent.*'; that '*a company working on the high-pressure battery system secured only 29 per cent.*'; lastly, he refers to '*the high-pressure battery system in Chelsea.*'"

May I secure equal publicity for the following statement, which Mr. Preece will, I am sure, be glad to endorse, namely: That the Chelsea Electricity Supply Company, which obtained, and works under, what is well known as the Chelsea Act of 1886, and which now supplies current under statutory powers in Chelsea and part of Kensington, in forty-one streets, squares, &c., of these parishes—does not use any method of supply that can be called the *high-pressure direct-current battery system*, and that its efficiency is certainly *over 75 per cent.*, and not *50 or 29 per cent.*, as the report of his Paper may be fairly supposed to imply.—Yours, &c., C. E. WEBBER, Maj.-General.

Leeds, Sept. 7, 1890.

THE ELECTRIC LIGHT AT BATH.

TO THE EDITOR OF THE ELECTRICIAN.

SIR,—Having recently had a run down to Bath, and having seen the most unsatisfactory burning of the arc lamps on Saturday, August 30th, and the fiasco of August 31st, I not unnaturally turned to my *Electrician* this week expecting you would have something to say about it. Thinking you might not be in possession of the facts, I beg to forward such information as I obtained.

The arc lamps were most unsteady between 10 and 11 on Saturday, August 30th, the cause being that the engineer in charge had allowed his steam to drop from 150 to 108lb. The dynamos had slowed down until the blowing arrangement (Thomson-Houston) ceased to work, the sparks flashing round the commutator.

On Sunday evening August 31st, all the incandescent lamps were out from 8 p.m. for the remainder of the evening. Forty-eight of the public arcs were out from 8.45 until 12, and all the arc lamps (some 83) were out from 11 to 12. I met the police going into the station to report "lamps out," and went in with them. The station was in a state of semi-darkness, the men having to work with two smoky paraffin lamps and three or four candles. The stoppage was due to an inability to get water into the boilers. The injectors had been in a general state of uselessness for a month or six weeks. They were depending entirely on one little donkey-pump for their feed-water, and it had been stopped by a piece of spun yarn about the size of your fist getting jammed in the suction-pipe. There was no rose fitted to the end of that suction-pipe, and no covers to the tanks from which the feed-water was drawn.

I noticed on walking round that the whole of their high-tension fuses and switches are entirely unprotected, fitted within a few feet of the ground, and only a few inches from the boys, aged 14 to 16, who are employed to work the rheostat in the exciting circuit.

I think such carelessness and its results have been sufficiently disastrous to call for condemnation.—Yours, &c.,

CHARLES POWELL.

38, St. Martin's-street, Leicester-square, London, W.C., September 6, 1890.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

August 7, 1890.

12,381. A. L. SHEPARD. London. An improved device for facilitating the connection and disconnection of electrical conductors.

12,383. A. L. SHEPARD. London. Improvements relating to electric lamps, and to apparatus connected therewith.

August 8, 1890.

12,394. W. P. ODHIM. Portarlington. Composite brushes for electric lighting.

12,422. J. JENG. London. An electric pendulum for firing ship's guns.

12,439. A. L. SHEPARD. London. Improvements in and relating to electric lamps or lighting apparatus.

12,440. A. A. DAY and H. J. DOWSING. London. Portable combination electrical testing set.

August 9, 1890.

12,475. E. TAUSSIG. London. Improvements in electrical smelting.

12,504. E. P. ALLAM. London. Improvements in holders for incandescent electric lamps.

August 11, 1890.

12,532. S. Pitt. London. Improvements in electric lighting (Sautter, Harlé, and Co., France).

12,562. W. O. Stanley. London. New or improved means or apparatus for generating electricity.

12,566. E. C. Russell. London. Improvements in electric arc lamps.

August 12, 1890.

12,628. H. E. Fowler. London. Improvements relating to the welding of metals by electricity.

12,634. T. M. Foote. London. Improvements in dynamo electric machines or electric motors.

August 13, 1890.

12,713. S. Ziani de Ferranti. London. Improvements in electric mains and in apparatus used in their manufacture.

August 14, 1890.

12,737. J. M. M. Munro. Glasgow. Improvements in appliances for conducting electric currents.

12,763. E. Buffet. London. Improvements in or relating to electrical batteries.

12,777. R. H. Gould and T. Gottschalk. London. Improved safety connections or couplings for electric conductors.

12,784. R. W. James. London. Improvements in underground conduits and conductors for electrical transmission (William John Brewer, United States).

August 15, 1890.

12,819. S. D. Williams. Newport. Improvements in column type printing instruments operated electrically, for telegraphic and other purposes, and in conductors therefor, which latter are also applicable for telephonic and electric transmission generally.

12,827. H. J. Hilton. London. Improvements in armatures for dynamo-electric machines.

12,830. H. H. Lake. London. Improvements in secondary batteries, and electrodes therefor. (George Augustine Johnson and Sidney Latham Holdrege, United States.)

12,832 E. Wilson. London. An electrical watt meter; also applicable as an ammeter or voltmeter.

ARTISTIC ELECTRIC LIGHT FITTINGS.

In a recent issue, reference was made to a number of admirably executed catalogues of artistic electric light fittings issued by several well-known firms of fittings makers. We have now received copies of new catalogues issued by other firms, to which we would call our readers' attention. As in our previous article, we would specially refer to the taste and originality displayed in the designs, and to their moderate cost. We cannot claim to have at all exhausted the books, nor have we yet received catalogues issued by several other firms of eminence in this department of electrical industry, but which we hope to receive for notice at an early date.

Messrs. Faraday and Son.—An artistically illustrated catalogue of 62 large folio pages has been issued this week by Messrs. Faraday and Son, in which is given a most varied array of artistic designs. We may specially note No. 63, a beautifully-chased bracket; No. 81, a silvered picture reflector for sideboard or walls; No. 67, a chased Louis XVI. sconce; Nos. 42 and 16, brackets and lanterns; No. 144, an iced-glass pine pendant; No. 162, a richly-cut bowl pendant, with chased mounts; No. 1,611, a handsome dining-room centre pendant, with chased mounts and fringe and gauze underscreen; No. 36, a beautiful electrolier with knurled stem and chased leafage; No. 171, a richly-chased corona, with cupids and shells; No. 8, an Italian Rénaïssance table standard; No. 25, a "Medusa" table standard. The catalogue also contains some very fine registered designs of classical figures, including "Iris," "Bacchus," "Cupid," and "Mercury." Only a few of the figures given in the catalogue are enumerated, and we recommend our readers to obtain a copy of the book, which is well printed and neatly bound. Messrs. Foraday and Sobs' show-rooms are situate at Berners-street, Oxford-street, London, W.

Messrs. Strode and Co.—We have recently received a catalogue from this firm, who are well known as manufacturers of high-class art metal work. A number of suspension lights, brackets, &c., are displayed, as well as many examples of really choice work, of which we may enumerate numbers 5,624, 5,164, 5,393, 5,392, and 4,961. No. 5,393 is a fifteen-light electrolier with two tiers of arms, enwrought with hammered leafage and flowers, fluted and repoussé stem and ceiling plate, and is very effective. Messrs. Strode and Co.'s show-rooms are situate at Osnaburgh-street, W.C., and St. Paul's Churchyard, E.C.

Messrs. O. Berend and Co.—The elaborate book of samples sent by this firm contains illustrations of a vast number of artistic electric light fittings in Saxonian bronze ware, for which Messrs. O. Berend and Co. are the agents in this country. Numbers 2,063, 2,064, 2,115, 2,315, 2,130, 2,141 and 2,142 may be described as suitable for heavy wear; whilst numbers 2,005, 2,091, 2,111, 2,120, 2,123, 2,143, are of most elaborate design. Many of the examples in the book are combination fittings for gas and electric light. The assortment shown is very large, and we understand that a considerable demand has already arisen for the Saxonian Bronze Ware Fittings. A number of suspension lights are illustrated in the book, whilst hall and vestibule lights, conservatory lights, brackets (many of which are very artistic in design), pillar lights (some of these again are in excellent taste), &c., make the specimen book very complete. Messrs. Berend's show-rooms are situate at 61, Fore-street, E.C.

Mr. Richard Crittall.—This gentleman has recently issued his illustrated catalogue of electric light fittings, many of which give evidence of considerable taste. We may select for special mention B 35, A 47, A 3, A 63, C 125 (a seven-light pedestal lamp), A 49, A 50, A 52, A 135, and A 101. The catalogue contains a large variety of brackets, pendants, hall lanterns, and table lamps. The fittings generally are made in wrought iron, copper, brass, and copper and brass combined, and are quoted at extremely moderate prices. A large assortment is on show at Mr. Crittall's show-rooms, 20, Baker-street, London, W.

TRADE NOTES AND NOTICES.

Tenders Wanted.—Mr. J. E. Keirby, Moorfield Villa, Swinton, near Manchester, invites tenders for fitting up a 50-light incandescent electric installation; dynamo and power already fixed.

————.The Corporation of Dublin will, on or before 5 o'clock p.m. on Monday, the 13th day of October next, receive tenders for the electric lighting of streets in the city of Dublin. The contractors will be required to build station, supply, erect, and fix all the necessary plant, machinery, engines, boilers, dynamos, conductors, pillars, &c. The specification, form of tender, and ground plan of site and streets proposed to be lighted, can be had at the office of Mr. Spencer Harty, C.E., Borough Surveyor, City Hall, Dublin. Tenders are to be addressed to Mr. John Beveridge, the Town Clerk, City Hall, Dublin. Further particulars will be found in our advertisement pages.

Removal.—Messrs. C. E. G. Gilbert and Co., Electrical Engineers and Contractors, have removed to larger premises at No. 16, Hanway-street, Oxford-street, W., where they have a spacious show-room and increased facilities for manufacturing.

The Sunbeam Lamp Company (Limited).—We have received from this Company an illustrated card, giving particulars and prices of Sunbeam lamps and lamp-holders, &c. The card includes a table giving the current required for the Sunbeam lamps, and also gives a list of sizes of lamps always in stock.

The Phospher Bronze Company (Limited).—We have received from this Company a new catalogue, giving exhaustive particulars of the manufactures of the firm. The catalogue contains a number of testimonials from large users of the Phosphor Bronze Company's products, and includes the correspondence recently appearing in our contemporary the *Engineer* upon the subject of the durability of phosphor bronze, concluding with a diagram giving the particulars of some interesting tests with Bull's patent metal, which is supplied by the Company.

"Electricity in Every Day Life."—We have received from Messrs. Goolden and Co. a well got-up popular brochure under the above title. The book is profusely illustrated, many of the engravings being of merit. It consists of 24 large octavo pages, and is on sale at the popular price of 1d. A large demand may safely be predicted.

CRICKET.

Eastern Telegraph Company v. Kenneth Anderson and Co.

This match was played at Barnes on Saturday last, and resulted in a victory for the latter firm by 22 runs, after a very enjoyable game. Mr. Kenneth Anderson very kindly offered a bat for the highest scorer on either side, and a ball to the one with the best bowling average. The Eastern Company, who were unfortunately without the services of two or three of their best men, won the toss, but made a bad start, six wickets falling for only 16 runs. Messrs. Cole and Faulkner then by means of very careful batting, carried the score to 37 before the latter was dismissed. The innings closed for 64, Mr. Cole's contribution being 30, which was made in good style. Messrs. Gurney and Jack proved the most successful bowlers, the former securing 3 wickets for 32 runs, and the latter 3 wickets for 12. With only about an hour to play Kenneth Anderson and Co. started batting, with Messrs. Gowenlock and A. Sloper, and from the first over, the former scored 10 runs, and continued to hit in vigorous style until 47 were placed to his credit (thus securing the bat), when he was bowled by Mr. Macmillan. The innings closed for 86, Kenneth Anderson and Co. winning by 22 runs. This result was in a great measure due to Mr. Gowenlock's brilliant display. Mr. Macmillan secured 6 wickets for 29 runs, going very close for the bowling prize. Mr. Cole took 2 wickets for 25, and Mr. R. E. Donaldson 1 for 7 runs. Score :—

COMPANIES' MEETINGS & REPORTS.

Brush Electrical Engineering Company (Limited).

The first annual general meeting of the Brush Electrical Engineering Company (Limited) was held at the Cannon-street Hotel, London, E.C., on Monday, September 8, 1890, to receive the report of the Directors and the accounts to June 30, 1890, and to transact the ordinary business of the Company. Lord Thurlow, F.R.S., presided.

Mr. E. GARCKE (the Manager and Secretary) read the notice calling the meeting, and the report of the Directors was taken as read.

The CHAIRMAN said: Gentlemen, as this is the first time I have had the honour of addressing you at an annual meeting of the Company, I think, perhaps, you will pardon me if I say a few words in explanation of the position which we at present occupy, and describe briefly the financial and other results of the amalgamation. In so doing I take it for granted that you would desire that I should take up as little time as is consistent with what I deem it to be my duty on the present occasion. You will recollect that the statutory meeting of this Company was held on November 25th, and on that occasion it was reported that the reconstruction of the Brush Company—that is to say, its amalgamation with the Australasian and Falcon Companies—had been satisfactorily carried out more or less at that time, still perhaps on paper. But as we stand here to-day that has assumed a practical reality. Then, as regards the reconstruction of the Anglo-American Brush Electric Light Corporation, I think there is very little more to be said beyond what you already know. We have retained, of course, our works in Belvedere-road and other works that we had. We have retained, in fact, everything that we possessed, and in addition we have acquired the valuable assets that you are aware of. New shares were issued for the old shares—that is to say, the old Brush shareholders got new shares in exchange at the agreed-upon rate of three-fifths ordinary, and two-fifths Preference. Then, as regards the Falcon business at Loughborough, I will at a later stage go at some length into a description of what those works consist of. At the present moment it will probably be sufficient for me to say that no time was lost in taking these works over, and that we immediately proceeded to spend what has turned out to be an amount of about £20,000 in erecting new shops to enable us to construct the heavy machines which we are now called upon to turn out. These shops consist chiefly of a foundry and large fitting and erecting shop. I will give you the actual measurements and details of some of these new works a little later. Then, as regards the Australasian Company, you will remember that the original scheme was that we should take over the whole of their business, including their patent rights and stores, and we were to issue to them £45,500 in shares and £500 in cash. Well, negotiations were very protracted in connection with this matter; they were protracted, not on account of the unwillingness of either party to enter into arrangements, but to the practical difficulty of assessing the value of some of the assets. However, these negotiations were satisfactorily conducted, but with a certain modification The modification was, that this Company, instead of taking over their stores and floating assets and liabilities, should take over only their patents and the shares in the Melbourne Company, and agree to issue £31,000 of fully paid-up shares to them in the same proportion as was agreed to in the ordinary and Preference shares—31,000 instead of 45,500. Then there were some subsequent negotiations following upon that, owing to the inability of the Australasian Company at the time to give a good title for everything that had been scheduled. There were one or two matters which we need not describe, matters of no material importance—at any rate, a certain deduction had to be made on that account. The final result was that we took over what I have said, the stores and patents and shares, and shares in the Melbourne Company for £27,500 in shares, in the same proportion as I have already stated—two-fifths in Preference and three-fifths in ordinary shares. Well, I think, perhaps you will allow me to say that which I have already said. There were difficult negotiations, and if it had not been for the conciliatory way in which we were met by the Chairman of that Company, Mr. Van Tromp, and by the liquidators who were carrying out the arrangement, I think the difficulties would have been so great that it might have fallen through; and I consider that that would have been unfortunate. Then, further negotiations are still taking place, because although that is the final result at which we have arrived, further negotiations are still taking place with a view to the Brush Company taking over the whole of their stores. From the first we said, and we adhere to that, that we would not take over their assets and liabilities, and from that decision we have not departed. We have consequently taken over the shares in the Melbourne Company, and practically their stores, and we have taken over their patents and all their business, not only in Australia, but in the Australasian Colonies. It has opened up for us an enormous field for business, and one which will require very considerable energy on our part to do justice to. To enable us to grasp more fully the position that we shall henceforth occupy in regard to that part of the world, we requested Captain Rowan, who was the very efficient manager of that Company for some years past, to come from Australia and advise us on all points. He came here, and we had lengthy meetings, and entered, I think, into every point that was at issue; and we have finally made satisfactory terms engaging him for a number of years, and he has gone out again to look after our interests and take charge of our business. The final outcome of the issue of shares on that amalgamation is as follows:—We have issued to the Anglo-American Brush shareholders 196,942 of ordinary shares, and 104,628 of Preference shares. We have issued to the Falcon Company 33,300 of ordinary shares, and 22,200 of Preference shares. We have issued to the Australasian Company 16,500 of ordinary shares, and 11,000 of Preference shares. The balance of capital which appears in the report and balance-sheet has been raised by subscriptions, making in all an additional £24,192 in ordinary shares, and £164 of Preference shares. Well, I think when you look at those figures, and when you see how they are represented in the balance-sheet, and see that on all these transactions we have only £256. 10s. of outstanding arrears, you will agree with me that the result is that the whole business has been transacted in a satisfactory manner. These arrears are being collected in due course, and they will very shortly disappear from the balance-sheet. Now I come to the Debenture issue. The Debentures of £75,000 which the new Company has issued could, of course, be issued only with the consent of the existing Debenture holders of the old Brush Company. We had to get them to consent; that is to say, we had to get them to convert their Debentures for new Debentures, or else we had to pay them off. The long and short of it was that they met us in a friendly spirit; they had perfect confidence in the value of the property, and I may say that the charge on these great properties is very light indeed. And all the Debenture holders agreed to take the new Debentures for the old, with the exception of £7,900, and that amount of Debentures had to be purchased by the liquidators of the old Company, and they are still in our hands, forming a valuable security for any shareholder who likes to get 6 per cent. for his money. It is a valuable security, and applications to the Secretary will meet with response. I think it is very desirable to keep these Debentures amongst ourselves for reasons which I need not go into, because they are perfectly obvious; and I strongly urge the shareholders of this Company to absorb that £7,900 of Debentures. We will retain them in our hands for that purpose. There is no difficulty in disposing of them, and there are plenty of brokers in the City asking for them already. I should like to say a few words on the general efficiency of the combined works we now possess. The Brush Works in the Belvedere-road are very perfect, and the Falcon Works by themselves for the class of work they turn out are extremely satisfactory; but the combination of the two for carrying on the electrical engineering business as we do now, places us in an unrivalled position. The situation of these Falcon Works is everything that could be desired. It is just far enough out of London, in the Midlands, to enable us to obtain the best, cheapest, and most skilled labour, together with the cheapest fuel; and in addition to that it is on one of the main lines of railway, one of the great arteries of the country, and we have the Loughborough station at our doors, with sidings actually into our works. So I think from every point of view the Falcon Works are an eminently satisfactory purchase. As I have said before, taken in conjunction with the Lambeth Works, they will enable us to distribute our heavy and light works—our light, fine work, of which we do a great deal—we can manufacture them more satisfactorily, I think, in these shops that we have in the Belvedere-road. The heavy castings and larger class of work and machinery no doubt we can make to very great advantage, as I may explain later, at the Falcon Works as compared with what we could do elsewhere. These Falcon Works contain, briefly, about seven acres of freehold land. It is many times bigger than the works we have in the Belvedere-road. Roughly speaking, about two-thirds of the space is built over with old shops, which existed before we took over the works, and those we have built subsequently for about £20,000. I think it would be highly satisfactory to any shareholder who takes an interest in these things, if he can find time and opportunity to go down, to go and look at these things for himself. The opinion he will carry away will be eminently satisfactory, and he will come to the conclusion that the purchase is a wise one. I have already said that it places us in a position in conjunction with the Belvedere works to manufacture for ourselves, and to take the immediate profits on a class of work we were not able to manufacture before. The lifting power provided at these new works is very full, as it must be for the heavy class of machines we are turning out now. I should now like to say a few words with reference to the expenses to which we have been put and to the profits which we have earned. The profits that we have earned appear in the balance-sheet, and you can judge for yourselves. As regards the charges for expenses, I know that shareholders when they get a balance-sheet of this description, although it is the first, and cannot fairly be compared with reports and balance-sheets of the Brush Company that have preceded it, involuntarily contrast the figures and see how they compare with the standing charges of the previously existing company, of which they were shareholders. You will find that the standing charges have undoubtedly slightly increased, and I am bound to say it could not be otherwise, when you consider the vast body of work we have done, the expenses of amalgamation and the expenses of having to run these additional works. The Brush standing charges of 1888 were £11,131, and those for the past year amounted to about £16,000. I do not know that I can hold out very much hope of these standing charges being much reduced in the uture. Of course, we shall do what we can, but I am bound to say that I do not hope they will be much reduced in the future. Our business is increasing daily, and if it continues to increase the general charges must

Digitized by Google

increase also. This is from no want of care; it is one of the inseparable results of increasing business. Then as regards the liquidators' balances and suspense accounts which figure for the small sum of £9,979, I think you may make your mind quite easy on that score. There is no less than £7,900 of the £9,900 represented by the Debentures of the old Brush Company, which the liquidators have purchased and hold ready for issue when any demand arises. Then the balance consists of sundry small debts and accounts, so that there is no reason for any feeling of uneasiness in your minds at the sight of that entry in your balance-sheet. Then, there is one other matter which I must allude to—a matter that used to be always before our minds when we simply represented the Brush—and that is litigation. We have pretty well washed our hands of litigation, as you all know, and I think we are all thankful for it. The only remnant is a thing called the King-Brown lawsuit. That, by-the-bye, was a compound-winding action. It was tried in the English Courts, and the decision given in our favour; our patents were upheld, and the result was that every manufacturer in England agreed to pay us tribute on every compound-wound machine. Well, a firm in Edinburgh thought it was worth while to try this case in the Scotch Courts. The Scotch Courts have been known to take a different view from the English Courts, especially in patent cases; and the case was tried in the Edinburgh Courts by those people, King-Brown, who are not very large makers. After a lengthy but not very costly litigation it was decided against us. We naturally appealed to the Court of Session, and we lost the appeal. We then notified our intention of taking it to the highest court of appeal in the Kingdom, the House of Lords, which we are enabled to do. It will not involve a very great expense. I say we were bound to bring it before the House of Lords for two reasons: first, because the English Courts had given it in our favour years ago; and, secondly, to justify our position in having charged and received these royalties from every maker in Great Britain for some years for every compound machine turned out in their shops. That is the last bit of litigation we had when we used to meet as members of the Brush Company. That will be wiped out, I suppose, shortly after the House of Lords meets. It is impossible to say what the decision may be. The House of Lords may decide to uphold the finding of the English Courts, or it may decide to uphold the Scotch Courts. If we gain, we shall continue a valuable source of revenue as royalty from these machines. Now I should like to mention the policy we have pursued in regard to a matter of importance, certainly, I think, second to none in electrical work, and that is with regard to obtaining Provisional Orders. You know the Board of Trade grant Provisional Orders, which have to be confirmed by Parliament. Well, you know that all these electrical companies who are competitors, have largely applied for these Provisional Orders, and we should have been left out in the cold if we had not done the same thing. But we have, as a general rule, confined our applications to places we had interests to support; for instance, such as Bournemouth and Cardiff, and places of that sort, where we had large interests involved; and we have as a result of these applications already acquired, as you know, the Bournemouth order; and we have acquired, which is no trifling matter, one-third of the City lighting. The City has been divided into three great districts. We have acquired the central one, which is certainly not second in importance to any of the others. The magnitude of that Provisional Order is great; but we have to carry it out under very favourable conditions, under strict terms as to dates, but still not at all impossible terms. We have, for instance, some months before us before we are compelled to commence work. After that the work has to be executed with reasonable delays, but with a lapse of time which I have no doubt will enable us to satisfactorily meet all the requirements of the case. The cost of carrying out the Provisional Order will, I suppose, amount to something like £300,000. That is a very large item of business. Of course, we do not suppose that we are going to do all that business for nothing. We think it a very valuable asset indeed, and we intend to proceed with it with all the care we can command. We have on our Board and in our offices most experienced men dealing with electrical and engineering work—the engineering work is almost as important as the electrical work—and they combine to the fullest extent the knowledge and experience of both branches of the business. We shall spare no time or labour, or, in fact anything, to carry out the Provisional Order in such a way as will redound to the credit of this Company, and also be productive, I venture to anticipate, of very considerable profit. I think I have very little more to say. I have, perhaps, spoken already at greater length than I had any business to do, but really I could enlarge upon a great many points for an almost unlimited time. I think, however, the most satisfactory plan would be to leave you to put any questions that you like on any particular points that may occur to you on which I have not given you such information as you might desire. I think I will only now, with your permission, before moving the adoption of the report and balance-sheet, say a few words about the dividend and the accounts. Well, you see the profit and loss account shows a gross profit of £36,698, and after deducting all standing charges, maintenance of plant and buildings, and interest on Debentures, there remains a balance of £14,235. Out of that it is proposed to apply £625 to reduction of preliminary expenses, £500 to reduction of Provisional Orders account, and £3,000 to reduction of property, patents, and goodwill account, to meet depreciation under these heads. I think you will find that will leave a balance of £10,426 to appropriate. Of course, out of that has to come the interest due on the Preference shares for the six months from February 10th last up to the present time. That comes to £3,505. We propose then to pay the dividend on the Preference shares, and to carry forward, after writing off the sums I have already mentioned a balance of £2,796 to our next account. But though we have chosen to recommend the writing off of certain amounts, I hardly think myself that it is necessary. For instance, we are writing off £500 on account of the Provisional Orders. And you might not think it necessary to write off £3,000 from our property account. You might not think it necessary to write off in the first year a proportion of our preliminary expenses, which only amounted to about £1,800. We propose, however, to write off one-third of that amount this year. It is no doubt very proper to write off these sums—and I hope you will agree to our recommendations—but you are not compelled to do so, and you will find in that event £6,800 available for dividend on your ordinary shares. That would represent a dividend on only 11 months' working of 3 per cent., after paying the fixed dividend on the Preference shares, the Debenture charges, and other legitimate charges, and without taking into consideration any profits accruing from the Australasian Company. I say that is not a very bad show for the first year of these three amalgamated companies. It is possibly within the recollection of some of you that when I stood here at this time last year I said that I should not have the courage to come before you again, unless we found ourselves in the satisfactory position which I prophesied. Well, I venture to hope that you will regard that pledge as being practically fulfilled. The dividend is there if you like to take it, but we do not recommend you to take it. We would rather you appropriated it in the way suggested in the balance-sheet. We feel sure it is necessary for us to occupy in the future a strong financial position as well as a strong manufacturing position; and nobody can occupy a strong financial position in this City of London unless they act on certain well-known and recognised rules. One of these recognised rules is to write off from your patents and property account as much as you can afford every year, and also a portion of other charges which may be of an exceptional character. I say, then, that the lines on which this balance-sheet has been drawn out and approved by our auditors and on which the appropriation scheme has been framed, is one of sound finance, and I think you will do very wisely in accepting it. There is another reason of the first importance why we should occupy a strong financial position. We have this big City contract, with £300,000 looming in the distance. I do not say we have to raise £300,000. Nothing of the kind. The £300,000 that we have to do work to the extent of will be provided for in our shops in the usual way. We shall receive payments on account in proportion as the work may progress; but undoubtedly you cannot enter upon the carrying out of a contract of these dimensions without a certain amount of ready money in hand. Although we have now fair cash balances, a large amount on deposit, and a large amount due to us from trade creditors, and everything in the most satisfactory shape, yet such a large contract as I have mentioned will very probably require some provision to be made for some extra financial assistance of a temporary or permanent character. At least, that is my opinion to-day. I do not mean to say that it is absolutely necessary, or that it will be so; but at any rate you need not be surprised if we have to come before the shareholders or the public or the Debenture holders for further money for the legitimate purposes of business. And, if such an event should occur, it is necessary, of course, that our last balance-sheet, which will be critically examined, should be a thoroughly sound and conservative document. For these reasons I hope you will see your way to accede to the appropriation scheme we have drawn out in the balance-sheet for the past year. The adoption of the report and balance-sheet will be seconded by Mr. Van Tromp, who was the Chairman of the Australasian Company which we have absorbed, and I think he will be able to tell you a great many interesting things connected with this Company. I will therefore not detain you any longer, but beg to move:—

"*That the report of the Directors and statement of account to June 30th last, now presented to the shareholders, be received, and that the same be hereby adopted*" (applause).

Mr. H. B. VAN TROMP seconded the motion, and said that had it not been for the invitation of the Chairman, he would not have desired to address the shareholders that day; but since the Chairman had asked him to speak he would offer just a few remarks, and on his own behalf and that of the other members of the Board, he could give the shareholders this assurance that, so far as they knew, the Company was on the high road to prosperity (applause), and that there was a great prospect of success, and there could be no doubt whatever that when they met at this time next year they would have a far better position of things to place before the shareholders than they did that day.

A VOICE: I hope so.

Mr. VAN TROMP, continuing, said that he had seen the works at Loughborough, and he did not hesitate to say that, for the purpose for which they were destined, there were very few better works in all England. They possessed appliances there which would enable them to do everything in connection with the utilisation of electricity as a motive power in the future. They could turn out anything there, from a common piece of electrical apparatus to a large locomotive or car. They could make anything that they liked. There was nothing in the whole world connected with railway traction that they could not manufacture at Loughborough, and with greater economy. He (the speaker), as they knew, was the late Chairman of the Australasian Company, and when that business was taken over by the Brush Company, it took over, which the noble Chairman had omitted to mention, the patents for the Cape of Good Hope and India. He (the speaker) looked upon India as the future great field for electric lighting. It was a country of luxury and wealth, full of very rich people and princes with enormous incomes. It was a very warm climate, and, therefore, the advantages of the electric light, as compared with gas, were very great. It was a field that he felt could be very largely developed with most beneficial results (applause). Their noble Chairman, probably in his desire not to say too much, had omitted any reference to the Company's business abroad—in Vienna and Austro-Hungary. It would be seen from the report that they were doing very well indeed at Vienna, and that they had already earned a considerable profit on the very small capital that had been spent there. They looked forward to continued success in this direction, and also to

Digitized by Google

still more satisfactory results in the future. As to Austro-Hungary, it was one of the very few places where electricity was actually beating gas on its own ground. The time might come when they would find these gasworks shut up altogether. He did not know that he had much more to tell the shareholders; he assured them on his own behalf and that of his colleagues, that they would do all in their power to make the Company a great success. Shareholders were generally satisfied when they received a good and regular dividend, even though the concern might very well have paid more than they received. Well, the Directors of this Company would not be content with giving the shareholders a good dividend, but would strive to pay them a very handsome dividend. He had much pleasure in seconding the resolution.

The CHAIRMAN invited discussion.

Mr. SMART felt that the Directors should be made acquainted with the feeling of the shareholders with regard to the non-receipt of any dividend for so many years past, and there were feelings of very great disappointment. It had always been much the same story—they were always being fed with promises for the future. This had been what they had to accept year after year; and as a shareholder of many years' standing, he could only express a feeling of very great disappointment at hearing the same remarks year after year. The Chairman had remarked in his speech that they could not very well expect a dividend this year, inasmuch that it was the first annual meeting after the registration of the Company.

The CHAIRMAN: I beg your pardon, the shareholders are getting a dividend this time.

A VOICE: Not the ordinary.

Mr. SMART, continuing, said that the Preference shareholders were getting their dividend; but as all the shareholders held both ordinary as well as Preference shares, it only made a dividend of something like 2 per cent. for the last 12 months. He thought that 2 per cent. was a very poor dividend for five years.

The CHAIRMAN: It is 6 per cent. per annum upon the Preference shares.

Mr. SMART said he would be very glad to know if there was any possibility of the ordinary shareholders being soon in the receipt of dividend. He felt very dissatisfied and disappointed, and that was the reason he had risen and given vent to these observations.

Mr. WARD referred to the large amount of salaries, £8,088; he thought it a very great deal, and would like some explanation upon the point. There was another matter to which he wished to also refer. He was very largely interested in tramways, and he looked forward to the time when tramways would be propelled by electricity. It, however, seemed to be a case of hope deferred, all the attempts that had been made in this direction up to the present time having been failures from a financial point of view. He would like to know from the Chairman whether it was probable that this Company would be able to run tramways by electricity successfully and profitably. He felt confident that any Company that could successfully solve this problem would have a wonderful future before it. He would be glad to have some information on the subject. Now, as to the question that had been raised by the previous speaker with reference to the dividend on the ordinary shares, he had to confess that at any rate the Preference shareholder had no cause of complaint, for he had got all that he could expect, viz., his 6 per cent. He himself held a larger number of ordinary than of Preference Shares, and he would very gladly look forward to the time when the ordinary shares would be in receipt of a dividend, but he did not think that it was fair on the present occasion to press the Board too closely on that question. He certainly hoped that when they met at that time next year the Directors would be able to declare a dividend on the ordinary shares, and he should look very closely into the accounts then presented.

Mr. WILLIAM BROWN referred to the fact that he was a shareholder riginally in the Australasian Company, and he wished to know upon what principle the shares were divided. It was true that he was only a small holder in the previous Company, having only £25 invested, but for that £25 he had only received under the amalgamation one Deferred share. He understood that the Preference and ordinary shares were to have been divided in equal proportions, and he wished to ask whether some people had had the pick of the Preference shares and others had had to be contented with the Deferred shares.

Mr. B. H. TROMP (late Chairman Australasian Electric Light and Power Company, Limited) answered the question and said that he could assure Mr. Brown that the shares had been equitably divided, and that whatever that gentleman had been entitled to he had received. He must bear in mind that £25 was a very small proportion of the capital of the Company, which was £160,000, or if they included the Edison shares £200,000. A circular was issued containing a schedule from which Mr. Brown would have seen that he had received what he was duly entitled to; but if he was still dissatisfied he (the speaker) would be happy to give him the fullest possible information as to the manner in which the whole of the shares were divided, and he assured him that he would find such information to coincide with what he (the speaker) was now stating.

Mr. WILLIAM BROWN said that he understood that he was to have received both Preference and ordinary shares, but he had not received any Preference.

The Rev. Mr. STOBART said that he also received the circular to which Mr. Van Tromp had alluded, and he considered it somewhat misleading. He was a holder of 50 shares in the old Company, and therefore he made out that he was entitled to receive two shares in the new Company, and he was exceedingly surprised to find that he got eight Preference and nine ordinary shares, or four times as many as he expected; he therefore had no reason to complain (laughter and hear, hear).

After some further discussion on the same subject, Mr. VAN TROMP said that he would write a letter to Mr. Brown, giving him all the information on the subject that he desired.

The CHAIRMAN, in reply to the various questions, said he agreed with Mr. Smart that it would have been more satisfactory if the Directors had had a large dividend to give to the ordinary shareholders on this occasion. He for one should have profited by it, as he had three-fifths of his holding in ordinary shares. But they could not expect everything at once. They knew the very great difficulties that had beset the electrical industry for all these years; but owing to various things—for instance, the last Act of Parliament removing the restrictions, which were quite prohibitive, and the public demand for the electric light—he thought they might be pretty sure that the time had come for reaping their harvest in the future. They had an indication of that in what they had already earned. So if they considered the advantageous position they now occupied, he thought they would agree with him that they were entitled to have very sanguine hope of the future. He hoped that in the future, as one speaker had remarked, they would have not only a good but a handsome dividend. With reference to electrical tramcars, this business had been beset with difficulties of various kinds—legislative and otherwise; but it was emerging now from these difficulties, and that was another of the obvious reasons why they amalgamated with the Falcon Works, which were so admirably adapted for the manufacture of electric tram cars. And moreover it got them into communication and actual touch with the people who were now using horse cars. There was a large number of horse cars turned out at the present moment from those works. Only the other day they received an order from the London Road Car Company for 60 new 'buses. That brought them into touch with the people who had control of the tramway interests in this country; and it stood to reason that when they adopted, as they undoubtedly would, these electric tramway cars this Company would come in for a fair share of the orders. This was a matter they had considered for years. They had made numerous experiments in their Belvedere works, and they were following them up; and whenever business came he felt sure they would get their share of it.

In the same way with electric launches. They were making a great many marine engines at the present moment, and the class of work they were executing now was so varied, and altogether opened up so many new avenues of future business, that he could not help having a sanguine view of their future from a pecuniary point of view.

The resolution was then put and carried.

The CHAIRMAN then proposed that the dividend as recommended be declared on the Preference shares.

The motion was seconded and carried.

The Auditors, Messrs. Cooper Bros. and Co., were re-elected, and a vote of thanks to the Chairman and Directors closed a lengthy meeting.

The Aluminium Company (Limited).

The third annual ordinary general meeting of the shareholders of this Company was held at the Cannon-street Hotel, on the 9th inst., when Mr. G. W. BALFOUR, M.P., presided, and in referring to the result of the past year's operations, he expressed the regret that he felt, and that was shared by his colleagues, at their unfortunate position. Still, it was a result for which the Directors took no blame to themselves. At the time when the Company was floated aluminium was a very expensive metal, something like 50s. to 70s. per lb., and they had hoped to have been able by their processes to have produced and sold it for 20s. per lb.; and if the hopes that had been entertained had been fulfilled, there was no doubt that they would have achieved a very great success. They were aware of the electrical processes to which the following paragraph in the report referred:—"But in the course of the past twelve months, by the introduction and successful working of electrical processes, a further very large reduction in price has taken place, until at the present moment the market price of pure aluminium stands at from 6s. to 8s. per pound." These electrical processes, up to the time of the formation of the Company had not proved a success, and therefore the Directors could not be blamed for not having foreseen subsequent events. Electrical processes, it was true, had produced alloys of aluminium, but not the pure article; and they at the time believed that it was impossible to produce a pure aluminium by the electrical process; but they were deceived, and they had been deceived in common with scientific experts, and therefore they could not be expected to foresee what the scientists could not foresee. With the success of the electrical processes their position became a very serious one, and they had to consider what was to be done. Had it not been for the other patents they would probably have had to adopt the course of calling the shareholders together and considering the question of liquidation; but, of course, that would mean a certain amount of loss. Well, Mr. Costner, their chemical engineer, set to work to develop these other patents belonging to the Company, with a whole-hearted energy in the interests of the Company that laid him up from overwork. The result was that the perfection of the new process was delayed, and they did not overcome the whole of the difficulties till the month of August; but they were now, he was glad to say, in possession of a method for the manufacture of aluminium, which, after the Directors and their experts had gone fully into the matter, convinced them that they would be able to compete in price with the aluminium which was produced under the electrical process. As far as he personally could judge, the new process as against electricity would be a complete success. They had a similar testimony from Sir Henry Roscoe, one of their Directors, and their expert in the matter, and they had arrived at the conclusion that the perfected new process would once more place them in a position to compete with the electrical process. Having dealt with various items of accounts, he concluded by moving the adoption of the report.

Sir HENRY E. ROSCOE seconded, and stated that no one could have foreseen that the electrical process would develope into the great success that it had done. He expressed his confidence in the success of the new process as a competitor to the electrical process, and in the future of the Company.

Mr. C. W. WOODS maintained that the Directors should have more fully inquired into the value of the process which they purchased, and which had subsequently been superseded.

Mr. BROOKIE asked the Chairman whether the Directors were aware that the process they bought and floated the Company upon was condemned by other people beforehand.

The CHAIRMAN, in reply, said that as to Mr. Brookie's statement the Directors were unaware that the Costner process was condemned by anyone. If it had been he felt that it could only have been condemned by a competitor.

The report was ultimately adopted unanimously.

NEW COMPANIES REGISTERED.

THE FREEDMAN BATTERY COMPANY (LIMITED).—Registered by William Webb and Co., 6, Essex-street, Strand, W.C., with a capital of £2,000 in £1 shares: To acquire an electrical battery, particulars of which are not detailed, in accordance with an agreement made with Charles H. Freedman. The first Directors are Edward F. Wyman, Charles H. Freedman, and T. F. B. Evans. Qualification not specified. Remuneration to be determined in general meeting after declaration of 10 per cent. dividend.

THE RAILWAY CONSTRUCTION AND MAINTENANCE COMPANY OF MEXICO (LIMITED).—Registered by Bircham and Co., 50 Old Broad-street, E.C., with a capital of £100,000 in £10 shares. Object: To construct, execute, repair, maintain, and work any railways or tramways, roads, canals, watercourses, warehouses, factories, harbours, docks, piers, wharfs, sewers, waterworks, gas, electric and other lighting works, and to solicit, apply for and obtain, either in the name of the company or of third parties or companies, concessions, subsidies, decrees, Acts of Parliament or other authorities for or in connection with the construction, working or maintenance thereof; to deepen any harbours, rivers, or channels, and to execute any other public works in the Republic of Mexico or elsewhere, and to carry on and do all such other businesses and things as are usually carried on or done by contractors for public works, builders, or engineers.

CITY NOTES, &c

AMERICAN BELL TELEPHONE COMPANY.—This Company has declared a quarterly dividend of 3 per cent., payable October 15th.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 5th amounted to £5,821.

COMMERCIAL CABLE COMPANY.—The transfer books of this Company will be closed from September 20th to October 2nd, for the payment of the usual quarterly dividend of 1½ per cent. on October 1st.

ELMORE'S FRENCH PATENT COPPER DEPOSITING COMPANY.—We learn that the prospectus of this Company, which has been formed to acquire the patents for France, will be issued to the public in a few days. The capital is to be, we understand, £200,000 in 100,000 shares of £2 each, of which it is intimated that 66,700 will be offered for subscription at a premium of 10s. per share.

MUNTZ'S METAL COMPANY.—The Directors have declared a half-yearly interim dividend at the rate of 5 per cent. per annum on the original and Preference shares.

PILSEN-JOEL AND GENERAL ELECTRIC LIGHT COMPANY, LIMITED (IN LIQUIDATION).—A meeting of shareholders in this Company was held on Friday, at 18, Laurence Pountney-hill, Cannon-street, to receive the liquidator's report; but the representatives of the Press were refused admission.

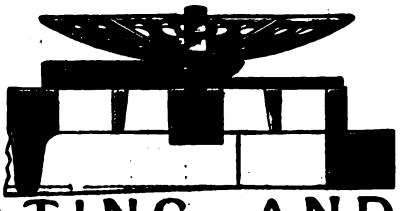
STOCK EXCHANGE.—The committee have ordered the following security to be quoted in the official list:—National Telephone Company (Limited)—2,284 additional shares, Nos. 436,701 to 438,984.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 5, 1890, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £4,590.

WESTERN UNION TELEGRAPH COMPANY.—This Company has declared a dividend of 1¼ per cent., payable October 15th.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 29th Sept. 1886.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 644.—Vol. XXV. FRIDAY, SEPTEMBER 19, 1890. Price Fourpence.

NOTES.

The very conveniently-arranged "voltapile," which was exhibited at the British Association by Sir William Thomson, is an elaborate form of the device which has been used in more than one laboratory. The generation of several hundred volts in this simple manner suggests that there is still room for a portable battery for providing a small current at high pressure for testing the insulation resistance of house wiring, &c. A continuous current would be more likely, we believe, to discover leaks than an alternating one. Insulation tests with two or three Leclanché cells and a detector are almost things of the past; but we do not think that a magneto giving, say, a hundred volts, is a sufficient test for the best and most important work. It may be pleaded that for wiring for alternate-current supply an alternate-current test should suffice, even if a continuous pressure of four or five hundred volts might break down an incipient leak. If this be granted, we still maintain that the testing pressure should be at least double that of the working pressure.

It is difficult, if not impossible, with our present knowledge to define a factor of safety, as in boiler-making or in other branches of engineering construction, since we rarely inquire at what pressure a given insulation may be expected to break down. But it must be remembered that in London, at all events, many hundreds of houses that were wired for alternate-current supply have gone over to direct current, either from the rearrangement and definition of districts of supply, when alternating currents have become no longer available, or from choice on the part of the consumer. But apart from this, anyone doing the best work will not object to a reasonably severe examination; and it appears that the application of four or five hundred volts by means of such a battery as that which was described by Sir William Thomson, charged with an acid solution, so that an appreciable current may be passed, would not be too stringent a test. If an equally portable dynamo could be constructed, it would in some respects be more convenient; but we doubt whether a satisfactory machine could be made which could really be easily carried about, and it would certainly be considerably more expensive than a battery.

Some troublesome polarisation effects have recently been experienced in the working of the Commercial Company's cables at Coney Island, New York. They have been caused by the passage of heavy currents through an electric traction circuit about half a mile away, and running nearly parallel with the cable for about five miles. Mr. Cuttriss, Electrician to the Company, has succeeded in showing that the ground at considerable distances from the railway lead was subject to variations in potential amounting to as much as 4·3 volts; and when the electrostatic capacity of the cable sheath and the delicacy of the receiving instruments are taken into consideration, it does not appear surprising that the earth currents set up between the rails and the sheath were sufficient at times to render signalling impossible. It will, fortunately, not often be necessary to lay the land end of an ocean cable for several miles in the neighbourhood of a conductor carrying heavy fluctuating currents; but when the need arises it may be advantageous to surround the part of the cable in question with a more perfectly conducting sheath, connected at one end with the earth terminals of the testing instrument, and at the other with the ordinary metallic sheath surrounding the part of the cable immersed in the sea. If the new sheath is long enough to prevent any appreciable action at the extremities, it will screen the interior conductor from the effect of potential variations outside, in the same way as Faraday's metallic cage shields the interior from the action of external electrified bodies.

In another column we reproduce a short but interesting Paper by Dr. Sheldon, who has succeeded in directly converting part of the energy of a beam of light into the energy of an electric current. As is well known, if polarised light is passed along the axis of a solenoid, its plane is rotated by the action of a magnetising current passing through the coil, and the rotation is much increased if the core of the solenoid is formed of heavy glass or liquid bisulphide of carbon. If energy is required to produce the shifting of the plane it must be obtained from the current, so that a back electromotive force must be set up in the coil by the rotation. If this is true, it follows that by merely rotating the plane of polarisation an electro-motive force must arise in the coil whether a current flows through the latter or not. Dr. Sheldon has succeeded in detecting the effect by making use of the extreme delicacy of the telephone. The demonstration seems satisfactory, for it is hard to imagine how the result obtained could have been brought about by any other action than the one stated.

The process of reasoning used by Dr. Sheldon in estimating the voltage set up in the magnetising coil is unfortunately

Digitized by Google

omitted, although, with the aid of some experimental results obtained by Mr. PREECE, it is easy to calculate it approximately. The current necessary to produce a perceptible sound in the telephone has been estimated by Mr. PREECE at something like 10^{-12} ampere (one million millionth of an ampere), and by multiplying this by 7 ohms, the resistance of the coil used in Dr. SHELDON'S experiments, we obtain an approximate estimate of the voltage. The number obtained is smaller than that given in the Paper; but this is probably due to the fact that the impedance of the coil, for such rapid alternations as were used, was considerably in excess of 7 ohms.

WE are glad to notice that with the approach of the stormy season the question of communication between lightships and the shore is again being discussed in the newspapers. All the arguments for and against the use of electricity in this connection were impartially set forth by the *Standard* a few days ago, with the unavoidable conclusion, as it seems to us, that nothing short of electrical cables, if capable of being permanently maintained, will meet all the requirements of the case. The experiment at the sunk lightship off Harwich proved costly and inadequate, but only because the cable, or its connection with the ship, frequently broke down. A perfect appliance has yet to be devised that will relieve the cable of the strain to which it is subjected by the shifting of the ship; but if this problem were solved, the Elder Brethren of Trinity House would probably be as strongly in favour of electrical communication as they are now opposed to it. At present they decline to incur the cost of an indefinite number of experiments like the one with the Harwich lightships; and we cannot blame them. It may be hoped, however, that proof will not long be wanting that a cable moored to a moving lightship may be made as trustworthy as one landed at a fixed point; and when this is done we are persuaded that the uses to which it will be put for signalling purposes, other than those relating to shipping disasters, will go a great way to repay the original outlay..

THE "magnetic brass" trouble to which we referred in our last issue is, as will be seen by Mr. SYDNEY EVERSHED'S letter this week, by no means confined to the humble compass case. A correspondent who has great experience in instrument making also writes:—"I have occasionally found a bit of *cast brass* slightly magnetic, but never *rolled*, to the best of my remembrance." The last paragraph of Mr. EVERSHED'S letter, however, shows that there is no safety even in rolled brass. There is, it would seem, room for a new patent non-magnetic brass, more amenable, it is to be hoped, to the tool than is the steel of that description.

THE recent letter from Mr. GLADSTONE to Sir ROBERT BALL, the Astronomer Royal of Ireland, raises the suggestion that we may find in the versatile ex-Premier the man who shall reorganise and firmly establish our system of electrical nomenclature. In the course of his omnivorous reading, Mr. GLADSTONE has studied Sir ROBERT BALL'S charming book "Starland," and he welcomes any knowledge which can be presented to him "in a form in which it makes a minimum demand upon a diminishing brain power." The enormous figures representing the distances of the fixed stars impressed Mr. GLADSTONE, as they do all readers of the subject; but he suggests that some symbols should be introduced which would simplify matters when vast quantities are introduced, which will convey more meaning than the rows of cyphers, or the verbal expressions of thousands of billions of miles. When Mr. GLADSTONE first became Chancellor of the Exchequer, he found that the Bank of England and the Treasury used the letter M as a conventional and convenient sign for £100. Mr. GLADSTONE improved upon this "by adopting M with a tail over the back for a million." The financial demands upon the Treasury rarely ran so high as the French milliard; but Mr. GLADSTONE daringly invented "M in a ring" as being equivalent to the milliard. "It occurs to me," writes Mr. GLADSTONE, "that symbols of this kind (replacing £ by miles) might be of some use, perhaps, in writing astronomical distances."

WE have already adopted **M** in magnetic work, and for the unit by which high vacua are measured; it is also used by some writers as a millionth of a millimetre in expressing the wave-length of a ray of light. It has a meaning of its own in kinematics; and, therefore, though it may be admirably adapted for astronomical work, we cannot accept it, nor indeed do we require a general symbol for a million or millionth. The symbols ω and Ω are sometimes used for ohm and megohm, although ω denotes angular velocity. Dr. OLIVER LODGE felt that the recent occasion on which he was invited to promulgate his "revolutionary views" on nomenclature at the British Association was not a suitable one, and he suggested another day for the debate, which eventually fell through. Symbols and nomenclature are closely allied. Who will lead us into battle?

WE understand that, owing to an advertisement issued by a responsible advertising agency in this country, some apprehension existed as to whether the tenders of a number of large English firms for the electric lighting of Stockholm would have been received in time. The original advertisement inviting tenders gave the time for their receipt as September 1st. This was subsequently extended to September 15th; and by the advertisement referred to above (which appeared in our issue of September 5th) this time was still further extended to October 12th. Several firms who had been working hard for some time upon the necessary details of this large contract found on inquiry at Stockholm that this last-mentioned extension was incorrect. The matter was then taken up by the London Chamber of Commerce, who succeeded in obtaining the valuable aid of the Foreign Office, and Mr. KENRIC MURRAY is now able to announce that an official telegram, received by him from Stockholm, states that tenders posted from this country not later than the 20th inst. will be considered. The issue of this misleading advertisement certainly requires explanation.

Scarborough.—Mr. Bernard Drake is preparing a report to the Corporation as to the course to be pursued by it having regard to the requirements of the Board of Trade Provisional Order.

Digitized by Google

St. Pancras.—During the past week the site for the Central Lighting Station has been cleared, and building operations will be commenced in the course of a few days.

Glasgow and West of Scotland Technical College.—The autumn session of this College will shortly commence, and courses of instruction have been arranged in mechanical and electrical engineering, industrial chemistry, metallurgy, mathematics, physics, &c.

Dresden.—Messrs. Siemens and Halske will supply the plant for the municipal electric light station at Dresden. Accumulators capable of supplying 25,000 lights simultaneously will be put down. There are to be three engines of 450 horse-power each and three 320-kilowatt dynamos.

Proposed Canada-Florida Cable.—Sir Ambrose Shea, Governor of the Bahamas, has had a conference with Sir John Macdonald regarding the establishing of a line of steamships between Canada and the West Indies, calling at the Bahamas, and also the laying of a cable from Nassau Florida.

Salford.—The Salford Corporation are taking steps to establish a technical school under the Act of last year. The Town Council, at its last meeting, empowered its special committee to purchase a plot of land and the property on it adjoining the Peel Park Museum, on which to erect a technical school.

Berlin.—At 9.30 in the evening of September 3rd, during a representation of Shakespeare's "Tempest," the whole of the incandescent lights in the Schauspielhaus, Berlin, were suddenly extinguished. On an examination it was found that the leads have been broken away from the mains at both junction boxes in the Schillerplatz.

Destruction of the New Jersey Telephone Exchange.—During a thunderstorm on Wednesday the building occupied by the New York and New Jersey Telephone Company was struck by lightning and burnt to the ground. Some 2,000 telephone wires have been destroyed, and the damage is estimated at £25,000.

Church Lighting.—An electric light installation is being carried out at the church and Parochial Hall of St. John's the Divine, Vassal-road, Brixton. About 300 incandescent lamps will be used. The plant consists of a gas engine, a dynamo, and a set of accumulators. An electric motor is also being put down for blowing the organ.

Dublin.—On Friday last Mr. C. P. Cotton, C.E., Chief Engineering Inspector of the Local Government Board, held an inquiry in relation to an application by the Corporation of Dublin, for the sanction of the Board to the following amongst other loans:—A sum of £50,000 for the purpose of an installation for the supply of electricity.

Pemberton Local Board.—By way of experiment, the Local Board have accepted an offer from a firm of electricians to light about 400 yards of Ormskirk road with one arc lamp and six incandescent lamps for two calendar months, at a cost of £20; the Board also providing the engine power and poles, and labour to assist in the fixing of the poles and wires.

Royal College of Science, Dublin.—The first term of the 1890-91 Session of this College commences on the 6th October. The Royal College of Science supplies courses of instruction in the sciences applicable to the Industrial Arts. Four Royal scholarships of the value of £50 per annum are attached to the College. Further particulars will be found in our advertisement columns.

Obituary.—We regret to have to announce the death, at the age of 48, of Mr. T. Blaikie, the Secretary of the National Telephone Company, who succumbed to an attack of appolexy on Thursday last week. The deceased had been connected with the National and United Telephone Companies for the last eight years, having joined the staff of the latter Company at the beginning of 1882.

Brighton.—The Lighting Committee have decided to give notice to the Electric Construction Corporation that the Brighton Corporation will only require two sets of storage batteries, switch-boards, instruments and appliances, instead of four sets, as provided in the specification annexed to the contract; and that the contract sum will consequently be reduced from £5,242 to £2,700.

Charterhouse Science and Art Schools and Literary Institute.—The winter session of this, one of the largest Science and Art Schools in the United Kingdom, and a school which has trained some thousands of teachers for the offices of science lecturers, will commence on September 27th. During the late session about 900 students, mostly elementary teachers, availed themselves of the privileges afforded by this Institution.

Search Lights and Coast Defence.—Experiments are being made with search lights at various forts round the Isle of Wight. Nine or ten of the torpedo boats anchored in Totland Bay tried the other day to pass round the Needles under cover of the darkness. The search lights were used to prevent their progress, and fire was opened from the forts as soon as the lights revealed their whereabouts. Only one of the torpedo boats "escaped."

University College, Dundee.—The Engineering Department is in charge of Prof. Ewing. This College offers a complete course of instruction, comprising lectures and drawing office, field and laboratory work for students of civil and mechanical engineering. There is a large engineering laboratory, fitted with testing machine, experimental steam engine, &c., and also a special laboratory of electro-technology. The autumn session of this College opens on October 14th.

Spanish African Cables.—The Spanish Government has invited tenders for the supply and laying of submarine cables to connect Spain with the different Spanish possessions on the African coast. The lines to be first laid down are:—From Tarifa to Tangiers, 31 miles; from Tarifa to Ceuta, 22 miles; from Almeria to Alboran, 84 miles; from Alboran to Melilla, 53 miles; from Melilla to the Chafarinas Isles, 30 miles; from Melilla to Alhucemas, 84 miles; and from Alhucemas to Penon, 31 miles, making a total of about 335 miles. The maximum price offered by the Government is 4,000fr. per mile.

Finsbury "Special" Lectures.—The special courses of lectures at the City and Guilds Technical College, Finsbury, during the coming autumn are two in number. Prof. Silvanus Thompson takes a short course on "Electric Meters" on Monday evenings, and Prof. Perry will lecture till Christmas on "Valve-Gear." Mr. Halliday, the instructor in drawing, has arranged that there shall be two evenings set apart in the drawing-office in each week for instruction in electrical engineers' drawing, examples being taken from the most recent dynamo machines, motors, and lamps. The art studios of the College are now lit by electricity.

Bristol.—The results of inspections made by the Electric Lighting Committee of the Corporation, to which we referred in our last issue, have now been embodied in a long report from Mr. W. H. Preece and the sub committee of visitors. The report recommends that an installation should be established; and that the whole establishment should be in the hands of the Corporation. The number of gas lamps it is proposed to displace will be 170, their candle power is estimated at 5,920, and their cost at £1,131 14s. 7d. per annum. The sub-committee are informed that 50 arc lamps of 1,200 candle power each will be sufficient for the whole of the district they propose to light, and that the cost of each lamp will be about £25 per annum.

Electric Lighting in Australia.—At a recent meeting of the New Australian Electric Company in Melbourne, the Chairman stated that the lighting business was steadily increasing. The Company's new station near South Yarra was nearly completed, and would be ready for work in a month's time. The equipment of the station had been pronounced by English experts to be one of the most perfect yet constructed, being a duplicate of one of the latest and most approved stations erected in London. The capacity of that portion of the station nearly completed was equal to about 15,000 lamps; but the building had been so arranged that its extension could be carried on from time to time to meet all requirements. The mains are being rapidly laid throughout Richmond, Prahran and South Yarra; Government House, the Observatory and the Prahran Public Library being the first points to be served.

Chelsea.—Mr. T. W. E. Higgens, Surveyor to the Chelsea Vestry, states, in his annual report, that only one case of the absence of statutory pressure in electric mains has been brought

Digitized by Google

to the notice of the Vestry. In this case, Mr. R. Chamberlain, M.P., of Cadogan-square, fixed a voltmeter in his own house, and found that on certain days the pressure had been below the limits permitted by the Board of Trade. This deficiency in pressure was probably owing to the fact that the Electric Light Company were at that time using temporarily a charging station at some distance from Cadogan-square. The Vestry left the matter in the hands of the Board of Trade, and no further complaint has since been received. There are in Chelsea about 139 houses now using the electric light, supplied as follows, viz. :—Chelsea Electricity Supply Company 113, Cadogan Electric Light Company 25, London Electric Supply Corporation 1.

A Differentially Wound Sprague Motor.—A differentially wound motor or generator, devised by Mr. F. J. Sprague and intended to avoid the difficulties due to distortion of the principal field by the field of the armature, has recently been described in the American technical journals. The method taken to accomplish this is as follows. The cross-magnetising effect of the armature produces an unsymmetrical field, and if the field produced by the regular magnetising coils be a symmetrical one, the result is sparking and other difficulties. Mr. Sprague attempts to counteract this by winding the field with unsymmetrical series coils, so that the distortion produced by the armature is in whole or in part counteracted by that produced by the series winding. To exactly what extent this ingenious device will accomplish the end in view remains to be seen. Whether the two cross-magnetising forces can be balanced so as to produce a uniform field can be proved only by experiment.

Gas Companies and Electric Lighting.—The following remarks in the last issue of the *Journal of Gas Lighting* may not be without interest to those who advocate the combination of the gas and electric lighting businesses. Gas companies, observes our contemporary, are not in any special way adapted for supplying the electric light or for the manufacture of lucifer matches; and they can no more powerfully urge a right to a monopoly of the one than they could of the other industry, supposing both to be subject to similar statutory regulations. There is nothing in gas plant, either manufacturing or distributing, that can be regarded as utilizable for an auxiliary electric lighting plant; and for a gas company to grasp at electric lighting as some foreign companies have done, is pure greediness of gain, which is invariably disappointed. There is no European gas company at this time making a profit by electric lighting; and if there are any in America, they have kept wonderfully quiet about it. It is to be hoped that no more will be heard of these petitions from British gas companies to be allowed to undertake electric lighting in the notices for the Gas Bills of next Session.

The Distribution of Lights in Textile Factories.—In our issue of August 15 we published a translation of a short article in *L'Electricien* on the distribution of arc lights in textile factories. In a recent number our contemporary gives the following extract from a letter of an engineer practically acquainted with the question of the distribution of light:—"In settling the height of arc lamps it is necessary to distinguish between outdoor lighting, such as that of railway stations and other open spaces where no work is being done, and open spaces where an intense light is required owing to the nature of the work which is being carried on. In the case of railway stations, yards, &c., the lamps should be very high. These are the heights at which we place them:—10 ampere arcs = 10 metres; 13 ampere arcs = 15–16 metres; 15 ampere arcs = 18 metres; 18 ampere arcs = 20 metres. When the spaces to be lighted up are used for some special purpose, such as wood-sawing, coal-screening, stone-cutting, &c., these heights may be reduced by 2 metres. With regard to globes, we find that large ones are preferable to small ones, since with the former the light has not the appearance of a sun-like disc. With large globes also the shadows of the illuminated objects are more broken up."

A Novel Telephonic Reaction.—We have recently, says the *Electrical World* of New York, had our attention called to an interesting phenomenon in connection with the telephone, which might be looked upon with suspicion by the uninitiated. While Messrs. Hibbard and Pickernell were conversing recently over one of the lines of the Long Distance Telephone Company, the former, in order to shut out some conversation, placed the receiver with the diaphragm end over the mouth-piece of the long-distance transmitter. The receivers at both ends at once began to give out a musical sound, which continued until the receiver was withdrawn from the mouth-piece of the transmitter. Investigation proved that the effect was due to an action similar to that employed in the well-known vibrating bell. An original impulse imparted to the transmitter is conveyed electrically through the primary and secondary circuits to the receiver, which, in turn, throws it back the transmitter through the intervening air, thus constituting a complete electric and acoustic cycle. This battledore and shuttlecock action between the receiver and transmitter is continuous as long as the receiver is held against the transmitter, and gives rise to a musical note of high pitch and great uniformity. Of course, it requires a powerful transmitter to produce the phenomenon, the ordinary Blake instrument being incapable of demonstrating it.

Bradford.—At the last meeting of the Town Council, Alderman F. Priestman proposed the adoption of the minutes of the Gas and Electricity Supply Committee, which included a resolution accepting the tender of Messrs. Siemens Bros. for the supply of machinery and cables required in the extension of the electricity works, for £450. Alderman Priestman said, with regard to the electricity works, that he had given a statement of the loss accrued to December 31st last; and he hoped to present a statement at the end of the present year. So far, the loss was short of £1,000. The electrical department had never been expected to pay in its earlier stages. An engine was now being laid down which would increase the output without augmenting the working cost; and he expected that in a few months the statement would be very much better than it would be if presented now. If the Council would appropriate a sum of say £10,000 from the profits of the Gas Department for the benefit of the electric lighting works, they could be made to pay their way. He hoped that ere long the Committee would be able to show that the electric lighting department was paying its way; but if not, it would be necessary to raise the price to the consumer. There was no cause to regret the steps taken in respect to this question. He had not the least doubt that if they had not taken the powers of supply themselves, they would have had to spend a great deal more money in keeping other people out. The minutes were then adopted.

A Chinese Telephone.—Our contemporary the *Engineer* is responsible for the following:—"A despatch from San Francisco states that the Bell Telephone Company is likely to have a persistent rival in a party of Chinese in that city whose ingenuity has enabled them to perfect an instrument which works remarkably well, and, it is asserted, is not an infringement on the Bell patents. The new instrument was brought to light through an investigation of the telephone company, which became suspicious of the increasing number of orders for the removal of the instruments from Chinese shops. For many months Wong Ching Wah, otherwise known as W. C. Young, a highly-educated and intelligent Chinese, has been engaged in electrical experiments, with a view to perfecting his smattering knowledge of the science obtained in an Eastern college. About a year ago he conceived the idea of attempting the construction of a telephone. From the electrical supply house in Mission-street he purchased the necessary parts of instruments; and a wood engraver in Kearney-street, under his Chinese customer's instructions, knocked together a box for the reception of the completed telephone. Wah screwed the parts together, and the result was so satisfactory that he straightway constructed a second similar instrument. This he set up in a neighbouring meat shop, the first instrument having already been placed in position in the Mission. It worked like a charm, and within a week the proud electrician had received from his friends and acquaintances a dozen orders for similar telephones. He filled orders as rapidly as possible; and as fast as new instruments were completed and put in position those of the Bell Company were removed."

CONTRIBUTIONS TO THE MOLECULAR THEORY OF INDUCED MAGNETISM.*

BY J. A. EWING, F.R.S.

(*Concluded from page 517.*)

The chief facts of permeability and retentiveness, and hysteresis generally, are therefore at once explicable by supposing that Weber's molecular magnets are constrained by no other forces than those due to their own mutual magnetic attractions and repulsions. No arbitrary constraining forces are required. In the model the centres of rotation are fixed; in regard to the actual solid we may make an equivalent supposition, namely, that the distances between the molecular centres do not change (except in so far as they may be changed by strain).

Hysteresis, then, is not the result of any quasi-frictional resistance to molecular rotations; it occurs whenever a molecule turns from one stable position of rest to another through unstable condition. When it is forced to return, it again passes through a condition of instability. This process, considered mechanically, is not reversible; the forces are different for the same displacement, going and coming, and there is dissipation of energy. In the model the energy thus expended sets the little bars swinging, and their swings take some time to subside. In the actual solid the energy which the molecular magnet loses as it swings through unstable positions generates eddy currents in surrounding matter. Let the magnets of the model be furnished with air-vanes to damp their swings, and the correspondence is complete.

A regular group of elementary magnets, especially when furnished with air-vanes, gives a good illustration of what has been called magnetic viscosity. When the imposed force H reaches a critical value one of the outer members of the group becomes unstable, and swings slowly round; its next neighbours, finding their stability weakened, follow suit, and the disturbance spreads through the group in a way eminently suggestive of those phenomena of time-lag in magnetisation which I have described in a former Paper.†

The model shows equally well other magnetic phenomena which presumably depend on the inertia of the molecules, such as the fact that a given force causes more magnetic induction when suddenly applied than when gradually applied, and leaves less residual magnetism when suddenly removed than when gradually removed.

The well-known effects of mechanical vibration in augmenting magnetic susceptibility and reducing retentiveness are readily explicable when we consider that vibration will cause periodic changes in the distances between molecular centres. This has not only a direct influence in making the molecular magnets respond more easily to changes of magnetic force by reducing their stability during the intervals when they recede from each other, but tends indirectly towards the same result by setting them swinging.

The effects of temperature which are common to the three magnetic metals may be stated thus:—Let any moderate magnetising force be applied, not strong enough to produce anything like an approach to magnetic saturation, and let the temperature be raised. Then the permeability *increases* until the temperature reaches a certain (high) critical value, at which, almost suddenly, there is an almost complete disappearance of magnetic equality. As regards the first effect, it is clear that an increase of permeability is to be expected from the theory; expansion with rise of temperature involves a separation of the molecule centres, and therefore a reduction of stability. As regards the almost sudden loss of susceptibility which occurs at a high temperature, it may do no harm to hazard a rather wild conjecture. We may suppose the molecular magnets to be swinging more or less, the violence of the swings increasing as the temperature rises, until finally it develops into *rotation*. Should this happen, all trace of polarity would of course disappear. The conjecture that the molecular magnets oscillate more and more as the temperature rises, is at least supported by the fact (carefully investigated by Hopkinson* in iron and nickel; data for cobalt also have lately been supplied by Du Bois†) that under *strong* magnetic forces rise of temperature reduces magnetism; for with strong forces the molecular magnets are already ranged so that their mean direction is nearly parallel to H; hence the earlier effect of heat (to diminish stability and facilitate alignment) does not tell, and the increased swinging simply results in reducing the mean value for each molecule of its moment resolved parallel to the magnetising force.

Before referring to effects of stress we may consider shortly the stability of a pair or line of magnets, treating each as a pair of poles subject to the law of inverse squares. Take first a single pair of equal magnets with centres at C and C′ (fig. 7). The poles PP′ would lie in the line CC′, but for the imposed force H, which produces a deflection CC′P′ or C′CP = θ.

Let α be the angle which H makes with the line of centres, m the pole-strength, and r the half length of the magnetic axis of each magnet. The deflecting moment is

$$2Hmr \sin(\alpha - \theta),$$

and the restoring moment is

$$\frac{m^2 \overline{CN}}{\overline{PP'}^2},$$

CN being drawn normal to PP′. The restoring moment at first increases with θ, but passes a maximum at a value of θ

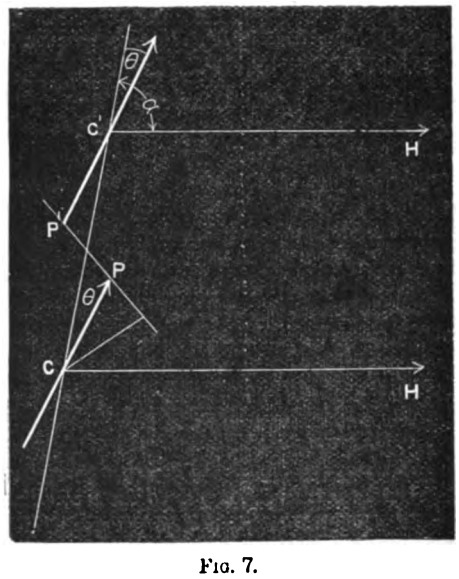

Fig. 7.

which depends on the relation of r to the distance between the centres. The condition of equilibrium is

$$2Hmr \sin(\alpha - \theta) = \frac{m^2 \overline{CN}}{\overline{PP'}^2};$$

and as H and θ are increased the equilibrium becomes neutral, that is to say, the condition of instability is reached, when

$$\frac{d}{d\theta}\{2Hmr \sin(\alpha - \theta)\} = \frac{d}{d\theta}\frac{m^2 \overline{CN}}{\overline{PP'}^2}$$

These two equations serve to determine the value of H and of θ at which instability occurs. If we have to deal with a long line of magnets instead of a single pair, we have to write $2m^2$ instead of m^2 in the restoring moment.

A considerable amount of stable deflection is possible when the distance between the poles is not small compared with r. When the direction of H is not much inclined to CC′ (that is, when α has a value approaching 0) there is no instability. In rows with various inclinations to H, the first to become unstable as H is increased will be that for which $\alpha - \theta$ is equal to $\frac{1}{2}\pi$.

If a, the half distance between the poles in the undeflected position, be small compared with r, there is but little deflection before instability occurs, and in that case, provided α be not small, nor nearly equal to π, the occurrence of instability is defined by the condition

$$\frac{d}{d\theta}\frac{\overline{C}\,\overline{N}}{\overline{P}\,\overline{P'}^2}=0,$$

which is satisfied when $\tan\phi=\frac{1}{\sqrt{2}}$; ϕ being the inclination of PP′ to the line of centres. Hence, with the same proviso (α not nearly equal to 0 or to π, and a small compared with r), the value of H which causes the instability is

$$H=\frac{m}{12\sqrt{3}\,.\,a^2\sin\alpha}$$

for a single pair of magnets, and twice this quantity for the middle members of a long row. This is of course least for magnets which lie normal to H.

In the special case when $\alpha=\pi$, instability occurs when

$$H=\frac{m}{8a^2}$$

with the single pair, or $m/4a^2$ with the row.

Applied to the case of a group of rows, uniform in distance between the centres, but various as regards their direction with respect to H, these considerations show that after H has reached a value sufficient to make the most susceptible members unstable, no very great increase is required to bring about instability in by far the greater number of the other rows. One general effect of increasing the distance between all the centres is to reduce the range of variation of H within which most of the different rows become unstable as the force is progressively increased.

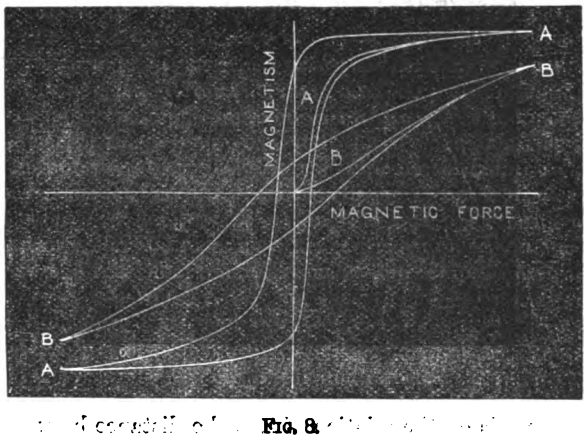

Fig. 8.

In annealed metal, where we may expect considerable general homogeneity, as regards distance between the centres of the molecular magnets, we find that practically the whole of the abrupt stage in the process of magnetisation is included within narrow limits of magnetising force. We accordingly obtain curves like AA (Fig. 8). When the metal is strained sufficiently to receive permanent set the curves take more rounded outlines (such as BB), showing less susceptibility throughout, less residual magnetism, and more coercive force. The most natural explanation of this, on the basis of the molecular theory, appears to be that set produces on the whole a shortening of the distances between molecular centres, hence greater stability and more coercive force; but this is associated with heterogeneity, that is variety in the distances, hence the rounded outlines of the curves. We know that set tends to develop, or at least to emphasize, heterogeneity; for instance, a bar of iron or steel pulled in the testing-machine stretches irregularly after the elastic limit is passed.

The effects of stress and consequent elastic strain on magnetic quality are so complex and so various in iron, nickel, and cobalt, that it would be premature to attempt any full discussion of them from the point of view of the theory now sketched. Only a few general features need be referred to at present. Some of these can be traced experimentally in the model by setting the supports of the magnets upon a sheet of thin indiarubber, which may be stretched or distorted to imitate the conditions of longitudinal or torsional strain.

When pulling stress is applied, those rows of molecular magnets which lie more or less along the direction of the stress have their stability reduced by the lengthening of the lines of centres; similarly, rows which lie more or less normal to the stress have their stability increased. The resulting effect on the general susceptibility of the material will depend on which of these conflicting influences preponderates. Let pull be applied before magnetisation begins, while the metal is still in a neutral state. The stretching of longitudinal lines and the contraction of transverse lines will not only alter the stability of those molecules which continue to lie in their original rows, but will tend to make the members of those rows which are much lengthened swing round and form transverse lines, in which they will be more stable than before. We may, therefore, reasonably expect that the permeability with regard to strong fields will be reduced by pull, as it actually is both in iron and in nickel, though with regard to weak fields the permeability may be increased, as it is in iron.

Again, the theory explains well why the effects of stress are by no means the same (1) when the stress is applied first and the magnetic force after, and (2) when the magnetic force is applied first and the stress after. Let a moderate magnetising force be applied, and then begin to apply stress. The first effects are in general large, for the strain precipitates into instability those molecular magnets which were already on the verge of instability. This is beautifully apparent in iron (see *Phil. Trans.*, 1885, Part II., plates 63 and 64); and the theory shows why the first effects are not reversible, why they do not disappear when the stress is removed, and why it is only in subsequent applications and removals of the stress that the magnetic changes become cyclic. The same remark evidently applies to the first effects of stress on residual magnetism; also to the first effects of temperature-change either on induced or residual magnetism. Again, the theory shows that when a cyclic change of stress is repeated, there will be hysteresis in the corresponding changes of magnetism, whether induced or residual, unless either the cyclic range is very small or the magnetism approaches saturation. During each application of the stress some molecular magnets will swing through unstable positions; during the removal of strsss they will swing back, but not at the same values of stress. And it will be characteristic of this hysteresis that the variation in magnetism will begin slowly when the change from applying to removing stress, or from removing to applying stress, begins. All this agrees with the facts.

Moreover, the theory shows that even in the absence of any resultant magnetisation a cycle of stress makes the molecular configuration pass through a series of changes which will at first not be cyclic, but will become cyclic when the stress-cycle is repeated, and in which any intermediate value of the stress will be associated with different configurations during the going and coming parts of the process. In other words, we see that there will be hysteresis in the relation of molecular configuration to stress when a cycle of stress is repeated. Hence certain rather obscure effects which have been observed in magnetic experiments; for instance, where an iron wire is loaded and partially unloaded down to a given load before being magnetised, its permeability is not the same as when the wire is completely unloaded and reloaded up to the same load. Experimental results of this kind led me in 1884 to write:—"If we apply and remove stress in a wire whose magnetic state is entirely neutral, *we cause some kind of molecular displacement in the relation of which to the applied stress there is hysteresis.*"* The theory now offered shows how this happens. Hence also the remarkable hysteresis which the thermo-electric quality of iron exhibits with regard to cyclic changes of stress, discovered by Cohn, and more fully described in *Phil. Trans.*, 1886, p. 361. The hysteresis of molecular configuration with respect to stress has been proved to be removable or reducible by vibration.

* *Phil. Trans.*, 1885, Part II. p. 614.

Digitized by Google

From this theoretical explanation of hysteresis in the effects of stress, it at once follows that a cyclic change of stress (provided it be not very small) involves some dissipation of energy in a magnetic metal, whether the piece be magnetised or not. We may expect this dissipation to be most considerable under conditions which make the magnetic hysteresis large. But it will occur even when there is no external trace of magnetism. This, of course, implies that, in a cyclic process of loading and unloading, work must be spent. There is no perfect elasticity in a magnetic metal, however slowly the process of straining be performed. Under any load there is less strain during application than during removal. This is borne out by experiments on the extension of iron wires (Brit. Assoc. Report, 1889, p. 502). The same action occurs to a marked degree in torsional strains. In a twisted specimen there will be a tendency on the part of the molecular magnets to range themselves along lines agreeing more or less with the direction of maximum contraction. Alternate twisting to opposite sides should therefore cause much molecular swinging through unstable positions, with consequent dissipation of energy, even in a piece which is not magnetised. Without going at present into details, it may be added that the phenomena of molecular "accommodation" studied by Wiedemann and by H. Tomlinson accord with the theory, and that it seems to lend itself well to explain the very remarkable results which have been obtained by Nagaoka* in experiments with nickel wire under twist or under a combination of pull and twist. It also agrees with what little is known as to the influence that previous magnetisation in one direction has upon subsequent magnetisation in another direction.

To sum up, I have endeavoured to show:—

(1) That in considering the magnetisation of iron and other magnetic metals to be caused by the turning of permanent molecular magnets, we may look simply to the magnetic forces which the molecular magnets exert on one another as the cause of their directional stability. There is no need to suppose the existence of any quasi-elastic directing force or of any quasi-frictional resistance to rotation.

(2) That the intermolecular magnetic forces are sufficient to account for all the general characteristics of the process of magnetisation, including the variations of susceptibility which occur as the magnetising force is increased.

(3) That the intermolecular magnetic forces are equally competent to account for the known facts of retentiveness and coercive force and the characteristics of cyclic magnetic processes.

(4) That magnetic hysteresis and the dissipation of energy which hysteresis involves are due to molecular instability resulting from intermolecular magnetic actions, and are not due to anything in the nature of frictional resistance to the rotation of the molecular magnets.

(5) That this theory is wide enough to admit explanation of the differences in magnetic quality which are shown by different substances or by the same substance in different states.

(6) That it accounts in a general way for the known effects of vibration, of temperature, and of stress upon magnetic quality.

(7) That, in particular it accounts for the known fact that there is hysteresis in the relation of magnetism to stress.

(8) That it further explains why there is, in magnetic metals, hysteresis in physical quality generally with respect to stress, apart from the existence of magnetisation.

(9) That, in consequence, any (not very small) cycle of stress occurring in a magnetic metal involves dissipation of energy.

DISCUSSION.

Sir WILLIAM THOMSON said the experiments made by Prof. Ewing were extremely beautiful and important. The fundamental idea of instability of the supposed molecular magnets seemed to be of very great importance indeed in explaining that most fascinating phenomenon known as magnetic induction. Now, that they saw an actual model produced in such an intelligible way, they might well believe in the reality of the molecular conception. What could be realised in steel, wood, iron, and paper, in a model made by human hands was realisable in the molecule itself. They had numerous models for explaining various parts of phenomena in physical science, but nothing in the way of models had so much of richness and completeness of explanation in itself as that which they had seen that day.

Prof. LODGE said Prof. Ewing's discovery was the most important they were likely to have before them in physical science: it got to the bottom of permanent magnetism. That sentence of Maxwell about the molecules being subjected to only their own forces he had endeavoured to attack mathematically; and here Prof. Ewing had attacked it mechanically, and had made one of the most brilliant Papers since Hertz.

Lord RAYLEIGH was not sure that Maxwell dwelt on the magnetic application; but there was a great deal of breaking down of a partially stable figuration, as illustrated in the model which Prof. Ewing had brought before them.

Prof. REYNOLDS expressed his admiration of Prof. Ewing's work. The Professor thought friction had nothing to do with magnetisation of hysteresis; but was he prepared to say that this model had nothing to do with friction? Prof. Ewing had here an opportunity of illustrating the mechanical action which, for want of that opportunity, they lost sight of, and that was that there was an infinitely multiple system of equilibrium of stability; and if they had an equal number of limited stability they would have virtually a quantity which was a friction.

Prof. FITZGERALD said it would be very unfortunate if the general question were confined merely to questions of magnetisation. There were a very large number of allied questions connected with annealing. How could the wire be stretched and obtain some sort of crystalline structure, which when heated and cooled it lost, so that the cycles of heating it and cooling it down was not a cycle of operations that brought it down to the original condition?

Prof. EWING, in reply, said that for some years past he had been very much impressed with the importance of the phenomena to which the name of hysteresis had been given. As soon as this explanation of the phenomena of hysteresis and induced magnetism was produced, it occurred to him that it should be worked out as suggested by Profs. Fitzgerald and Reynolds; and, of course, friction was one of the many instances.

RECENT DETERMINATIONS OF THE ABSOLUTE RESISTANCE OF MERCURY.*

BY R. T. GLAZEBROOK, F.R.S.

We are here to-day to discuss some of the determinations of the value of the ohm when expressed as the resistance of a column of mercury, with a view to seeing if any action is practicable by which the standards in general use may be brought nearer to their theoretical value than they are at present. The time is opportune, for we have the advantage of having in Leeds M. Mascart, of Paris, and Prof. Rowland, of Baltimore, under whose directions some of the most important of the investigations we are to consider to-day have been made, and Prof. Barker, one of the American representatives at the Paris Congress. Moreover, it seems probable that a Congress will again meet shortly to consider this question, and a preliminary discussion here may be of value in clearing the ground.

The question at issue is whether the results of experiment are sufficiently in accord with each other to render it probable that any number adopted by us would be generally accepted, and, if so, to determine what that number is.

The problem has two sides. The resistance of a wire is expressed by means of one series of experiments in terms of a length and a time, while by another series of experiments it is expressed in terms of the resistance of mercury; and thus the resistance of mercury is found absolutely. Frequently, however, there is an intermediate step; the resistance of the wire is expressed in terms of some standard resistance, and this standard is expressed in terms of mercury.

The methods employed to compare a standard resistance with that of mercury are all very similar in their nature, and the experiment is not one of very great difficulty. Accordingly we find that the results of the experiments are fairly concordant.

In the Table, column 5 gives the values found in B.A. units for the resistance of a column of mercury 1 metre long, 1 square mm. in section at 0°C.—a Siemens unit as it is called. The values found by Lord Rayleigh and M. Mascart are higher than later ones. A comparison of the values found for the B.A.U. in ohms and for the Siemens unit in B.A.U. by M. Mascart, leads to the conclusion that possibly his B.A.U. had changed a little between the time at which it was compared with the standards at Cambridge and the time at which it was used. As to Lord Rayleigh's value, the fact that the coil F was his principal standard, and that coil F has certainly changed relatively to the other coils in the last two years, may help to explain the difficulty, but it must be remembered that F had the same value relatively to the others in 1888 as it had in 1881, when examined by Dr. Fleming, and some other cause for the difference must be sought. The other numbers are in close accord, except one result of Salvioni's, which must, I think, be capable of a simple explanation. Strecker, Kohlrausch, and Salvioni differ somewhat from Wilkes and myself, in consequence, I believe, of the fact that they worked at the temperature of the room, while Wilkes and I worked at the temperature of melting ice. A small change in the temperature coefficient used by them would easily account for the difference. Wuilleumeier's mercury tubes were the same as those employed by Mascart, Benoit, and de Nerville. We may thus take ·9535 B.A.U. as being very accurately the resistance of a column of mercury 100 cm. long 1 square mm. in section.

But when we inquire what are the results which have been obtained for the value in ohms of the B.A.U., or of the mercury unit, the discrepancies are considerable.

Let us consider the methods. An admirable summary of these will be found in Wiedemann's *Electricitat*, Vol. IV., p. 910, or in Mascart and Joubert's *Leçons sur l'Electricité* II., pp. 581, *et seq.* They have also been critically discussed by Wiedemann and by Lord Rayleigh in the *Phil. Mag.*, Vol. XIV., 1882. We will take them in order.

1. *Kirchoff's Method.*

This has been used by H. F. Weber, Rowland, Mascart, and Glazebrook. The formula may be written

$$R = \frac{4\pi M}{T} \cdot h \cdot \frac{a}{\beta}.$$

Where M is the coefficient of induction between the coils, T the time of swing of the galvanometer needle, a the deflection due to the primary current, β the throw due to the induced current, and h a ratio either of two galvanometer constants, or of two resistances; all small corrections are omitted.

The main difficulty is in calculating the value of M, which depends approximately on a^2/b, if a is radius of either coil and b the distance between the coils.

In the coils used by myself the value of a was about 26 cm.; that of b varied from 12 to 24 cm. An error of ·1 mm. in b produces an error in the result between 1 in 1,500 and 1 in 2,000. In one position of the coils, the correction arising from the fact that the cross-section of the channel was of finite area was less than 1 in 1,000. There should, it seems to me, be no difficulty in finding M to one or two in 10,000. The coils used by Rowland and Weber in their earlier experiments, and by Mascart, were smaller. In his last experiment in 1883 Weber used coils of 32 cm. radius. In their later experiments Rowland and Kimball had large coils, about 50 cm. in radius.

The various results are:—

H. F. Weber	105·37
Rowland	106·29
Mascart	106·33
Glazebrook	106·29

It will be noticed that all H. F. Weber's results are very low. He used as his standard wire a 10-Siemens unit taken from a resistance-box, not a coil which had been compared directly with mercury, and it seems possible that a common error in this affects all his results; he also used large magnets. The other values are in fair agreement, though we may probably agree with Lord Rayleigh in thinking that the limit of accuracy of the method has not been reached.

II.—*Weber's Method.*

The approximate formula again is

$$R = \frac{2\pi G g}{T\beta} = \frac{4\pi^3 N N'}{T\beta} \frac{a^2}{A},$$

where G is the constant of the galvanometer, g the area of the earth inductor, and in the second expression a is the radius of the inductor, A of the galvanometer, N and N′ the number of turns on either.

This method was followed by Mascart, who used with a coil of 15 cm. diameter and a galvanometer the constant for which was compared with one of known constant, viz., the inductor. The time taken to turn the inductor was one-fifth of the time of vibration of the galvanometer needle. There is the difficulty of making the axis vertical and the effect of the time of duration of the current on the throw of the galvanometer needle to consider. My experiments show that if the effect of the induction current be prolonged for a period of one second, the time of swing being 23 seconds, then the deflections are reduced by ·1 per cent. With the circuit open for two seconds effects are marked.

Digitized by Google

The same method has been used by G. Wiedemann, who is inclined to think it the best; he employed coils of W. Weber and Zollner, one metre in diameter, which were wound and measured twice. He calculated G, using as galvanometer coil a counterpart of the inductor; the effect of the current was determined by measuring the effects of a series of impulses at proper moments. The time of turning the inductor was two seconds, while the period of the needle was one minute. This would tend to reduce β, this to increase R, and hence to decrease the length of the column, which was found by comparison with a Siemens unit; the same unit was compared with mercury.

Mascart thinks difficulties inspire with doubt the results thus obtained. Experiments near the magnetic equator would, Lord Rayleigh points out, decrease the effect of level error. Wiedemann considers this method is to be recommended for final determinations. Rowland criticises the method.

The results obtained are:—

Mascart	106·37
Wiedemann	106·19

III.—*Method of British Association Committee.*

$$R = \pi^2 N^2 a \Omega \cot. \phi$$

The only measurement, apart from corrections, is that of mean radius. The corrections, however, are important for the self-induction of the rotating coil requires to be known; while the magnetic field in which the coil is moving is modified by the presence of the magnet at its centre, so that the magnetic moment of this magnet has to be determined. In order to reduce the amount of this correction, this magnetic moment is made small, and this again leads to difficulties.

The following difficulties are urged by Wiedemann:—

(1) Correction due to self-induction. (2) Diffiulty of levelling. (3) Want of steadiness from draughts, &c. (4) Small magnetic moment.

In reply we may say

(1) Can be corrected for.

(2) Level error common to several methods. (See II. above).

(3) Effect can be eliminated by experiments with open circuit.

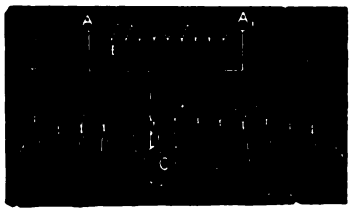
(4) Theory of the correction is very simple; a knowledge of M/H only is required.

The method was used by Lord Rayleigh, leading to the result, 106·24. It was also employed by H. F. Weber, who used rotation about a horizontal diameter in the magnetic meridian to avoid the correction depending on M/H.

IV.—*Foster and Lippmann.*

$$R = 2\pi^2 \Omega \frac{a^2}{A} \cot \phi \, NN'.$$

A rotating coil is used, but contact is made only at the moment when the E.M.F. is a maximum, and E.M.F. is balanced by that due to an external current through a known resistance. Observations have been recently carried out by Wuilleumeier by this method with modifications. He used the induction from a long spiral M N (see figure), 2 metres long 30 cm.



diameter, placed east and west, wound with one layer of wire 2 mm. in diameter. A coil, C, wound on a disc of hard wood, 20 cm. in diameter, rotates in this, and the circuit is closed when the E.M.F. in C is a maximum; the E.M.F. thus produced is balanced against that produced by the current in the spiral when flowing through a resistance, R, the action of the earth's magnetism being compensated. One point, A, of R is in connection with the coil through E, the other end is straight, and a moveable contact is established at A_1, A_2, &c. Corrections for its ends are obtained by shifting the spiral coil. The resistance of R was about ·3 ohm., made from a strip of German silver of rectangular section 34·72 metres long, 1 cm. broad, ·3 cm. thick, immersed in naphtha. The primary current was 12 amperes. A Lippmann electrometer was used. The E.M.F. was nearly four volts. The diameter of the rotating bobbin was 20 cm. Hence, error of 1 mm. in mean radius makes error of one in 1,000. The formula assumes spiral to be uniformly wound. Result is 106·267.

V. *Method of damping.*

Set a magnet in a coil. The motion of the magnet sets up currents which react on the magnet and damp it. A relation can be found between these currents and the rate of damping. To a first approximation, λ λ_0 being logarithmic decrements,

$$R = \frac{\pi}{2} \frac{1}{T} G^2 \frac{M}{H} \frac{(\pi^2 + \lambda^2)}{\lambda - \lambda_0}$$

G has to be compared with the constant of another coil, because of the size of the coil. Let h be the ratio—

$$R = \frac{2\pi^3}{T} \frac{N^2 h^2}{A^2} \frac{\pi^2 + \lambda^2}{\lambda - \lambda_0} r^3 \tan \alpha$$

Where A is the radius of the standard coil, N the number of its turns, α the deflection which the magnet produces in Gauss' first position when at a distance, r.

Further corrections are required for length of magnet, and for the uncertainty as to the distribution of its magnetism and for self-induction. In the opinion of Lord Rayleigh and Rowland, the final formula is enough to show that it cannot compete with the others. Other difficulties are that the calculation assumes the arc of oscillation is small, G is not independent of the displacement. Currents are set up in the magnet, which affect its motion. A correction is required for temporary induced magnetisation due to action of current; this may be appreciable. In general there are difficulties in applying the theory.

The method was used by H. F. Weber. His magnet was 8 cm. long, his coil 16 cm. in radius, and G was calculated, a uniform distribution of magnetism being assumed.

Dorn introduced corrections to the theory, he found G by comparison with a large coil, compared result with a Siemens unit, verified by Strecker; his magnet was 17 cm. long, closely surrounded by the coil. Wild suspended the magnet bifilarly; it was 29cm. long, and the coil closely surrounded it; a resistance-box used.

Kohlrausch's magnet was 20cm. long, with brass ends. The coil was close to it, G was compared with a large galvanometer. Resistance compared directly with a tube calibrated by Strecker.

The results are:—

H. F. Weber	104·77
Dorn	106·24
Wild	106·03
Kohlrausch	106·32

VI.—*Lorenz Method.*

$$R = n M.$$

The main difficulty lies in the calculation of M; this is more easy than in 1, for the disc can readily be measured.

In Lord Rayleigh's apparatus an error in the radius of the coil does not greatly affect result. Further increase of size possible and desirable. The smallness of the effect, and therefore of R is not fatal. See Lord Rayleigh's observations.

Thermo-electric effects can be compensated for.

Results:—

Rayleigh	106·24
Rowland	106·29
Lorenz	106·19

Lorenz value is too low, because of the size of the mercury tubes used by him.

VII.—*Roiti and Himstedt.*

$$R = n M \frac{a}{\beta} = n 4 \pi^2 a^2 \frac{N N'}{L} \frac{a}{\beta}.$$

There is a difficulty in having many contacts for, if the contact does not last all the time supposed, β would be too small, R too large, and the length of the column too short. There is also an important correction for the ends, and the assumption is made that the coils are uniformly wound. Another difficulty is the theory of the galvanometer under such discharges.

The resistances were compared with a Siemens unit, and in the case of Roiti with one of Strecker's coils.

The results are :—

Roiti	105·89
Himstedt	105·98

VIII.—*Calometric Methods.*

The results by these methods cannot claim any great accuracy.

Having thus completed the review of the methods, we must look at the results; and after what I have said we may, I think, reject all work previous to 1882.

The results of H. F. Weber are manifestly too low, while serious doubts attach to the methods of Roiti and Himstedt. For Weber's first method, the early results of W. Weber and Zollner may be omitted compared with those of G. Wiedemann, while the results given by the method of damping will be sufficiently represented by the work of F. Kohlrausch, who alone of those who used this method compared his results with the resistance of mercury directly. The experiments of Lorenz will not, I think, stand rigid criticism, while, unless I am much mistaken, Lenz, who also used Lorenz' method, has only published results and not details.

We are thus left with the following list, including the results only of those who have made both the mercury and absolute determinations :—

Lord Rayleigh	106·23
Mascart	106·33
G. Wiedemann	106·19
Rowland	106·32
Kohlrausch	106·32
Glazebrook	106·29
Wuilleumeier	106·27
Mean	106·28

If we take in Lord Rayleigh's results for the value of the B.A.U. in ohms, for 100 cm. of mercury in B.A.U. the value ·9535 instead of ·9541, as given by his own experiments, we get, instead of the values 106·21 and 106·24, the values 106·27 and 106·30. The mean, then, of the whole would be 106·29. If we include the three numbers (9, 10, 11) of the table we get the value 106·30.

It seems then, to me, that the number 106·30 certainly expresses the true value within one or two in 10,000, and that the time has come for carrying the conclusions of the Paris Congress one place further. The establishment of the new standardising laboratory calls for some authoritative expression of opinion here in England. Are we prepared to express our opinion?

In 1886, the Standards Committee agreed, on the motion of Sir W. Thomson, (1) to recommend for adoption for a term of 10 years the legal ohm of the Paris Congress as a legalised standard sufficiently near to the absolute ohm for commercial purposes, and (2) that at the end of 10 years the legal ohm should be defined to a closer approximation to the absolute ohm. The Government took no action on this matter, and the opportunity is afforded us of revising, not in ten years, but in four, our provisional suggestion. Shall we replace the 106 cm. by 106·30 c.m. For my part I should be guided greatly by the amount of acceptance that such a decision would meet with. If Prof. Rowland and Prof. Barker, who was with us in 1886, can tell us that they would agree in recommending the Government of the United States to adopt the same view, and if M. Mascart thinks that such a course would meet with the approval of himself and his distinguished colleagues in France, I should be heartily glad of it. If, on the other hand, they press for further time in order that experiments of a higher degree of accuracy—which can no doubt be attained, though probably at great cost—may be carried out, I should deprecate the committee coming to any conclusion which might pledge them to a number which does not meet with general acceptance.

ON THE CHARACTER OF STEEL USED FOR PERMANENT MAGNETS.*

BY W. H. PREECE, F.R.S.

In the discussion which followed the reading of Dr. John Hopkinson's Presidential Address to the Institution of Electrical Engineers, I took the opportunity to point out that the quality of magnetic steel in England had deteriorated, and that it was not to be compared with that produced in France in 1881. This statement was questioned at the time, and I determined to make an exhaustive test of the various steels that are now in the market. Specimens were, therefore, obtained from the leading firms in Sheffield, viz., Messrs. Joseph Ashforth and Co., Messrs. Saunderson Bros. and Co., Messrs. Thomas Jowitt and Sons, Messrs. Vickers, Sons and Co.; Mr. G. P. Wall, and also from the following manufacturers in France :—M. Marchal and M. Clemandot. Mr. Webb, of Crewe, also gave me some samples of the steel used in those works.

The magnetometric method has been followed throughout in this inquiry. Square bars, approximately 10cm. long and 1 square cm. in section, were chosen as test pieces in preference to the long wires, ellipsoids, or other special forms of magnet usually employed in very accurate investigations. These bars are comparable in dimensions with the magnets actually employed for telegraphic purposes; they are very convenient for use with the magnetometer, they can be kept in a relatively small compass for periodical testing, and they enable us to compare the magnetic qualities of different steels with very great accuracy. Although they can only be regarded as approximately solenoidal, yet it is believed that the values of the induction intensity of magnetisation, and specific magnetism, calculated from the magnetic moments of the various specimens, are sufficiently accurate to be of scientific interest. In order to facilitate calculation, it was desirable that the bars should be exactly 10cm. long, by 1 square cm. in section, but it was found that the specimens received could not be worked to this precise size. I have therefore determined their dimensions and weights by careful measurements, and have given the details in the Tables on p. 548. All the English specimens were carefully and uniformly tempered in water in accordance with our usual practice. Of the four magnets made of Allevard steel two were tempered in water, and two in mercury. The Clemandot compressed steel and the Marchal magnets were already tempered and magnetised when received from Paris.

For magnetising the bars a powerful electro-magnet (of a form suggested by Prof. Perry) was employed (*see* Fig.) The coil of the electro-magnet is wound with 136 turns of ·508cm. copper wire, the length of the coil between the cheeks being 9·3cm. The soft iron core is 10cm. long and 3cm. in diameter, and the pole-pieces are 11·5cm. and 3cm. square. The upper pole-piece (which may be removed and replaced by one of a form suitable for maximum induction experiments) is furnished with a thumb-screw and a small movable block, so that the bars to be magnetised may be clamped in position, care being taken that their ends are well faced, and make perfect contact with the pole-pieces.

In the first series of experiments the magnetising current employed was 100 amperes (13,600 ampere-turns), and it was kept on for 30 seconds for each bar.

In the second series the current was increased to 325 amperes (44,200 ampere-turns), and kept on for three seconds in each case. Generally speaking this increased current did not increase the permanent magnetisation of the bars; but, on the contrary,

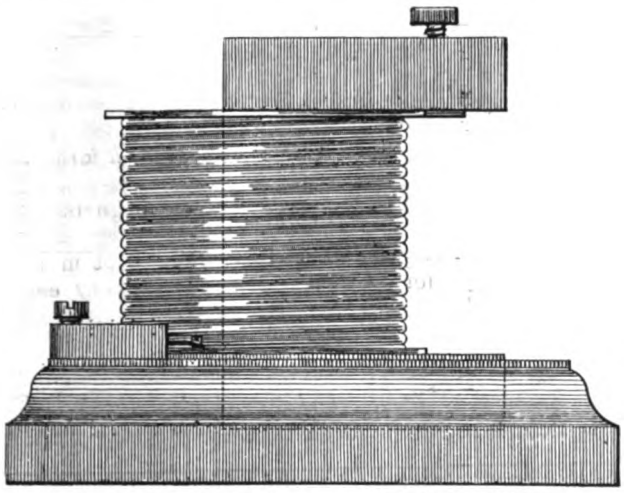
* Paper read before the British Association in Section A, Leeds September, 1890.

Digitized by Google

the magnetisation was, in most cases, apparently slightly less than it was after magnetisation with 100 amperes three months previously. The magnetisation of the Clemandot and Marchal magnets was, however, considerably *increased* by the same treatment, as will be seen from the tabulated result of the *experiments*.

The magnetometer employed is simply a Thomson mirror, suitably mounted with levelling screws, and placed over the centre of a millimetre scale two metres long. The scale for reading the deflections is of the usual straight kind with central zero, and is placed at a constant distance of 100cm. from the mirror. The magnets were, in most cases, tested with their centres at distances of 100 and 75cms. from the mirror, the mean of readings on either side of zero in each position was taken. The moments have been calculated from the formula: $M = \frac{H}{2}\frac{(r^2 - l^2)^2}{r}\tan.\ \theta$; r being the distance of the magnet from the mirror, and l half the length of magnet (= 5cms. very nearly). The maximum value of 2θ being only about 4°, tan. θ has been taken as equal to $\frac{\tan.\ 2\theta}{2}$.

The value of H for the room in the General Post Office in which the first series of experiments were made was determined both by the coil method and by the method of vibrations.



Electro-magnet used for Magnetising the Steel Bars.

1. Experiments with a coil of 18 turns, and a mean radius of (15·6) cms. :—

Date.	Current.	Distance of coil from mirror.	Deflection.	Tan. θ.	H.	Mean value of H.
	amperes.	mm.	mm.			
June 12th...	·5	1,000	21·01	·01047	·1268	
„ „	·53	600	96·14	·04803	·1275	
„ 15th...	·5	1,000	20·93	·01046	·1269	·1276
„ „ ...	·47	750	44·79	·0224	·1285	
„ „ ...	·44	600	79·53	·03965	·1282	

2. Experiments with glass hard magnetised wires. H calculated from the formula, $H^2 = \frac{8\pi r K}{T^2 (r^2 - l^2)^2 \tan.\ \theta}$.

June 15th.	Moment of inertia K.	r.	Deflect.	Tan. θ.	Time of complete vibration, T.	H.	Mean.
		mm.	mm.		secs.		
No. 1 wire..	5·6421	400	17·58	·00879	7·075	·1278	
„ 2 „ ..	5·574	„	12·14	·006069	8·462	·1278	·1277
„ 3 „ ..	5·574	„	17·48	·008738	7·062	·1276	

The values of H thus obtained, although agreeing closely with each other, being surprisingly low, the same wire magnets were taken to a spot four or five miles from the G.P.O., and it was then found that their periods of vibration were reduced respectively to 5·99, 7·14, and 5·95 seconds, making H about ·1782, and showing that the previous determinations were fairly accurate.

During the second series of experiments the following values of H were obtained by the coil method :—

Date.	Current ampere.	Distance of coil from mirror.	Mean deflection.	Tan. θ.	H.	Mean value of H.
		mm.	mm.			
Aug. 23.....	·48	1,000	20·09	·010045	·1269	
„ 23.....	·47	750	44·37	·022185	·1·97	·1280
„ 24.....	·455	„	42·70	·021350	·1269	
„ 24.....	·44	„	41·86	·02093	·1287	

Taking the strongest magnets of each group in the second series of experiments, and arranging them in order, we have:—

	Induction.
Marchal, No. 1	2,835
Clemandot, No. 1	2,362
"Allevard," No. 3 (water tempered)	1,879
Ashforth, No. 4	1,779
Jowitt, No. 2	1,745
Wall, No. 4	1,689
Saunderson, No. 1	1,610
"Allevard," No. 2 (mercury tempered)	1,528
Crewe "spring," No. 1	1,436
Vickers, No. 2	1,297
Crewe" rivet," No. 3	217

If we take the mean induction of the magnets of each group, which is probably a fairer method of comparison, we obtain a slightly different order, viz. :—

	Mean Induction.
Marchal	2,540
Clemandot	2,265
Ashforth	1,704
Allevard (water tempered)	1,660
Wall	1,519
Jowitt	1,503
Saunderson	1,435
Crewe "spring"	1,391
Allevard (mercury tempered)	1,315
Vickers	1,174
Crewe "rivet"	186·6

The induction in these short straight bars is comparatively low, because we measure only the lines (Maxwell's B) that radiate from the ends. Prof. Perry has succeeded in getting as much as 12,700 with Jowitt steel, through the middle of a magnet of a special horse-shoe form. It ought, apparently, to be possible to get about 20,000 with the best French steel. I happen to have in my possession two small horse-shoe magnets of Allevard steel which were made for Mr. H. Edmunds, and magnetised in Paris in 1881. The induction of one is now 3,287·3, and of the other 3,552·5. They have never been touched since 1881. The retentiveness is therefore very good.

The marked superiority of the Marchal magnets over those made of English steel is evidently not due to the method of magnetisation adopted by the maker, since their mean induction was increased by 38 per cent., and their magnetisation rendered more uniform by re-magnetisation in our coil. Their greater strength must therefore be due either to the quality of the steel, or to the mode of tempering—most probably the latter. The Clemandot compressed steel magnets, too, which were very poor when first tested, had their mean induction more than doubled by re-magnetisation. In view of the results of these experiments, I purpose to investigate further the methods of tempering magnet steel. It is pretty clear there is room for improvement in our present practice.

I am indebted to M. Trotin, of the French Telegraphic Administration, for having kindly procured the French specimens for me.

All these measurements have been made with great patience and skill by Mr. Henry Hartnell.

DISCUSSION.

Prof. PERRY said that when some months ago, at the Institution of Electrical Engineers, Mr. Preece made a remark about the greatest induction obtainable in comparing the inductions in steel, he thought that gentleman was speaking of the maximum permanent induction that could be obtained; but, of course, he was really speaking of the maximum per-

manent induction when obtained in a tap of a particular shape. He supposed they could not have a fairer way of trying different steels than in comparing them in this way—that is, taking the same size of tap; and they must take the comparative numbers given by Mr. Preece as representing the facts, at all events when the steel is used for magnetic needles, and so on. Whether, however, a different result would not be obtained if the greatest maximum permanent induction were sought after, he was not quite sure. He rather understood from the Paper that the steels were not all tempered in exactly the same way. The English steels were tempered at the Post Office, tempered in water, and perhaps one or two may have been tempered in mercury.

Mr. PREECE: One in mercury.

Prof. PERRY, continuing, said he understood no tempering was done in England in the case of the Allevard steel. He considered that point was of great importance, and he understood that Mr. Preece's own view was that the whole thing may have been due to the tempering. Minute differences had been discovered among the best English steels, which might be due to slight differences in the tempering. Might not the Allevard people have a secret for tempering which we did not have in this country? He had had steel from a certain maker, and wanted to get the best result he could from it. His object was to get the very best induction he could. He had three specimens, which seemed to be of the same material. He tempered one in water, making it as hard as he could. The second he tempered in mercury; but he came to the conclusion that the mercury he tempered it in was not large enough in bulk. The third he tempered in a large quantity of cold mercury; and he found, speaking from memory, three times the induction. It was quite an astonishingly large increase that he obtained from the steel tempered in the large bath of mercury. Mr. Preece was quite right in thinking that a great deal was due to tempering, and that an investigation into the effects of different kinds of tempering might lead to very important results.

Prof. BARRETT said a good deal of this question would be taken up by the Committee on recalescent points. The exact temperature at which the heated steel was hardened by quenching, as well as the rate of quenching, would be found to be important. If quenched short of the recalescent point no hardening ensued, and steel could not be tempered. Hence the subject connected itself with the Committee of which he was Secretary, on the magnetic and other phenomena connected with the recalescent point in steel. He would be very glad if Mr. Preece would favour the Committee with specimens of the steel he was using. Dr. Ball, in a recent Paper read before the Iron and Steel Institute, had shown that both the tensile strength and magnetic properties of steel underwent a sudden change when the steel was quenched at two critical points, one about 700° C., and the other about 1,300° C. In his experiments, Mr. Preece would probably find it very necessary to make use of the thermo couple. The extremely interesting point was the exact temperature at which the steel was suddenly hardened or suddenly quenched in water.

Mr. PREECE said it was his intention to pursue the question of tempering. He was going to take a great number of samples of steel, raise them to different temperatures, and quench them in different cooling mixtures, such as oil, water, and mercury. If anyone wanted any experiments tried, or had any suggestions to make to him, he should be very glad to hear from them.

Prof. PERRY then described a magnet which he had constructed, and of which he subsequently drew the following sketch on the blackboard. He said

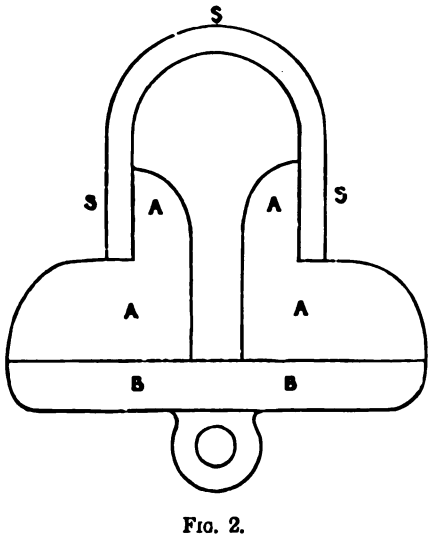

FIG. 2.

that after Mr. Preece's statements at the Institution of Electrical Engineers, he had made it his aim to get the very highest maximum permanent induction that he could. Mr. Preece had spoken of about 1,700 as the usual thing in English steel. He had obtained with English steel about 12,700, and believed that he could have obtained a good deal more by shaping his magnet better. He knew that it was a magnet which would not be employed in any instrument, but for his purposes he thought it was the best. Probably he could scheme a worse. First of all he made experiments in steel, and he found that the harder he made the English steel the better. He had hardened in cold mercury, but if he could harden in something better than that it would be better suited for a great permanent magnetic induction.

Sir WM. THOMSON said he was reminded by Prof. Grey that some years ago in experiments they were making they had experienced great difficulties in getting exactly similar specimens of steel from the same maker. They found the specimens differed exceedingly—10 to 20 per cent.—in their magnetic value, although the maker alleged that they were as nearly the same as he could make them. When they got a very good specimen, and asked the maker to give them more like that, they had very great difficulty in obtaining what they required. One thing they arrived at quite early—that it could not be too hard. He was at first assured that it would not do to make it very hard; specimens were sent, and they did not come up to what he knew they ought to. He sent some specimens back and asked to have them tempered as hard as they could be made. He was told, "We cannot be sure that they will not split;" he answered, "I do not care if it is split along the whole length, give it me as hard as you came make it;" and it was only when he had impressed that idea on the different makers that he got good results. They left the subject in a crudely developed state, and he was exceedingly glad that Mr. Preece had taken it up so effectively. He thought the results would be exceedingly valuable—not merely interesting to science, but very valuable indeed for many important purposes, because notwithstanding what had been said on dynamos, there was still a great career for hardened steel magnets. They reckoned always in intensity of magnetisation, and he wished people would come back to that. The standard result used to be for the very best steel 100 C.-G.-S. intensity of magnetisation per gramme weight; and he was greatly pleased to see such high results as Mr. Preece had put before them. They were enormously better than had previously been supposed to be attainable. One hundred magnetic moment per gramme, multiplied by the specific gravity of steel 7·8 (that was a convenient way to put it), gave them 780 as the magnetic moment per cubic centimetre, and that was formerly considered to be the highest that could be attained. It seemed now that 10 per cent. more than that, and possibly even double that, might be looked for.

SIR WILLIAM THOMSON'S ELECTRIC METER.

The following are a few particulars of the new electric meter shown by Sir W. Thomson to Section G, full details of which we hope shortly to give to our readers:—The general principle may be described as that in which a specimen of the current is chosen at certain intervals and is measured on a counter train. The current is measured on the Weber dynamometer principle. A moveable coil in a shunt circuit, having a non-inductive resistance in series with it, is carried at the top of a long vertical lever or double pendulum pivotted close to its centre of gravity. A "wheel-barrow integrator," consisting of a counter train, whose unit arbor is provided with a rolling disc, forms the counterpoise to the coil. A series coil, fixed to the back of the case, repels the shunt coil as in Sir William Thomson's balances. The lever thus constitutes an inspectional amperemeter. Beneath the counter revolves a large drum, or rather part of a drum or cylinder, the cylindrical surface being cut away in such a manner that the part which is left would, if developed, be the curve representing the movement of the shunt coil for different currents. This drum revolves once in six minutes. When a heavy current is passing, the wheelbarrow integrator is swung in towards the disc which carries the drum, and it rolls on the cylindrical surface for a considerable portion of one revolution. With a smaller current the integrating wheel will touch that part which has been more cut away. The principle and the method by which it is carried out resembles, therefore, the Frager meter, which is extensively used in France, and which was fully described in *The Electrician* of July 11, 1890.

With regard to the fact that as the instrument stands at present it is in a rather expensive form, Sir William Thomson said that the reduction of expense is the life and soul of engineering. Economy must always be considered except in the building of ironclads, and the work of Section A. There work should be done regardless of expense. The construction of standardising laboratories and of the instruments used in them should also be carried out without any attempt at economy. His endeavour was always first to make the most perfect instrument possible, and after it was completed economical considerations might be entertained.

The Telephone in the French Army Manœuvres.—The captive balloon, whose capabilities are being put to the test at the French army manœuvres near Cambrai, is placed in telephonic communication with the troops which it accompanies.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xv.) are accepted up to 5 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1890 Edition consists of about 850 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

Orders for the 1890 issue should be forwarded AT ONCE *to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.*

ELECTRICAL BOOKS AND PUBLICATIONS.

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

EWING'S THEORY OF MAGNETISM.

Once more must the pen of the chronicler record an important piece of scientific progress. The satisfaction with which the news will be received by the majority of our readers will, doubtless, be redoubled when they learn that the honour of the new advance rests with British science. It is with no new invention that we are confronted; not even with a discovery, in the popular sense of the word. The advance, which is none the less important because as yet it has not indicated the way to any commercial invention, is nothing more or less than a new theory of molecular magnetism. The new theory is acceptable beyond all previous attempts simply because it succeeds, where all previous theories have failed, in explaining the facts upon a simple and reasonable basis. Unlike so many hypotheses which go by the name of theories, the new theory needs no elaborate mathematical symbols to set forth its merits: it appeals to the logic of experiment and to the sense of observation.

To put the matter in a clear light we must go back to the older theories. POISSON'S suggestion that every molecule of a magnetisable body contained two magnetic fluids within it, and that the act of magnetisation consisted in separating the two fluids within each molecule, may be dismissed along with the now-abandoned fluid theories of all kinds. The germ of truth in it was the notion that magnetism was a property resident in the molecules rather than in the mass. AMPÈRE'S brilliant speculation that magnetism consists in the presence of electric currents circulating incessantly around each magnetic molecule is at the present time susceptible neither of proof nor of disproof; but without further assumptions it cannot afford a complete explanation of the known properties of magnets. WEBER bettered the theory of magnetism in two ways. Instead of supposing, with POISSON, that the magnetism of the molecule was something produced in it by the act of magnetisation, he assumed the molecules of an ordinary piece of iron to be always magnets, but that their axes of magnetisation lie indifferently in every direction in a perfectly miscellaneous

Digitized by Google

fashion; and that when a magnetising force is applied they simply are turned from their initial positions so as to point more or less in one direction, the whole body thus gradually becoming a magnet. WEBER'S second point was that to such a motion of turning of the molecules there was offered a force of restitution which opposed their change of position, making it difficult to magnetise the body. WEBER'S theory offered some advantages over anything previously proposed. It accounted for the then imperfectly known fact that there is, for each substance, a limit in the amount of magnetisation that can be imparted to it. To this supposition MAXWELL added the suggestion that there might occur, by internal forces resembling friction, something which gave the molecules on being turned a permanent set. This accounted for the coercive force or retentivity shown by certain qualities of iron and steel; for all that was needful to suppose in their case was that in these substances the internal molecular friction was relatively great. In recent years some further attempts have been made, notably by Prof. HUGHES, to elucidate the *modus operandi* of molecular magnetism by observing the effects on magnetisation of subjecting the iron to torsional forces. HUGHES has laid down the view that in iron or steel which has been magnetised, and subsequently demagnetised by violent torsion or vibration, the molecules have rearranged themselves in closed chains or groups, which thereby cease to exercise external actions, their arrangement in molecular circuits having the effect of mutually satisfying their polar forces.

The facts for which any magnetic theory has to account are, however, somewhat complex; and of late years the advances made in our knowledge of magnetic phenomena have seemed to render theorising difficult. The retentivity exhibited by hard steel has been found to be only an extreme case of a much more general phenomenon, known now by the name of *hysteresis*, a phenomenon which has been thoroughly explored by Prof. EWING, to whom we owe, indeed, this useful name. The disappearance of energy which is observed in carrying a mass of iron (even well-laminated iron) through a complete cycle of magnetic operations is another recent fact needing to be accounted for, and suggestive of WEBER'S notion of internal friction. The study of the curves of magnetisation plotted out from observations upon the relative amounts of magnetism obtained with different degrees of magnetising force showed them all to agree in one peculiarity of form. For very small degrees of magnetising force the curves were all nearly straight lines of gentle slope; then they suddenly turned upward, and finally bent over in a sort of knee, as so-called saturation was neared, continuing thence a slow gentle slope upward as before. To find a simple algebraic expression for the complex physical relation indicated by these curves was no easy matter. In vain did MÜLLER, LAMONT, FRÖLICH, and even MAXWELL, essay to lay down a formula. The law of the electro-magnet was not to be so easily brought to terms. The sudden rising of the curve at a certain stage of the magnetisation, showed that as the magnetizing force was increased the iron somehow became suddenly more magnetisable than it was for either smaller or larger forces. A sort of instability or slip was hinted at, which the frictional theory failed to account for. Elastic forces tending to keep the molecules in their original heterogeneous or chain-like grouping might account for the initial proportionality between the force and its effect; but one had to imagine some further action to occur when the proportionality suddenly came to an end. MAXWELL, indeed, seems to have had a glimmering that the force tending to restitution might be due, not to elastic constraint, but to a mutual action between the members of the group of molecules; but this suggestion he left infertile, embalmed between the sines and cosines of WEBER'S theory.

Upon all this maze of ideas a flood of light has now been thrown by Professor EWING. A true descendant of old GILBERT, the father of magnetic science, he has demonstrated by experiment that for which others sought in vain by curious speculation. As GILBERT demonstrated the theory of the mariner's compass by constructing a magnetic model of the globe, so EWING has demonstrated the theory of magnetism by constructing a model of a magnet. He has built up his model by the simple device of procuring a large number of pivoted steel magnets, and grouping them together so that their mutual actions may, on a gross and magnified scale, resemble those of the molecules within a magnetic body. These groups of magnets he has then exposed to the action of an external magnetic force, by surrounding them with a copper wire spiral traversed by an electric current. In this way he has obtained a direct view of the molecular interactions, and possessed himself of the secret that had evaded all mathematical analysis. The molecular magnets arrange themselves, not indeed in rings or chains, but in certain heterogeneous groups, which, under the application of an external magnetising force, are modified. Small magnetising forces cause small motions of nearly proportional amount. Larger magnetising forces may produce such large deflections that some of the needles in the groups will suddenly swing round, having reached a position of unstable equilibrium; but having once turned round they will remain turned, even though the magnetising force is removed. The effects which Prof. EWING has seen and chronicled can be entirely explained by the supposition that the only internal molecular forces concerned are those due to the mutual magnetic forces existing between the members of the groups. One does not need to postulate elastic constraint, nor mechanical friction between the molecules to hold them stuck when turned far round. Internal magnetic forces suffice to account for the whole of the effects hitherto ascribed to internal friction. The whole thing is so simple, so perfect, that its novelty seems almost absurd. Once having learned it, one seems to have known it for years. Strange, indeed, it would be if no one had ever before experimented with a group of compass-needles exposed to external magnetic forces, or noticed their singular and unstable behaviour as the magnetic force was increased. Every one who has a taste for magnetic experiments ought to give himself the pleasure of reading Prof. EWING'S account of his singularly beautiful research, and of repeating the experiments forthwith.

Comparison of Electricity and Compressed Air.—In a Paper recently read before the South Staffordshire Institute of Mining Engineers, an abstract of which appears in the *Journal* of the Iron and Steel Institute, Mr. H. W. Hughes collected details of cost and efficiency of electric transmission of power, and compared them with the cost of pneumatic transmission. At the Chapin Mine, in Michigan, air is compressed to 60lb. pressure at 60° F. by four turbines, and is conveyed through a 24in. pipe for three miles. The pipe cost £12,000, and the total cost of the plant is estimated at £100,000. A test showed 1,430 indicated horse-power at the compressors, and the sum of the indicated horse-power at the mines was only 390; the loss is, therefore, nearly 73 per cent., and this amount does not include friction of the compressors. In a second case a 500 horse-power turbine compressed air and delivered it three miles distant. The efficiency was 32 per cent., and the cost of the plant £84,000. An electrical company (he states) have agreed to give an efficiency of 60 per cent. from a similar turbine for a cost of £17,520, inclusive of the entire electrical equipment.

SUGGESTIONS TOWARDS A DETERMINATION OF THE OHM.*

BY PROF. J. V. JONES.

"On the whole I am of opinion that if it is desirable at the present time to construct apparatus on the most favourable scale, so as to reach the highest attainable accuracy, the modification of Lorenz's method, last described, is the one that offers the best prospect of success. Before this is done, however, it appears to me important that the value now three times obtained in the Cavendish Laboratory, by distinct methods, should be approximately verified (or disproved) by other physicists. To distinguish between this value and those obtained for instance by Kohlrausch, by Lorenz, or by the first B. A. Committee, should not require the construction of unusually costly apparatus. Until the larger question is disposed of, it seems premature to discuss the details of arrangements from which the highest degree of precision is to be expected."

The above passage, which concludes a Paper communicated by Lord Rayleigh to the *Philosophical Magazine*, in November, 1882, nearly two years before the Electrical Congress in Paris, at which the legal ohm was defined to be the resistance of a column of mercury of 1 sq. mm. section and 1,060 mm. long, seems not to have met with adequate response in this country. So far as published experiments in English laboratories are concerned, the determination of the ohm remains where Lord Rayleigh left it, except for the contribution made by Glazebrook and Fitzpatrick in their measurement of the specific resistance of mercury in terms of the B. A. unit, which is one of the elements in the determination of the specific resistance of mercury in absolute measure by Lord Rayleigh's adaptation of Lorenz's method.

But though in England the scientific world has during the last seven or eight years occupied itself with other things, in other countries, and more especially in America and France, measurements have been made which have confirmed the Cavendish Laboratory result as against the other values mentioned by Lord Rayleigh in the passage quoted. Further, indication has already been given of the intention to employ as the unit of electrical resistance in the new Government Standardising Laboratory not the so-called legal ohm, but the true ohm as nearly as it can be determined; and Major Cardew, in the Paper recently read by him before the Institution of Electrical Engineers, has invoked the assistance of Lord Rayleigh and the British Association Electrical Standards Committee in the preparation of the required unit. The work judged necessary by Lord Rayleigh before the condition of a more accurate determination could be advantageously discussed having been done; and practical necessity for an authoritative determination having arisen in connection with the standardising laboratory, the time seems right for a consideration of arrangements likely to secure high accuracy; and it is with this view that I venture to bring before the Section the suggestions embodied in this Paper.

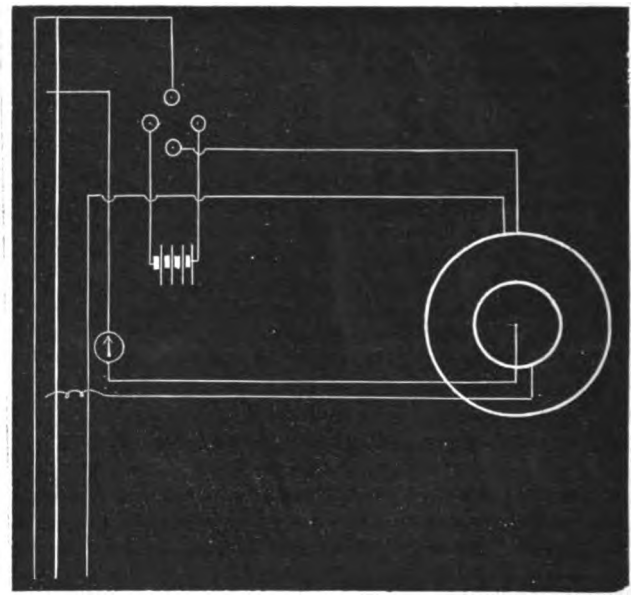
In the hope of paving the way for a more accurate determination (and initially moved to the work by the invitation given in the passage which I first read), I have for a considerable time been engaged in submitting to the test of experiment certain modifications of the method of Lorenz which occurred to me as likely to lead to increased accuracy and certainty. I do not propose to trouble the Section with the details of these experiments, which I hope may be published elsewhere. I mention them merely to give the suggestions brought forward the support derived from a determination actually made on the lines indicated. The experiments have been made in the laboratory of the University College at Cardiff, with apparatus for the most part constructed in the College workshop. Five complete sets of observations were taken in the spring of this year with the following results for the specific resistance of mercury at 0° C.:—

(i.)	94,103 absolute units.	(iv.)	94,045 absolute units.
(ii.)	94,074 " "	(v.)	94,021 " "
(iii.)	94,093 " "		

Mean 94,067 ± 10 (probable error). The result may be otherwise expressed by saying that the ohm is equal to the resistance of a column of mercury of 1 square mm. sectional area, and 106·307 centimetres long, the probable error being ±0·012.

It is far from my intention to bring these numbers forward as the best determination possible by the method I have used. I do not think they at all represent the accuracy attainable if the apparatus were to be constructed on a scale a little larger, and with a certain perfecting of detail. Under such circumstances I am of opinion that a single set of observations will give a result accurate to one part in ten thousand, and that as a mean of a number of observations we may, perhaps, aim at the hundred thousandth if regard is paid to the maintenance of definite temperatures in all parts of the apparatus, and if we can be said to know our lengths standards to this degree of accuracy.

In Lorenz's method a metallic disc is made to rotate in the mean plane of a coaxal standard coil (see diagram). Wires touching the centre and circumference of the disc are led to the ends of the resistance to be measured, and the same current is passed through this resistance and the standard coil. The connections being rightly made we may, by varying either the rate of rotation of the disc or the resistance to be measured, so arrange matters as to have no change of current in the circuit



of the disc and wires joining it to the ends of the resistance when the direction of the current through the resistance and the standard coil is changed. When this arrangement is effected there is a balance between the electromotive force due to the motion of the disc in the magnetic field of the current in the standard coil, and the difference of potential at the ends of the resistance due to the current traversing it. If this adjustment is made, let us say that the apparatus is in an equilibrium position.

If M = the coefficient of mutual induction of the standard coil and the circumference of the disc;
n = the rate of rotation of the disc (number of revolutions per second);
R = the resistance;
γ = the current through the standard coil and resistance;
then, in an equilibrium position,

$$M n \gamma = R \gamma$$

or

$$M n = R.$$

In practice it is not possible to take the coefficient of mutual induction, and the rate of rotation large enough to make the measured resistance more than a small fraction of an ohm*; and

* Paper read before the British Association, in Section A, Leeds, September, 1890.

* Lorenz ·0008 ... ... ·002
Rayleigh ·002 ... ... ·004

Digitized by Google

this has usually been regarded as one of the difficulties of Lorenz's method.

In order that the absolute unit may be recoverable at pleasure without the fatigues of a new absolute determination, it must be defined in practice by reference to the specific resistance of some standard substance, and for many reasons there is a consensus of opinion in making this standard substance mercury. The determination of the ohm as a practical problem, therefore, becomes identical with the determination of the specific resistance of mercury in absolute measure, and the small resistance measured by the method of Lorenz's must, in order to complete the investigation, be brought into relation and compared with the specific resistance of mercury. Lorenz himself evaded the difficulty by taking for his measured resistance the resistance of a mercury column contained in a glass tube; the resistance of the column was then obtained in absolute measure, and the specific resistance calculated from the dimensions of the column. It is hardly possible, however, that the latter calculation can have been, or is likely to be, achieved with accuracy, however accurately the tube be calibrated. For, on the one hand, if the wires from the disc (the terminal portions of which may be called the electrodes) are led to the ends of the tube, the equipotential surfaces touched by them are not plane; and, on the other, if they are let into the tube at some distance from the ends, it is difficult to see how the distance between them is to be measured with the requisite accuracy.

Under these circumstances Lord Rayleigh preferred to use solid conductors, overcoming the difficulty of comparing the resistance measured with ordinary standards by a shunt method, which made it possible to express it at once in terms of the B.A. unit. The B.A. unit being thus found in absolute measure, a separate investigation of the specific resistance of mercury in terms of the B.A. unit completed the determination. Rowland and others have adopted the shunt method of Lord Rayleigh, which may be said to be an essential feature in the more probable determinations by Lorenz's method. Spite of the conspicuous success which has attended the use of solid conductors by the shunt method, I venture to suggest a reversion to Lorenz's use of mercury. The physical constant to be measured is the specific resistance of mercury; and if this can, by direct measurement, be determined with accuracy, it seems inconvenient and undesirable first to determine the resistance of the B.A. unit in absolute measure, and then to determine the specific resistance of mercury in B.A. units. If consistently with accuracy the artificial B.A. unit can be dropped out of our experiments as well as out of the result; and the measurements made directly on mercury, the simplicity would seem to be a recommendation, and the argument is perhaps enforced by the consideration that there is very nearly as much divergence in the results of different observers for the specific resistance of mercury in B.A. units as there is in the values obtained for the B.A. unit in absolute measure.

The objections to the use of mercury in a tube are unanswerable; but the difficulties disappear if instead of placing the mercury in a tube, it is placed in a long trough, and if instead of measuring the distance between the two electrodes, one electrode is kept fixed while measurement is made of the distance moved through by the other between two equilibrium positions corresponding to two different rates of rotation of the disc. The latter measurement it is easy to make with accuracy, for the movable electrode may be rigidly attached to the movable headstock of a Whitworth measuring machine or some other measuring bank placed parallel to the length of the trough; and the two equilibrium positions may be taken near the middle of the trough so as to avoid danger of curvature in the equipotential surfaces passing through the electrode in its two positions.

Let n_1, n_2 be the rates of rotation of the disc, and let l be the distance between the corresponding equilibrium positions of the movable electrode.

Then $$M(n_1 - n_2) = \frac{l}{A}\rho$$

where ρ = the specific resistance of mercury.
A = area of section of the mercury column.

But we are met by a new difficulty, the determination of the section of the mercury column. The capillary depression at the sides of the trough would make it a most serious task to determine the section by direct measurement to the required degree of accuracy.

Fortunately, this difficulty may be overcome by a further differential method, viz., by making observations with the mercury at two different heights in the trough.

Let b = the breadth of the trough;

$h_2 - h_1$ = the difference of height of the mercury surface in the two cases;

and let A = the section of the mercury column when the mercury is at the lower position.

Then we have, denoting by dashed letters, the new values of the rates of rotation and the distance between the corresponding equilibrium positions—

$$M(n_1 - n_2) = \frac{l}{A}\rho$$

and $$M(n'_1 - n'_2 = \frac{l'}{A + b(h_2 - h_1)}\rho$$

whence eliminating A

$$\rho = \frac{M\, b\, (h_2 - h_1)}{\frac{l'}{n'_1 - n'_2} - \frac{l}{n_1 - n_2}}$$

It is assumed in the above formula that the sides of the trough in that part of it traversed by the movable electrode are plane, parallel, and vertical.

Hence the determination of the specific resistance involves the determination of:—

(i.) Four equilibrium positions, two at each depth, with the rates of rotation of the disc to which they correspond.

(ii.) The breadth of the trough in that part of it traversed by the movable electrode.

(iii.) The difference of level of the mercury surface at the two depths.

(iv.) The co-efficient of mutual induction of the coil and disc.

The difficulties attached to the determination of equilibrium positions and the coefficient of mutual induction belong to all forms of Lorenz's method, whether the resistance measured is that of a solid conductor or that of a mercury column. Those specially incident to the use of a mercury column are:—

(i.) The manufacture of an accurate trough, and

(ii.) The accurate measurement of the difference of level of the mercury surface in its two positions.

The trough used by me in the experiments of which I have spoken, was cut in paraffin wax contained in a strong casting of iron with its sides strengthened by outside ribs. The channel is approximately 43·5in. long, by 1·5in. broad, by 3in. deep. It was first cut by a cutter rotating about 2,000 times a minute, attached to the slide rest of the College Whitworth Lathe, and subsequently finished by a scraper, attached in similar fashion, which took a very thin cut off sides and bottom. The result of the scraping was a very smooth and highly-finished surface.

This method of obtaining a channel for the mercury was adopted in the hope that, so cut in the lathe, it might present a breadth constant to two or three ten thousandths of an inch. This hope was not realised; the results of subsequently calibrating the trough over the 10in. of it traversed by the movable electrode indicated a variation of as much as ·001in. in its breadth. The objections to the use of paraffin wax are:—

(i.) Its softness makes it necessary to proceed with great care in measuring its breadth, lest damage should be done to the surface. This difficulty is satisfactorily surmounted in the form of internal callipers adopted in the calibration, which I must not stay to describe.

(ii.) The coefficient of expansion of paraffin wax is very large, its linear coefficient of expansion being about ·0003. A change of temperature would, therefore, cause distortion in the wax channel, seeing that the wax is enclosed in an iron casing.

Digitized by Google

We endeavoured to meet the danger of inaccuracy due to this cause by measuring the breadth of the trough as nearly as possible at the same temperature as that at which the electrical observations were made, care being taken to maintain the trough at a uniform temperature throughout the observations. During the month of the observations, the temperature inside the box in which the trough was placed did not vary more than half a degree. But, notwithstanding this care, I am of opinion that the difference in the result of different sets of observations depends in the main upon variations in the trough due to varying temperature. But it is impossible to apply a correction, for paraffin wax is so bad a conductor of heat that its temperature could not be assumed to be that of the thermometers in the mercury channel; its temperature at any part would really be a function of ancient history.

Under these circumstances, I have come to the conclusion that I made a mistake in my choice of a substance; the disadvantages outweigh the apparent ease of construction. Probably a much more satisfactory result would be obtained by building up the trough of worked glass or scraped marble. I do not doubt that a sufficiently accurate trough might be made in either of these substances without straining the resources of the English mechanical engineer. We may observe that small errors become of less importance as the breadth of the trough is increased; and nothing but practical convenience limits the size of the trough we may employ, provided it is long enough in proportion to its breadth to make the equi-potential surfaces plane over the part of it traversed by the moveable electrode. It is further to be noticed that it is only the latter part of it that needs to be finished with the highest accuracy, and when the mechanical engineer has done his best, it is still possible to obtain a further approximation by a process of calibration.

The position of the mercury surface in the trough may be determined electrically by means of a pointed steel spherometer screw. The screw may be moved downwards until an electric circuit, comprising the screw and the mercury, is completed. It is of the utmost importance that the point of the screw should be kept clean, and that the mercury surface should be free from an oxide film, otherwise successive observations may differ from one another as much as ·001in.; but with clean mercury, if the point is carefully wiped with filter paper before making the observations, half a dozen observations may be without difficulty obtained, none of which differ from the mean by more than ·00004in. To preserve the point, sparking at the mercury surface should be reduced as much as possible. In order that the capillary surface should be of the same shape at both levels, the surface should always be brought to its measured position by pouring mercury into the trough, and never by taking mercury out of it.

I am of opinion that both the measurements to which I have referred as peculiar to the direct use of mercury by the differential method—viz., that of the breadth of the trough and that of the difference of level of the mercury surface—may be made with an accuracy which will compare favourably with that which we can hope for in the determination of the equilibrium position; and, perhaps, also with that which we may expect in the measurement of the coefficient of mutual induction—measurements which are common to all forms of Lorenz's method. Probably, also—though here I speak with hesitation and without experience—the accuracy will be as great as, if not greater than, that which attends the calibration of a glass tube, necessary to the determination of the specific resistance of mercury in B.A. units.

The electrical observations in Lorenz's method consist, fundamentally, in the determination of equilibrium positions, together with the rates of rotation to which they correspond. The equilibrium position is obtained when, if the direction of the current is reversed through the standard coil and trough, the reading of a galvanometer inserted in the disc circuit is unaffected. In the experiments I have made, I have found it best—following Lord Rayleigh—to take two sets of galvanometer readings for each equilibrium position, one set giving the change of galvanometer reading corresponding to reversal of the battery current for a position of the electrode slightly to one side of the equilibrium position; the other, the change of galvanometer reading corresponding to reversal for a second position slightly on the other side of the equilibrium position. The galvanometer reading corresponding to the two positions of the commutator being called E and W, passage through an equilibrium position is indicated by a change in the algebraic sign of W – E. When W – E has been found for two positions slightly differing from one another, and including between them the equilibrium position, the latter may be found by simple interpolation. Since the readings, E and W, are not quite fixed, owing to small changes in the speed of the disc and variations at the brush contacts, it is necessary to take a number of reversals and to find W – E as the mean of the values obtained by combining the first value of E with the first of W, the first of W with the second of E, the second of E with the second of W, &c. The more quickly the reversals can be made to succeed one another, the better will be the results, for with rapid reversal variations in the position of the needle corresponding to no current through the standard coil (*i.e.*, variations due to change at the brush contacts), are less likely to supervene. It is, therefore, best not to wait for the needle to come even approximately to rest after the disturbance due to the induction current on reversal, but to take the readings for the extreme positions in an oscillation, and having previously found the coefficient of damping, to calculate the position of rest from these two readings.

The whole difficulty in determining an equilibrium position arises from the want of constancy in the readings E and W; and this want of constancy is due to two causes:—

1. Variations in the electromotive force at the brush contacts.
2. Variations in the rate of rotation of the disc.

It was with a feeling akin to despair that I watched the dance of the galvanometer needle during the first running of my apparatus, when the brush at the circumference of the disc was composed of a number of layers of thin phosphor bronze sheet controlled by a spring, and the dance continued, however well the circumference of the disc and brush were amalgamated at starting. Trials were made in the hope of improvement with amalgamated copper and amalgamated lead, and with the substitution of a dead weight pressure for the spring. But no satisfactory result could be obtained. It was noticed, however, that after amalgamation the readings were fairly steady for a short interval, and it occurred to me that if mercury could be continuously supplied to the surface of contact between the brush and the disc, this steadiness might be maintained. This led on to the idea of a brush consisting of a single wire perforated by a channel through which a constant flow of mercury might be maintained from a cistern of adjustable height; and a brush of this description was finally adopted. It presents very great advantages over any other form of brush tried.

Prof. Rowland used three brushes on the circumference instead of one, and I do not doubt that a multiplication of brushes is advantageous. Three or more such brushes as I have described, resting by dead weight pressure on the circumference of a disc ground true in place, would, I believe, give an excellent result. The grinding of the disc in place is an important aid to steadiness of galvanometer reading.

It is to be noticed that the value of W – E for a position at a given distance from the equilibrium position is proportional to the current through the standard coil. Hence the small variations due to the brush contacts which do not at all depend on the current through the coil become proportionately of less importance as the current is increased. We ought, therefore, from this point of view, to use as large a current as possible. But the magnitude of the current is limited by the fact that it has to traverse the wire of the standard coil, which must not be made so hot as to risk the destruction of its insulation. This consideration points to the use of wire of considerable diameter in the standard coil. If the wire of the coil is made of large diameter, attention must be paid to the influence on the coefficient of mutual induction of the non-coincidence of the current with the axis of the wire.

The second cause of want of steadiness in the galvanometer needle is variation in the rate of rotation of the disc; and this is the real crux. We are not helped in determining the equilibrium position either by increasing the sensitiveness of the galvanometer or the magnitude of the current through the coil,

Digitized by Google

unless we procure a corresponding increase of steadiness in the running of the disc. We may increase the value of W – E for a position at a given distance from an equilibrium position in either of these ways; but unless there is a corresponding improvement in the constancy of the disc rotation no advantage results, for the variations in W and E resulting from changes of speed are proportional to W – E. Hence in the construction of apparatus for a new determination, mechanical engineers should be invited to do their very best to procure a constant rotation. No time or trouble spent in securing this will be lost for the purpose in view.

In my experiments the disc was turned by an electromotor directly coupled to it, and driven from a battery of secondary cells. Each bearing was fitted with sight feed lubricators, and a heavy steel flywheel was attached to the motor. The current passed to the motor through resistance coils, and could be varied continuously through a small range by a slide resistance of platinoid wire, after the larger adjustment had been made to obtain a speed, approximately that which was required. A shunt worked by a lever also provided the means of taking out or putting in a small resistance suddenly, so as to allow the observer taking note of the speed to counteract small variations, due to alteration in the lubrication of the bearings.

To obtain improved steadiness, the chief point needing attention is lubrication. Some forced system of lubrication may be employed. Either oil may be pumped through the bearings, or they may be fed from a cistern placed at some height above them. Attention might also be directed to the friction of the brushes on the motor commutator. I do not think we can look hopefully to an increase of steadiness from the employment of any hand brake controlled by the observer, for the mischief is done, and the alteration has come about before he observes that it is his duty to put the brake on or off. In fact, the galvanometer needle picks up the alterations much sooner than the observer's eye. An electro-magnetic brake might be useful for adjusting the speed, but could not give any additional steadiness to the galvanometer needle. This can, I think, only be procured by perfection of mechanical workmanship, and increased attention to the truth of all rubbing surfaces, and their proper lubrication.

It remains to speak of the measurements necessary to enable the calculation of the coefficient of mutual induction to be performed. To facilitate an accurate determination of the mean radius of the standard coil, I desire to suggest that it should be a coil consisting of one layer of wire. The advantage in constructing a standard coil with a single layer of wire is that every part of it is visible, and that nothing is done to alter the position of the wire after measurements are made. If a coil consists of many layers, it is not quite easy to say where, after measurement, the lower layers go to under the pressure of the superincumbent layers. Lord Rayleigh found, in the case of certain coils used by him, that the mean radius calculated from measurements made in winding was greater by one part in 2,000 than the mean radius calculated from measurements made in unwinding, a result clearly due to the compression of the lower layers by the layers above them. We should, therefore, expect that if the mean radius of a coil of many layers is calculated from measurements made in winding, it will be reckoned too large. In the face of this, it is interesting to note that in the measurements made by Lord Rayleigh by the method of Lorenz, the series in which the coils are so placed as to make the induction coefficient nearly independent of the mean radius, gives a result rather larger than the other series, which is what might be expected, if the mean radius is over-estimated. But the smallness of the variation (a little over one part in 10,000), seems to show that the error of mean radius must be very small for the pair of coils used by Lord Rayleigh. In general, we should expect, as far as this cause goes, that values of the specific resistance in determining which coils of many layers are used would come out too low, since an over-estimate of the mean radius of the coil means an underestimate of the coefficient of mutual induction. The apparent disadvantage of a coil of a single layer is that the number of turns will be fewer; and, therefore, the coefficient of mutual induction of the coil and disc smaller than in the case of a coil of many layers. We may, however, in order to get a sufficient number of turns, make the coil of greater axial length than has been customary. But we cannot, in that case, use Lord Rayleigh's formula of approximation in calculating the coefficient of mutual induction. Under these circumstances, a new formula, applicable to a coil of moderate axial length, was a desideratum. Such a formula I obtained by the direct integration of the expression $\int\int \frac{ds\,ds'}{r}\cos\epsilon$ for a circle and coaxal helix.

It is of the form

$$M = -8n\pi\frac{Aa}{A+a}\Sigma(-1)^m\frac{1.3.5..2m-1}{2.4.6...2m}\cdot\frac{1}{2m+1}\left(\frac{x}{A+a}\right)^{2m}Pm.$$

Where A = the radius of a circular section of the cylinder determined by the helix.
a = the radius of the circle.
n = the number of turns of the helix.
$2x$ = the axial length of the helix.*

and $$P_m = \int_0^{\frac{\pi}{2}}\frac{\cos 2\theta\, d\theta}{(1-c^2\sin^2\theta)^{\frac{2m+1}{2}}}$$

when $$c = \frac{2\sqrt{Aa}}{A+a}$$

P_m may be expressed in terms of c, F (c), and E (c).

This is the formula I have used in calculating the coefficient of mutual induction of the coil and disc in the experiments already mentioned. The coil is of double silk-covered copper wire of about ·02in. diameter, resting in a screw thread of ·025in. pitch, cut on a hollow cylinder of brass of about 21in. external diameter. The axial length of the cylinder is something over 4·5in., and 185 turns of wire are wound on it. The disc has a radius of about 6·5in., and the coefficient of mutual induction is about 17,000in. This is a little more than a tenth of the coefficient of mutual induction of the coils and disc used by Lord Rayleigh in the first and second series of his experiments by the method of Lorenz, but it was found to be ample for the purpose in hand.

The mean radius of the coil was measured in the Whitworth measuring machine.

Uncertainty arose from two causes :—

(1). The silk covering of the wire;

(2). The ellipticity of the coil cylinder.

The silk covering of the wire is of slightly varying thickness, and suffers compression to a varying extent during a series of measurements.

A standard coil, consisting of naked wire wound in a screw thread cut on a cylinder of insulating material, would be preferable to one of covered wire wound on a metal cylinder. There is, however, difficulty in finding a suitable insulating material. Wood immediately occurs to one's mind, but a large coil of wood, even though it be built up many pieces, is apt to change its shape with age and varying atmospheric conditions. But if a suitable insulating material, that can be turned true and that will retain its shape can be found, a single layer of naked wire in a screw thread cut on a cylinder of this material, would give us a coil the mean radius of which might be easily measured with certainty in the Whitworth machine to far more than one part in ten thousand.

The ellipticity of the coil cylinder deserves notice. The cylinder was turned with great care in the lathe already mentioned. It was cast with three lugs by which to bolt it to the face plate, and subsequently in precisely similar fashion to the strong brass frame which serves as its support during use. The first operation was roughly to fit the lugs to the face plate by filing. A roughing cut was then taken over the entire surface of the cylinder, so as to get rid of as much as possible of the internal strain due to unequal cooling of the casting. It was next unbolted and the lugs were carefully scraped to fit the face plate, and after again bolting it to the face plate the final turning was proceeded with. Very fine

* *Phil. Mag.*, January, 1889. Read before Physical Society, November 10, 1888.

cuts were taken in finishing, and it was hoped that by these precautions we should secure a true right circular cylinder. Nevertheless, measurements made in the Whitworth measuring machine show that the section of the cylinder at right angles to its axis is slightly oval. The longest diameter is 21·1056, and the shortest 21·0898, from which it appears that there is a difference of about ·008in. between the longest and shortest radius. It appears, indeed, to be a task of no ordinary difficulty to turn a cylinder of large size that shall remain true to the thousandth of an inch. Every fresh cut seems to alter its internal equilibrium, and after the cut is complete it adjusts itself to a new shape. The remedy lies in having a sufficiently massive cylinder carefully annealed to work on, and a fund of patience to make the requisite number of fine finishing cuts with a sufficient interval of time between them. In conclusion, the main suggestions I have to offer for consideration are the following:—

(I.) That the time is ripe for a new determination of the ohm that shall be final for the practical purposes of the electrical engineer.

(II.) That such a determination may be made by the method of Lorenz, the specific resistance of mercury being obtained directly in absolute measure by the differential method described.

(III.) That the standard coil should consist of a single layer of wire, the coefficient of mutual induction of the coil and disc circumference being calculated by the new formula.

EXPERIMENTS TO DETERMINE WAVE VELOCITY IN CERTAIN DIELECTRICS.*

BY F. T. TROUTON.

The method employed was described in *Nature*, February 21, 1889, and depends essentially on interposing a sheet of the dielectric between the reflector and the resonator in Hertz's well-known experiment of electro-magnetic "loops and nodes." The effect of this is to move in towards the reflector the system of maximum and minimum sparking positions. The amount of the displacement thus resulting depends on the rate of propagation of the disturbance through the dielectric sheet.

In the experiments made the sheet was placed immediately in front of the reflector. The circular form of resonation was employed to determine the position of the "loops and nodes," and it was always held so as to be only effected by the magnetic component.

If the reflection, which occurs at both surfaces of the sheet, be neglected, (μ) the index of refraction will be found by dividing (l) the thickness of the sheet into its air equivalent $\mu = \frac{(x_0 - x)}{l}$ where x is the distance from the sheet to the first node or magnetic minimum position, and x_0 the distance of the node from the reflector when the sheet is removed—that is to say, one-quarter the wave-length in air.

When the reflection from the surface of the dielectric is considered the expression for μ is not quite so simple. If we suppose the metallic reflector in optical contact with the dielectric sheet, we can then sum up the multiple reflections resulting, very much as in the well-known way of doing so for Newton's rings. Let the amplitude of the incident radiation be taken as unity, and let b be that of the reflection at the front surface of the sheet, and c of the part penetrating. This portion on reaching the metallic reflector is supposed returned, and at the front of the sheet is again divided; let the part reflected back to the metal be $c\,e$, and that sent out $c\,f$, and so on. The reflected wave is found by summing up these terms. If $\sin\phi$ is taken to represent the incident radiation at the front surface of the dielectric, the total reflection then is $b \sin\phi + c\,f\{\sin(\phi+\delta) + \epsilon^2 \sin(\phi+2\delta) + \epsilon^4 \sin(\phi+4\delta) + \ldots\}$, where $\delta = m\,2\,l\,\mu$, m standing for $\frac{2\pi}{\lambda}$. This can be written as $A \sin(\phi + 2mr)$, when $\tan 2m = r\frac{(1-b^2)\sin\delta}{(2b+(1+b^2)\cos\delta)}$. This give for μ, remembering that $b = \frac{(\mu-1)}{\mu+1}$; $\tan 2mr = \frac{2\mu \sin 2m\mu l}{\{(\mu^2-1)+(\mu^2+1)\cos 2m\mu l\}}$.

Here r is the equivalent distance in air, or $r = x_0 - x$.

Some experiments have been made with sheets of pitch, solid paraffin, sulphur, and plaster of Paris. In the case of pitch, the value of μ calculated from the above results is about what would be expected, namely, about 1·7 (Hertz by means of his pitch prism found 1·69); but in the case of the others the calculated values of μ are evidently much too large, those for paraffin and sulphur lying between 3 and 4. The area of the pitch sheet was 60 by 45c., that of the paraffin and sulphur 60 by 29c.; the thicknesses were 6·3, 3·5, and 3c. respectively. The zinc reflector placed behind the sheets was the same size as the sheets. It may be due to the small sizes employed that these unsatisfactory results were obtained, the small size of the reflector introducing diffraction phenomena—that is to say, the first node is situated at more than $\lambda/4$ from the reflector. This is due to the electrically-charged edges of the metal reflector. This is more fully referred to in *Phil. Mag.*, March, 1890. An approximate calculation of the action of such a reflector can be obtained by supposing it equivalent to a Hertz vibrator; in this way are obtained values for the velocity of the disturbance near the reflector greater than the normal. It may possibly be that these abnormal velocities (or whatever may be the true phenomenon which is equivalent to such) are effected in a greater ratio than the normal velocity is by the substitution of other dielectrics for air. In fact, taking Hertz's value for the velocity at distance ν as $v = V\frac{m^2\nu^2+1}{m^2\nu^2}$, we find something of the kind. For a dielectric whose index of refraction is μ, $v_1 \quad V_1\frac{m^2\nu^2\mu^2+1}{m^2\nu^2\mu^2}$; and the value of the index at distance ν, $\mu_\nu = \frac{v}{v_1} = \mu\left(\frac{m^2\nu^2+1}{m^2\nu^2+\frac{1}{\mu^2}}\right)$. This gives μ_ν as greater than μ the normal value.

It must, however, be remembered that at the distances in the present case the formula can hardly be satisfactorily applied. The thing might be experimentally tested by placing the sheet at a little distance in front of the reflector. There is no question but that the employment of larger dielectric sheets and metal reflectors, so as to give the equiphasial surfaces plane instead of curved, will be the best solution of the main enquiry.

When there is a space left between the dielectric sheet and the reflector, the calculation is more complicated than before, owing to the reflection from the back of the dielectric as independent of the metal. In the following this distance is supposed nothing but the back reflection from the sheet left. The result can be written as $\tan 2m\nu = \frac{A\sin\alpha + C\sin\gamma}{A\cos\alpha + \cos\gamma}$, where A is the amplitude of the reflection from the dielectric sheet alone, the metal being removed, and α the alteration in phase introduced; and where C is the amplitude of the point resulting from replacing the metal reflector, and γ the alteration in phase belonging to it. A and α are found precisely as in Newton rings.

$$A^2 = \frac{2b^2(1-\cos\delta)}{1-2b^2\cos\delta+b^4} \qquad \tan\alpha = \frac{b^2-1}{b^2+1}\cot\frac{\delta}{2}$$

To find C, let the transmitted beam be written as $B\sin(\phi+\beta)$ when

$$\tan\beta = \frac{\sin\delta}{\cos\delta - b^2},$$

and suppose this returned by the metal reflector. Part of this will be transmitted by the sheet, and part sent back a second time to the metal. The part transmitted is $B^2\sin(\phi+2\beta)$; the part reflected back to the metal is $AB\sin(\phi+\beta+\alpha)$. This

* Paper read before the British Association in Section A., Leeds, September, 1890.

Digitized by Google

is again reflected by the metal, and is again divided up. The part transmitted is $A B^2 \sin(\phi + 2\beta + \alpha)$; the part reflected is $A^2 B \sin(\phi + \beta + 2\alpha)$ and so on. Then we have to solve

$$C \sin(\phi + \gamma) = B^2 \{\sin(\phi + 2\beta) + A \sin(\phi + 2\beta + \alpha) + A^2 \sin(\phi + 2\beta + 2\alpha) + \ldots \ldots \}$$

and summing up we get the values of C and γ. Putting in for the sines their exponential values and recollecting that $B^2 = (1 - A^2)$ we get $C^2 = \frac{(1 - A^2)^2}{1 - 2A\cos\alpha + A^2}$ and $\gamma = 2\beta + \tan^{-1}\frac{A \sin\alpha}{1 - A\cos\alpha}$.

The calculations of μ from this result in practically the same values as given above. In the case of some substances it was found quite impossible to make a determination of μ after the method described, as they afforded of themselves such strong reflection. Glass even 2c. thick gave considerable reflection, as did also a limestone flag 2·5c. thick. Slate and sandstone gave reflection, but not so strong as the other two. A sheet of coal 2·5c. gave very slight reflection, but a sheet of thin battery carbon reflected like metal. No reflection could be obtained from ebonite 2·5c. thick, shellac 2c., or tallow, pitch, paraffin, or sulphur. This reflection is doubtless due to absorption of the beam reflected from the back surface, which thus weakened cannot sensibly interfere with that from the front surface. Owing to the nature of the apparatus and the fact of its constantly changing in sensitiveness, no precise measurements are possible, but a considerable number of comparisons between different substances were made in this wise. The resonator was set so as to only just spark on placing, say, a sheet of glass behind it as reflector, then quickly a sheet of, say, sandstone, and again glass. In this way it could be found that while glass caused sparking the sandstone did not. A cell (adjustable as to thickness) made of cardboard, which could be filled with various substances in a broken-up state, such as quartz, sand, chalk, lamp-black was tried. When 2c. thick no reflection, or hardly any, was found with sand, fair reflection with chalk, and lamp-black gave as "good as the limestone flag." Before the chalk was well dried it seemed to give stronger reflection. These sheets were about 1ft. square. Some quantitive method, such as that used in Germany by Rubens and Ritter, but which could be applied on a small scale, would be desirable, for these experiments are necessarily of the very roughest sort.

Prague.—A report, says *Industries*, has been issued by the Vienna Elektrotechnischer Verein, showing the present condition of electric lighting in Prague and the neighbourhood. From this it appears that at the end of last year there were 8,365 glow lamps and 143 arc lamps in various factories, theatres, and restaurants. These were supplied with current from 47 dynamos of a total capacity of 425 kilowatts. The motive power was partly derived from steam engines and partly from gas engines, the proportion of the latter being 23 per cent.

A NEW FORM OF VOLTA PILE, USEFUL FOR STANDARDISING OPERATIONS.

In exhibiting this instrument before Section G last week, Sir William Thomson said that Prof. Rowland had described a similar arrangement, but the one he had brought to the meeting contained several improvements in the details and mounting, which were the outcome of constant use in the laboratory.

Four hundred staples, constructed with one limb of copper and the other of zinc, were mounted in an ebonite frame, standing on four wooden legs. The adjacent staples were set at a distance less than $\frac{1}{10}$in. apart, their ends pointing downwards. A copper tray, with handles, was placed below the frame, and contained water. On lifting the tray, so that the ends of the staples were immersed, and lowering it again, a drop of water was left hanging by capillary attraction between the zinc and the copper of the adjacent couples. The whole then formed a simple battery of four hundred cells. The battery was not made for giving a current, but was used with an electrometer, and saved a great deal of trouble and expense compared with the setting up of a number of ordinary batteries. It had been found to be particularly useful in measuring the capacity of cables. The volts were found to be very constant from element to element, and any number could be readily taken, or they could be divided into two or more sets by means of a plug, which was merely pressed in between any pairs.

BRITISH ASSOCIATION.

DISCUSSION ON ELECTRICAL UNITS.

The reading of Mr. R. T. Glazebrook's Paper on "Recent Determinations of the Absolute Resistance of Mercury" (*see* page 543) and of Prof. Viriamu Jones' Paper on "Suggestions towards a Determination of the Ohm" (*see* page 552) before Section A, on Friday, 5th September, gave rise to the following discussion:—

Prof. HENRY A. ROWLAND, Ph.D., said, as one of the members of the United States Commission for the determination of the ohm, the matter was entrusted to his hands, the Commission consisting of Prof. Barker, Prof. Trowbridge, and himself. The experiments were carried out at the John Hopkins University, under his own supervision, with a considerable appropriation from the United States Government. The experiments had been in progress for very many years, for although the results were here given of what they originally determined—the first experiments, he might say—yet they had continued to investigate the subject to the present time; and, indeed, the whole matter had been gone over by one of his associates, who was a professor of applied electricity; and he and the students had determined not only the absolute unit, but they had made the complete determination of the mercury unit once more. He was sorry that he did not make preparations for this occasion. He had been travelling abroad for many months now, and he had made no preparation, nor had he brought any figures with him. All he could say was that the students had gone over the figures very carefully; and he thought that the number of 106·32 had been slightly diminished. He thought that it was more like the mean which Mr. Glazebrook gave; but his own recollection was not sufficient to be certain on the point. Dr. Duncan had also gone over the experiment, and got very nearly the same result. The apparatus had been brought to the John Hopkins Laboratory, where they could experiment, and the results were very similar to the mean that Mr. Glazebrook gave upon the board. He had no doubt himself that this was very near to the figure. Mr. Glazebrook had gone over it so carefully, and his criticisms had been so exhaustive, that he could say very little more with respect to it. They were agreed as to the best method, Lorenz's, and the results obtained by that method he thought agreed now and were of very great accuracy. The Commission of the United States would be perfectly willing to recommend the figures, based upon the experiments so far determined. They would recollect that the United States Commission never recommended to the United States Government any figures whatever. The 106 which was decided upon at the Paris Congress of 1884 was never accepted by the United States, even provisionally; and therefore the matter had been left entirely open up to the present time. But they felt sure that they would come to some figure of that sort, and therefore they were prepared to recommend some figure based upon the results here given. He might mention that the new superintendent of the Coast Survey had intimated to the Commission that the Government was willing to establish a standardising bureau under the charge of the United States Coast Survey.

Lord RAYLEIGH, Sec.R.S., said he felt rather antiquated when he saw his name at the head of the list of 18 with his 1882 and 1883 observations. He thought Mr. Glazebrook was right in beginning at that point. Before 1882 the results were comparatively wide. At that time the discrepancies reached 3 per cent. It was very satisfactory to find that the question was now narrowed to about 1 in 1,000, instead of 3 in 100.

Digitized by Google

From the figures put before them it certainly looked very much as if his number for the specific resistance of mercury (·9541) was rather too high. The observations were, however, carefully made, and agreed well among themselves, though the conditions were considerably varied. Since the publication of Mr. Glazebrook's measures in which the same method and, to a large extent, the same apparatus was employed, he had gone very carefully into the matter in the hope of finding where the difference between them lay, but he had been unable to find any material error in the larger number. A reduction to ·9539 might perhaps be admitted, on account of imperfect cooling to zero of the extremities of the mercury column. He quite agreed with Mr. Glazebrook that the balance of evidence was in favour of 106·30 as representing the length of the column of mercury equal to an ohm; but he thought we could hardly regard this as certain to ·02. Perhaps too much relative importance was attached to the ascertainment of this number. If we knew to 1 in 100,000 the value of the ohm in terms of mercury, what use could we make of our knowledge? The electrician did not find it convenient to set up a mercury tube to obtain the standard, and in a factory still less would mercury be employed. To make any use of the determination they must have a wire. Thus, in Prof. J. J. Thomson's recent investigation of "v" the reference to mercury does not enter, but only the relation between the B.A. unit and the ohm. From this point of view it was satisfactory to find so good an agreement between the numbers obtained by various observers for the latter ratio. The only other thing that occurred to him to say was that he did not understand why so much more importance seemed to be attached to the determination of the ohm than of the ampere or volt. For the former we had a long series of measures carried out in all parts of the world. But, so far as he knew, the ampere still rested upon the work of Kohlrausch and himself. He suggested to those prepared to tackle these questions the further determination of the ampere, which was liable to more uncertainty than the ohm.

Prof. BARKER said that he had been struck with the justness of Mr. Glazebrook's conclusions which had been placed before them, and for which the Section should be under very great obligations. He felt that they in the United States occupied a somewhat anomalous position with regard to the ohm. When the Congress of 1881 determined to submit to experimental determination in the various countries the determination of the length of the mercury column, its work was undertaken on behalf of the United States by our Commission and the work was delegated to Prof. Rowland. A great deal of care was devoted to the work, and it occupied some time, and in consequence it was delayed; and when the meeting in April, 1884, took place the Commission petitioned for a further postponement in order to enable the results of the experiments to be presented to the Paris Conference. However, the action was taken in Paris upon results which did not include the American observations, so that the Americans had no part nor lot in the 106 centimetre ohm; and therefore they might be supposed to be entirely independent as to whether 106 should be adopted or not. It was a very fortunate thing that the English Government took no action in the recommendation of the British Association four years ago. He had the great pleasure of assisting at that Committee, and he supposed that the pressure of having some legalised standard led to the suggestion of Sir William Thomson that 106 should be adopted. It seemed in view of the knowledge of that time extremely desirable that the standard adopted should come up to our then actual knowledge, and 106 was conceded to be actual knowledge. It was therefore an opportune time now to take decided action—to take legal action; and he was glad to unite with Prof. Rowland to express the opinion that the United States would be very glad to adopt 106·3 with the Committee of the British Association, and to recommend it for adoption as the legal ohm. It would be a great satisfaction if M. Mascart should secure simultaneous action in France in the same direction. He hoped that this would be done. With reference to the remarkable address of Sir Frederick Abel as to the state of electrical matters in the United States he felt in common with his countrymen. He felt that they were very much indebted to England for the work that had been done, and particularly the British Association and its Committees, for the present state of affairs. He might be allowed, although not germane to the discussion, to refer to another matter in which they in the United States, having so large an interest in electrical matters, felt some concern. It would be remembered that at the Congress of 1881 the name Weber was taken away from the unit of current, and the name of Ampère substituted. At that time he suggested that America was entitled to some representation of that sort, and he suggested the name Franklin for one of those units; and, although a Professor seconded the suggestion, it was not thought desirable. He would simply now, *per contra*, in reply to Mr. Glazebrook, suggest that the United States should support England in 106·3, and that England should support the name of Franklin (applause).

Sir WILLIAM THOMSON, F.R.S., said that from some things that had passed it might be thought that he was a partisan of 106; but he begged to say that he was not. He thought that Mr. Preece would bear him out that they both fought for 106·25 at the Paris Congress; but it turned out that the case was 106 or nothing. The German scientists and instrument makers desired that the Siemens unit should be left. Sir William Siemens and Dr. Werner Siemens were present, and they desired very much that a mercury unit should be kept, and showed very good reasons for keeping it so. The mercury unit, then, was adopted; and the question was, How many centimetres instead of the Siemens' 100 was to be taken for the new unit? It so happened that there were no observers present whose results went above 106, although there were a considerable number of distinguished men there from Germany and Italy. The average of all the results before the Congress came to almost exactly 106. He urged very hard that Lord Rayleigh's was worth all the others put together, and he believed he persuaded the minds of some of the Congress, but he could not get them to vote for it. Four years ago he proposed a 10 years period, and that was carried by the British Association. Electricians did not live so fast then as now, and he was glad to find that these last four years had done the work of 10 years; and he cordially agreed with Mr. Glazebrook, and Prof. Barker and Prof. Rowland in feeling very thankful indeed that the British Government did not take any action on the resolution of the British Association four years ago. He cordially concurred in the idea of what was held by persons present and perhaps by all the best judges, that now had come the time for fixing the standard at 106·3. That was much nearer than 106·2 or than 106·4; he thought they had reason to believe that it was one or two parts in ten thousandths of the true value. As to the British Association method, he did not know that there would be any proposal to go on with more elaborate methods; but if any more great experiments were to be made he would say again for the British Association method that they had not yet seen all that it could do. The question of levelling the instrument had been carefully considered by Clerk-Maxwell and himself. They had come to the conclusion that the proper place to make the measurement was the Equator, and Maxwell was quite ready to go there to do it. If he had been spared it would have been kept in view. Going to the Equator would greatly increase the sensibility, and it would do away with all trouble in the matter of level. If further observations were to be made by the British Association Committee he hoped that they would be made at the Equator rather than at Cambridge. He would call attention to the very remarkable agreement among the results of able observers whose work had been described by Mr. Glazebrook, operating by different methods.

Mr. W. H. PREECE, F.R.S., said that to a certain extent he must accept the responsibility of having advised H.M.'s Government to decline to adopt the 105 as the legal unit in 1886. The reasons for that course were very powerful and very numerous. To make any change, unless it were a change that would ensure absolute accuracy, would have meant serious and unnecessary expenditure. The number of B.A. rheostats, the number of instruments of all sorts and kinds adjusted to the B.A. unit, not only in this country but in all its Colonies and all over the world, was so very great, that if any change were made would have been a matter involving, one could not say how many, thousands of pounds, and it would certainly involve another change within 10 years. He was quite certain that the course he adopted was right. There was no doubt whatever that a change then would have been wrong, but on the other hand, there was equally no doubt that at the present moment they should be perfectly right in accepting the change. After listening to what Mr. Glazebrook had said; after following nearly all those investigations, and considering the matter with Lord Rayleigh, Sir William Thomson, and others, at the present moment he should not have the slightest hesitation in recommending those associations with which he was connected to take 106·3 as the length in centimetres of a column of mercury of one square millimetre sectional area as representing the true ohm. They must remember this, that although it might not be absolutely accurate, it was more accurate than most of those instruments of measurement that they daily used. It was much more accurate than a foot-rule that most engineers carried in their pockets; it was infinitely more accurate than a thermometer, by which so many observations were made. If they took any ordinary instruments of measurement, he thought they could say that their electrical standards of measurements far surpassed them all in accuracy. Lord Rayleigh wanted to know why they did not measure the ampere. Of course the measurement of the ampere was not only dependent upon the accurate measurement of the ohm, but also upon the accurate measurement of the volt; and when they had a volt represented as accurately as they should now have the ohm, then they might fall back upon the ampere. At the present moment the only standard measure of E.M.F. was a measurement of the Clark's cell made by Lord Rayleigh himself; but that one was not so accurate as the mean results brought before them that day. The discussion before them took in view general electrical units not alone that of the ohm. He did not wish to raise any discussion on that point. They had quite enough to decide in what should be the ohm. But he wanted electricians to take into consideration the necessity, at some future day, of considering the entire alteration of the volt. It was a most unfortunate thing that the volt was taken to be ten to the power of eight C.G.S. units (10^8). It was done because that particular force and the E.M.F. of the Daniell cell were nearly alike. If it had been ten to the power of nine instead of eight (10^9), and our unit were practically accurate, the ampere would have been exactly the same as the unit C.G.S. current that was used in nearly every magnetic inquiry. The day was not far distant when all electricians would have to take into consideration the enlargement of the volt; and it would have this advantage, that it would also enlarge at the same time other units. For instance, the watt was too small. To use the watt as a unit of power they had to call it a kilo-watt. If they raised the volt to the power of nine then the watt would become nearly one-eighth of a so-called horse-power—it would, in fact, be a *man-power*—and they would have a unit of power that would be scientific in its accuracy. With respect to Prof. Barker's suggestion they were all agreed in this: That if it was possible to slip in Franklin anyhow, they would do so. But Franklin was not the only American who deserved this honour. There was Henry; and it had been suggested in America and carefully considered by others that the use of the word Henry might very well be applied to the unit of self-induction. It was not yet before the Committee; but if any new nomenclature was wanted, the names Franklin and Henry should certainly receive careful consideration.

Mr. SWINBURNE asked whether it would not be better to measure the resistance of a mercury trough made at random, and then to submerge an insulating cylinder. A cylinder can be made much more accurately than a trough by the method used in grinding calender rollers, or even by turning. To get rid of thermo-electric effects in the disc arrangement, a double disc with a conducting band connection might be used, making the errors cancel out.

LORD RAYLEIGH said he was very much interested in Prof. Jones's Paper. When he himself first planned the observations by the method of

Digitized by Google

Lorenz, he cast about to see whether he could imitate Lorenz, and deal with an actual column of mercury. He found several difficulties which at the time shook him off, and which Prof. Jones had overcome. He was quite confident that good results could be obtained by Prof. Jones' suggestions. It was a distinct variation upon the methods used by others. Prof. Jones had brought mercury directly into the actual measurement. He was not quite sure whether he rightly understood Prof. Jones as to the manner in which the connection with the mercury column was made. What he attempted in his own experiments to do was this:—He took a glass tube about an inch in diameter, and in order to get the lateral connections which constituted the difficulty, he divided the tube—cut it as clean as he could by a file in two places into two parts; and then filing a groove in the edges, he put them together again with a thin layer of cement, leaving in that way the cavities through which the lateral wires could be introduced. The disturbance of the regular section produced in that way was not much; and if gone into in a more careful manner good results might be got. Prof. Jones had used an open trough with a free surface. That seemed satisfactory. The only remark that occurred to him, as Prof. Jones explained his method, was this: that it seemed to require four observations to get a result. That rather accumulated errors of reading, but probably not to any serious extent. He had very little doubt that extremely accurate results might be got; and, if the Professor pursued the subject, he would surpass what had been already done. As to the temperature of the mercury, in using a fine tube there was no difficulty in immersing it in ice. As to the temperature of Prof. Jones's experiments, he did not know what it was. Was it zero?

Prof. JONES: No; it was 15·5deg. throughout.

LORD RAYLEIGH: I have no doubt the correction to zero is made with a good deal of accuracy, but it takes away something from the directness of the method.

SIR WM. THOMSON said there was one point in Prof. Jones's method which might possibly be the source of not negligible error, viz., the meniscus. No doubt Prof. Jones would attend to that, but it would be necessary to see that the error from meniscus should not vitiate the results. In respect of temperature, he should have thought that the determination might be had with great accuracy by thermometers in the mercury itself at points a considerable distance from the parts subjected to the differential test. If it were two or three times the breadth of the trough, the distance from the point where the current was tapped they would produce but little electrical disturbance. He was glad that Lord Rayleigh advised Prof. Jones to pursue the method, and to seek for still further results, which seemed so far so exceedingly satisfactory.

LORD RAYLEIGH said he appreciated the immense advantage of reducing the coil to a single layer. There was also the question of the uniformity of the winding in the other direction.

Prof. JONES: No; it is on a screw frame.

LORD RAYLEIGH: I suppose, then, that matter may be taken as quite satisfactorily provided for.

Prof. JONES then replied. He said with regard to the temperature he admitted Lord Rayleigh's proposition. The real determination was the specific resistance of 15·5deg. The two thermometers were placed in the troughs as Sir W. Thomson had mentioned, one at one end of the trough and one at the other, just in front of the iron plates: and the mean of these temperatures were read before and after each set of galvanometer readings. With regard to the capillary surface it must be remembered that a very slight variation in the capillary angle would make a difference. The trough in his own experiments was 2½in. in breadth, and might be made 5in. or 6in. in breadth in order to eliminate more errors. Nothing but the practical inconvenience of having so large a trough limited the breadth. Probably the suggestions of Mr. Swinburne with regard to the regulations of speed might be useful.

Dr. GLAISHER, in closing the discussion, thanked Mr. Glazebrook and Prof. Jones for the very able communication they had made. He had no right to say anything himself on that subject; but in reference to Lord Rayleigh's remarks about their being no practicability in such great accuracy, he thought that an accuracy of one in a ten thousandth part was something; and he hoped it would be determined by Prof. Jones to the extent of showing the difference that a few years could affect in accuracy when the ablest intellects were at work upon it.

THE MAGNETO-OPTICAL GENERATION OF ELECTRICITY.*

BY SAMUEL SHELDON, PH.D.

While experimenting upon the effects of alternating currents of electricity upon the plane of polarised light, results were obtained which made it feasible to try a series of experiments in which the Faraday arrangements were reversed. Although the series is incomplete, yet the little that has been accomplished seems worthy of publication.

It is well known† that if a beam of plane polarised light be passed through a tube containing bisulphide of carbon, and if the tube and beam lie in the direction of the lines of force of an electromagnet about to be excited, the plane of the emergent beam will be rotated upon exciting the magnet. The direction of rotation will be the same as that of the exciting current, and the amount of rotation will depend upon the strength of the current. If the current be reversed, the plane will be rotated in an opposite direction and by exactly the same amount. Thus the rapidly alternating current would produce a rapid swinging to and fro of the plane of light.

Now, if a difference of potential, under these conditions, produces such a rotation of the plane, why should not a rapid rotation of the plane under exactly the same conditions produce an inverse difference of potential between the terminals of the coil? A continuous rotation should produce a continuous current of electricity and an oscillating of the plane an alternating current. The experiments which have been performed verify the latter supposition.

The coil employed was wound upon a thin brass tube as a core. This was closed at each end by plates of glass and was provided with holes for filling with carbon bisulphide. Its length was 175mm. and its diameter 23mm. Upon this was wound the coil from double silk-covered copper wire of 0·85mm. diameter. When wound the length of the coil was 150mm. and its diameter 45mm. The resistance was 7·21 ohms.

A quantitative measurement of the Faraday effect was first made, and in the following manner:—A beam of light from an incandescent lamp, after passing through a large Nicol, was made to traverse the bisulphide of carbon in the coil. Upon emerging the beam was brought to extinction by the proper adjustment of an analysing nicol. A measured current of electricity was now passed around the coil. This necessitated a readjustment and rotation of the analysing Nicol to reproduce extinction of the beam. Within the limits tried, this rotation was proportional to the current strength. As a mean of many measurements, it was found that a current of 1 ampere required a rotation of 78 minutes of the analyser. Accordingly, 278 amperes would be required to rotate the plane through 360°, providing the proportionality between current strength and rotation remained unaltered.

Now, if we consider a plane polarised ray of light to be made up of two opposite circularly-polarised rays, then a particle of ether in the bisulphide of carbon describes a simple harmonic oscillation in a plane. This motion in a straight line is the resultant of the two oppositely directed, equiperiodic, circular rotations of equal amplitude. If now a magnetic field be created, the particle undergoes an instantaneous circular electric displacement which results in the retardation of one and the acceleration of the other component rotation. The line of oscillation suffers rotation as a result, and assumes a new position. The displacement must be instantaneous, for, were it continuous, the line of oscilation would continue to rotate, and the analyser could not be made to produce extinction. If now, instead of allowing the magnetic field to produce this circular displacement, we superimpose, by mechanical means, a third rotation upon the two existing components, then a magnetic field should result, and an electromotive force be induced in a coil surrounding that field. Such a result would be obtained by rotating the polarising Nicol. The rapidity of rotation must be very great, and if it requires 278 amperes (an impressed electromotive force of 2,000 volts) to rotate the plane through 360°, then to produce this electromotive force the polariser must be revolved with a frequency of the same order as of the oscillations of light. But a Nicol cannot be revolved much above 200 times per second. The centrifugal force resulting from a higher rate will, owing to the strain produced, interfere with the performance of its functions as a polariser. This rate of 200 revolutions per second would produce, in the apparatus employed, an electromotive force of perhaps 0,000,000,001 volt, giving a current too small to be detected by any galvanometer in my laboratory. Hence use was made of the extreme delicacy of the telephone as a substitute, and a swinging of the plane instead of a revolution.

The arrangement of apparatus was as follows—Light from an arc lamp, after passing through a large Nicol, was reflected, at a very obtuse angle, from a small movable mirror, and then passed through the bisulphide of carbon in the coil before mentioned. The two terminals of the coil were carried to a room three stories below, and in another part of the building. Here they were connected through a telephone and a switch. The mirror (10×30mm) was fixed in a brass frame, free to rotate about an axis nearly parallel with the ray of light. This frame was connected by an eccentric and gears to the main shaft in the workshop. By this arrangement the mirror was made to oscillate through 45deg., about 300 times each second. The plane of polarisation was thus twisted through twice that amount, or 90deg., in the same time. While this oscillation was going on in the workshop, an ear placed at the telephone at the other end of the circuit could easily distinguish a tone, which, however, was the octave above that made by the moving mirror. When the circuit was broken the sound ceased to be heard, but upon again closing the tone became audible. With a rate of 200 oscillations per second the note was not so easily distinguished. But upon closing the circuit that peculiar sizzling noise so common in telephone circuits was heard.

During the experiments the mirror was frequently broken by the high rate of vibration. But another was quickly substituted by my assistant, Mr. Baker, whom I have to thank for this and the construction and management of the rotating apparatus.

THE ELECTRO-MAGNET.*

BY PROF. SILVANUS P. THOMPSON, D.SC., B.A., M.I.E.E.

(Continued from page 528.)

HISTORICAL SKETCH *(continued)*.

At the date of Sturgeon's work the laws governing the flow of electric currents in wires were still obscure. Ohm's epoch-making enunciation of the law of the electric circuit appeared in Poggendorff's *Annalen* in the very year of Sturgeon's discovery, 1825, though his complete book appeared only in 1827, and his work, translated by Dr. Francis into English only, appeared (in Taylor's "Scientific Memoirs," Vol. II.) in 1841. Without the guidance of Ohm's law it was not strange that even the most able experimenters should not understand the relations between battery and circuit which would give them the best effects. These had to be found by the painful method of trial and failure. Pre-eminent amongst those who tried was Prof. Joseph Henry, then of the Albany Institute, in New York, later of Princeton, New Jersey, who succeeded in effecting an important improvement. In 1828, led on by a study of the "multiplier" (or galvanometer), he proposed to apply to electro-magnetic apparatus the device of winding them with a spiral coil of wire "closely turned on itself," the wire being of copper from $\frac{1}{40}$th to $\frac{1}{25}$th of an inch in diameter, covered with silk. In 1831 he thus describes[33] the results of his experiments:—

"A round piece of iron, about $\frac{1}{4}$ of an inch in diameter, was bent into the usual form of a horse-shoe, and instead of loosely coiling around it a few feet of wire, as is usually described, it was tightly wound with 35ft. of wire, covered with silk, so as to form about 400 turns; a pair of small galvanic plates, which could be dipped into a tumbler of diluted acid, was soldered to the ends of the wire, and the whole mounted on a stand. With these small plates the horse-shoe became much more powerfully magnetic than another of the same size, and wound in the same manner, by the application of a battery composed of 28 plates of copper and zinc, each 8in. square. Another convenient form of this apparatus was contrived by winding a straight bar of iron, 9in. long, with 35ft. of wire, and supporting it horizontally on a small cup of copper containing a cylinder of zinc; when this cup—which served the double purpose of a stand, and the galvanic element—was filled with dilute acid, the bar became a portable electro-magnet. These articles were exhibited to the Institute in March, 1829. The idea afterwards occurred to me that a sufficient quantity of galvanism was furnished by the two small plates, to develop, by means of the coil, a much greater magnetic power in a larger piece of iron. To test this, a cylindrical bar of iron, $\frac{1}{2}$in. in diameter and about 10in. long, was bent into the shape of a horse-shoe, and wound with 30ft. of wire; with a pair of plates, containing only $2\frac{1}{2}$ sq. in. of zinc, it lifted 15lb. avoirdupois. At the same time a very material improvement in the formation of the coil suggested itself to me on reading a more detailed account of Professor Schweigger's galvanometer, and which was also tested with complete success upon the same horse-shoe; it consisted in using several strands of wire, each covered with silk, instead of one. Agreeably to this construction a second wire, of the same length as the first, was wound over it, and the ends soldered to the zinc and copper in such a manner that the galvanic current might circulate in the same direction in both, or, in other words, that the two wires might act as one; the effect by this addition was doubled, as the horse-shoe, with the same plates before used, now supported 28lb.

"With a pair of plates 4in. by 6in., it lifted 30 lbs., or more than 50 times its own weight.

"These experiments conclusively proved that a great development of magnetism could be effected by a very small galvanic element, and also that the power of the coil was materially increased by multiplying the number of wires without increasing the length of each."[34]

Not content with these results Prof. Henry pushed forward on the line he had thus struck out. He was keenly desirous to ascertain how large a magnetic force he could produce when using only currents of such a degree of smallness as could be transmitted through the comparatively thin copper wires such as bell-hangers use. During the year 1830 he made great progress in this direction, as the following extracts show:—

"In order to determine to what extent the coil could be applied in developing magnetism in soft iron, and also to ascertain, if possible, the most proper length of the wires to be used, a series of experiments was instituted jointly by Dr. Philip Ten Eyck and myself. For this purpose 1,060ft. (a little more than one-fifth of a mile) of copper wire of the kind called bell wire, ·045 of an inch in diameter, were stretched several times across the large room of the Academy.

"*Experiment* 1.—A galvanic current from a single pair of plates of copper and zinc 2in. square was passed through the whole length of the wire, and the effect on a galvanometer noted. From the mean of several observations, the deflection of the needle was 15deg.

"*Experiment* 2.—A current from the same plates was passed through half the above length, or 530ft. of wire; the deflection in this instance was 21deg.

By a reference to a trigonometrical table it will be seen that the natural tangents of 15deg. and 21deg. are very nearly in the ratio of the square roots of 1 and 2, or of the relative lengths of the wires in these two experiments.

"The length of the wire forming the galvanometer may be neglected, as it was only 8ft. long.

"*Experiment* 3.—The galvanometer was now removed, and the whole length of the wire attached to the ends of the wire of a small soft iron horse-shoe a quarter of an inch in diameter, and wound with about 8ft. of copper wire with a galvanic current from the plates used in Experiments 1 and 2. The magnetism was scarcely observable in the horse-shoe.

"*Experiment* 4.—The small plates were removed, and a battery composed of a piece of zinc plate 4in. by 7in., surrounded with copper, was substituted. When this was attached immediately to the ends of the 8ft. of wire wound round the horse-shoe, the weight lifted was 4½lb.; when the current was passed through the whole length of wire (1,060ft.), it lifted about half an ounce.

"*Experiment* 5.—The current was passed through half the length of wire (530ft.) with the same battery; it then lifted two ounces.

"*Experiment* 6.—Two wires of the same length as in the last experiment were used, so as to form two strands from the zinc and copper of the battery; in this case the weight lifted was four ounces.

"*Experiment* 7.—The whole length of the wire was attached to a small trough on Mr. Cruickshanks' plan, containing 25 double plates, and presenting exactly the same extent of zinc surface to the action of the acid, as the battery used in the last experiment. The weight lifted in this case was 8 oz.; when the intervening wire was removed, and the trough attached directly to the ends of the wire surrounding the horse-shoe, it lifted only 7oz. . . .

"It is possible that the different states of the trough, with respect to dryness, may have exerted some influence on this remarkable result; but that the effect of a current from a trough, if not increased, is but slightly diminished in passing through a long wire is certain. . . . .

"But be this as it may, the fact that the magnetic action of a current from a trough is, at least, not sensibly diminished by passing through a long wire is directly applicable to Mr. Barlow's project of forming an electro-magnetic telegraph; and it is also of material consequence in the construction of the galvanic coil. From these experiments it is evident that in forming the coil we may either use one very long wire or several shorter ones, as the circumstances may require; in the first case, our galvanic combinations must consist of a number of plates, so as to give 'projectile force;' in the second it must be formed of a single pair.

"In order to test on a large scale the truth of these preliminary results, a bar of soft iron, Fig. 5, 2in. square and 20in. long, was bent into the form of a horse-shoe, 9½in. high; the sharp edges of the bar were first a little rounded by the hammer, it weighed 21lb.; a piece of iron from the same bar, weighing 7lb., was filed perfectly flat on one surface, for an armature or lifter; the extremities of the legs of the horse-shoe were also truly ground to the surface of the armature; around this horse-shoe 540ft. of copper bell wire were wound in nine coils of 60ft. each: these coils were not continued around the whole length of the bar, but each strand of wire according to the principle before mentioned, occupied about 2in., and was coiled several times backward and forward over itself; the several ends of the wires were left projecting and all numbered, so that the first and last end of each strand might be readily distinguished. In this manner we formed an experimental magnet on a large scale, with which several combinations of wire could be made by merely uniting the different projecting ends. Thus, if the second end of the first wire be soldered to the first end of the second wire, and so on through all the series, the whole will form a continued coil of one long wire.

"By soldering different ends the whole may be formed into a double coil of half the length, or into a triple coil of one-third the

length, &c. The horseshoe was suspended in a strong rectangular wooden frame, 3ft. 9in. high and 20in. wide, an iron bar was fixed below the magnet, so as to act as a lever of the second order ; the different weights supported were estimated by a sliding weight in the same manner as with a common steel-yard (*see* sketch). In the experiments immediately following (all weights being avoirdupois) a small single battery was used, consisting of two concentric copper cylinders with zinc between them ; the whole amount of zinc surface exposed to the acid from both sides of the zinc was $\frac{2}{3}$ths of a square foot ; the battery required only half a pint of dilute acid for its submersion.

"*Experiment* 8.—Each wire of the horseshoe was soldered to the battery in succession, one at a time ; the magnetism developed by each was just sufficient to support the weight of the armature weighing 7lb.

"*Experiment* 9.—Two wires, one on each side of the arch of the horseshoe, were attached ; the weight was lifted 145lb.

"*Experiment* 10.—With two wires, one from each extremity of the legs, the weight lifted was 200lb.

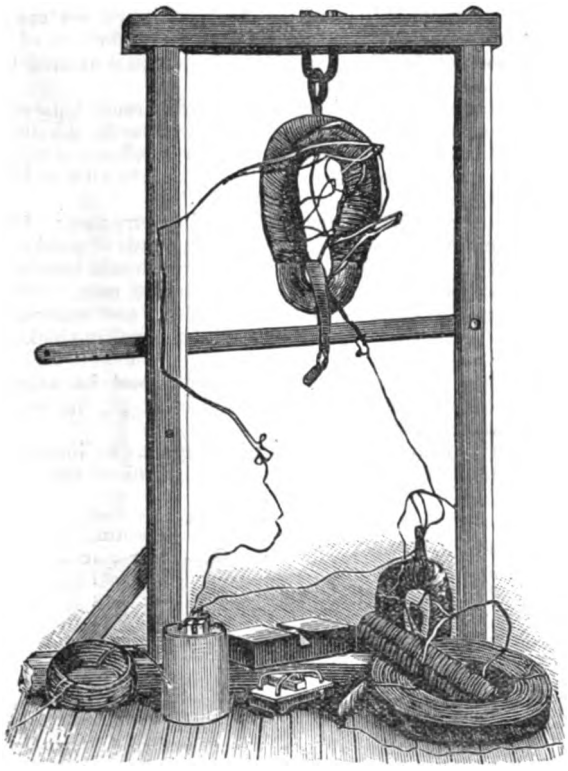

FIG. 5.—Henry's Electro-Magnet.

This figure, copied from the *Scientific American*, December 11, 1880, represents Henry's electro-magnet, still preserved in Princeton College. The other apparatus at the foot, including a current-reverser, and the ribbon-coil used in the famous experiments on secondary and tertiary currents, were mostly constructed by Henry's own hands.

"*Experiment* 11.—With three wires, one from each extremity of the legs and one from the middle of the arch, the weight supported was 300lb.

"*Experiment* 12.—With four wires, two from each extremity, the weight lifted was 500lb. and the armature ; when the acid was removed from the zinc, the magnet continued to support for a few minutes 130lb.

"*Experiment* 13.—With six wires the weight supported was 570lb. ; in all these experiments the wires were soldered to the galvanic element ; the convexion in no case was formed with mercury.

"*Experiment* 14.—When all the wires (nine in number) were attached, *the maximum weight lifted was* 650*lb.* ; and this astonishing result, it must be remembered, was produced by a battery containing only $\frac{2}{3}$rhs of a square foot of zinc surface, and requiring only half a pint of dilute acid for its submersion.

"*Experiment* 15.—A small battery, formed with a plate of zinc 12in. long and 6in. wide, and surrounded by copper, was substituted for the galvanic elements used in the last experiment ; the weight lifted in this case was 750lb.

"*Experiment* 16.—In order to ascertain the effect of a very small galvanic element on this large quantity of iron, a pair of plates, exactly 1in. square, was attached to all the wires ; the weight lifted was 85lb.

"The following experiments were made with wires of different lengths on the same horseshoe.

"*Experiment* 17.—With six wires, each 30ft. long attached to the galvanic element, the weight lifted was 375lb.

"*Experiment* 18.—The same wires used in last experiment were united so as to form three coils of 60ft. each ; the weight supported was 290lb. This result agrees nearly with that of Experiment 11, though the same individual wires were not used ; from this it appears that six short wires are more powerful than three of double the length.

"*Experiment* 19.—The wires used in Experiment 10, but united so as to form a single coil of 120ft. of wire, lifted 60lb. ; while in Experiment 10 the weight lifted was 200lb. ; this is a confirmation of the result in the last experiment. . . . .

"In these experiments a fact was observed which appears somewhat surprising ; when the large battery was attached, and the armature touching both poles of the magnet, it was capable of supporting more than 700lb., but when only one pole is in contact it did not support more than 5 or 6lb., and in this case we never succeeded in making it lift the armature (weighing 7lb.). This fact may perhaps be common to all large magnets, but we have never seen the circumstance noticed of so great a difference between a single pole and both. . . . .

"A series of experiments was separately instituted by Dr. Ten Eyck, in order to determine the maximum development of magnetism in a small quantity of soft iron.

"Most of the results given in this Paper were witnessed by Dr. L. C. Beck, and to this gentleman we are indebted for several suggestions, and particularly that of substituting cotton well waxed for silk thread, which in these investigations became a very considerable item of expense. He also made a number of experiments with iron bonnet-wires, which, being found in commerce already wound, might possibly be substituted in place of copper. The result was that with very short wire the effect was nearly the same as with copper, but in coils of long wire with a small galvanic element it was not found to answer. Dr. Beck also constructed a horseshoe of round iron 1in. in diameter, with four coils on the plan before described. With one wire it lifted 30lb., with two wires 60lb., with three wires 85lb., and with four wires 112lb. While we were engaged in these investigations, the last number of the *Edinburgh Journal of Science* was received containing Prof. Moll's Paper on 'Electro-Magnetism.' Some of his results are in a degree similar to those here described ; his object, however, was

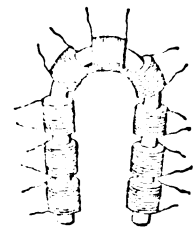

FIG. 6.—Henry's Experimental Electro-magnet.

different, it being only to induce strong magnetism on soft iron with a powerful galvanic battery. The principal object in these experiments was to produce the greatest magnetic force with the smallest quantity of galvanism. The only effect Prof. Moll's Paper has had over these investigations has been to hasten their publication ; the principle on which they were instituted was known to us nearly two years since, and at that time exhibited to the Albany Institute."[35]

In the next number of *Silliman's Journal* (April, 1831), Prof. Henry gave "an account of a large electro-magnet, made for the laboratory of Yale College." The core of the armature weighed 59½lb., it was forged under Henry's own direction, and wound by Dr. Ten Eyck. This magnet, wound with 26 strands of copper bell-wire of total length of 728ft., and excited by two cells which exposed nearly 4⅗ square feet of surface, readily supported on its armature, which weighed 23lb., a load of 2,063lb.

Writing in 1867 of his earlier experiments, Henry speaks[36] thus of his ideas respecting the use of additional coils on the magnet and the increase of battery power :—

"To test these principles on a larger scale, the experimental magnet was constructed, which is shown in Fig. 6. In this a number of compound helices was placed on the same bar, their ends left projecting, and so numbered that they could all be united into one long helix, or variously combined in sets of lesser length.

"From a series of experiments with this and other magnets, it was proved that in order to produce the greatest amount of magnetism from a battery of a single cup a number of helices is

[35] Scientific Writings of Joseph Henry, p. 49.

[36] "Statement in relation to the History of the Electro-Magnetic Telegraph :" from the Smithsonian Annual Report for 1857, p. 99.

required; but when a compound battery is used then one long wire must be employed, making many turns around the iron, the length of wire and consequently the number of turns being commensurate with the projectile power of the battery.

"In describing the results of my experiments the terms 'intensity' and 'quantity' magnets were introduced to avoid circumlocution, and were intended to be used merely in a technical sense. By the intensity magnet I designated a piece of soft iron, so surrounded with wire that its magnetic power could be called into operation by an intensity battery; and by a quantity magnet, a piece of iron so surrounded by a number of separate coils that its magnetism could be fully developed by a quantity battery.

"I was the first to point out this connection of the two kinds of the battery with the two forms of the magnet, in my Paper, in *Silliman's Journal*, January, 1831, and clearly to state that when magnetism was to be developed by means of a compound battery one long coil must be employed, and when the maximum effect was to be produced by a single battery a number of single strands should be used. . . . Neither the electro-magnet of Sturgeon nor any electro-magnet ever made previous to my investigations was applicable to transmitting power to a distance. . . . The electro-magnet made by Sturgeon, and copied by Dana, of New York, was an imperfect quantity magnet, the feeble power of which was developed by a single battery."

Finally, Henry[37] sums up his own position as follows:—

"1. Previous to my investigations the means of developing magnetism in soft iron were imperfectly understood, and the electro-magnet which then existed was inapplicable to transmissions of power to a distance.

"2. I was the first to prove by actual experiment that in order to develop magnetic power at a distance, a galvanic battery of 'intensity' must be employed to project the current through the long conductor, and that a magnet surrounded by many turns of one long wire must be used to receive this current.

"3. I was the first to actually magnetise a piece of iron at a distance, and to call attention to the fact of the applicability of my experiments to the telegraph.

"4. I was the first to actually sound a bell at a distance by means of the electro-magnet.

"5. The principles I had developed were applied by Dr. Gale to render Morse's machine effective at a distance."

Though Henry's researches were published in 1831, they were for some years almost unknown in Europe. Until April, 1837, when Henry himself visited Wheatstone at his laboratory at King's College, the latter did not know how to construct an electro-magnet that could be worked through a long wire circuit. Cooke, who became the coadjutor of Wheatstone, had originally come to him to consult him,[38] in February, 1837, about his telegraph and alarum, the electro-magnets of which, though they worked well on short-circuits, refused to work when placed in circuit with even a single mile of wire. Wheatstone's own account[39] of the matter is extremely explicit:—"Relying on my former experience, I at once told Mr. Cooke that his plan would not and could not act as a telegraph, because sufficient attractive power could not be imparted to an electro-magnet interposed in a long circuit; and to convince him of the truth of this assertion, I invited him to King's College to see the repetition of the experiments on which my conclusion was founded. He came, and after seeing a variety of voltaic magnets, which even with powerful batteries exhibited only slight adhesive attraction, he expressed his disappointment."

After Henry's visit to Wheatstone, the latter altered his tone. He had been using, *faute de mieux*, relay circuits to work the electro-magnets of his alarum in a short circuit with a local battery. "These short circuits," he writes, "have lost nearly all their importance, and are scarcely worth contending about since *my discovery*" (the italics are our own) "that electro-magnets may be so constructed as to produce the required effects by means of the direct current, even in very long circuits."[40]

We pass on to the researches of the distinguished physicist of Manchester, whose decease we have lately had to deplore, Mr. Joule, who, fired by the work of Sturgeon, made most valuable contributions to the subject. Most of these were published either in Sturgeon's "Annals of Electricity," or in the "Proceedings of the Literary and Philosophical Society of Manchester," but their most accessible form is the republished volume issued five years ago by the Physical Society of London.

In his earliest investigations he was endeavouring to work out the details of an electric motor. The following is an extract from his own account ("Reprint of Scientific Papers," p. 7):—

"In the further prosecution of my inquiries, I took six pieces of round bar iron of different diameters and lengths, also a hollow cylinder, $\frac{1}{13}$th of an inch thick in the metal. These were bent in the U-form, so that the shortest distance between the poles of each was half an inch; each was then wound with 10ft. of covered copper wire, $\frac{1}{40}$th of an inch in diameter. Their attractive powers under like currents for a straight steel magnet, 1½in. long, suspended horizontally to the beam of a balance, were, at the distance of half an inch, as follows:—

	No. 1. Hollow	No. 2. Solid.	No. 3. Solid.	No. 4. Solid.	No. 5. Solid.	No. 6. Solid	No. 7. Solid.
Length round the bend in inches.....	6	5½	2⅜	5¼	2½	5¼	2½
Diameter in inches...	½	½	½	⅜	⅜	¼	¼
Attraction for steel magnet, in grains	7·5	6·3	5·1	5·0	4·1	4·8	3·6
Weight lifted, in ounces	36	52	92	35	52	20	28

"A steel magnet gave an attractive power of 23 grains, while its lifting-power was not greater than 60oz.

"The above results will not appear surprising if we consider, first, the resistance which iron presents to the induction of magnetism, and, second, how very much the induction is exalted by the completion of the magnetic circuit.

"Nothing can be more striking than the difference between the ratios of lifting to attractive power at a distance in the different magnets. Whilst the steel magnet attracts with a force of 23 grains and lifts 60oz., the electro-magnet No. 3 attracts with a force of only 5·1 grains, but lifts as much as 92oz.

"To make a good electro magnet for lifting purposes:—1st. Its iron, if of considerable bulk, should be compound, of good quality and well annealed. 2nd. The bulk of the iron should bear a much greater ratio to its length than is generally the case. 3rd. The poles should be ground quite true, and fit flatly and accurately to the armature. 4th. The armature should be equal in thickness to the iron of the magnet.

"In studying what form of electro-magnet is best for attraction from a distance, two things must be considered, viz., the length of the iron, and its sectional area.

"Now I have always found it disadvantageous to increase the length beyond what is needful for the winding of the covered wire."

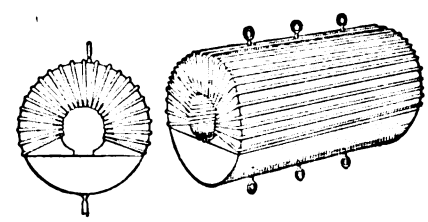

FIG. 7.—Joule's Electro-Magnet.

These results were announced in March, 1839. In May of the same year he propounded a law of the mutual attraction of two electro-magnets, as follows:—"The attractive force of two electro-magnets for one another is directly proportional to the square of the electric force to which the iron is exposed; or if E denote the electric current, W the length of wire, and M the magnetic attraction, $M = E^2 W^2$." The discrepancies which he himself observed he rightly attributed to the iron becoming saturated magnetically. In March, 1840, he extended this same law to the lifting power of the horse-shoe electro-magnet.

In August, 1840, he wrote to the "Annals of Electricity," on electro-magnetic forces, dealing chiefly with some special electro-magnets for traction. One of these possessed the form shown in Fig. 7. Both the magnet and the iron keeper were furnished with eye-holes for the purpose of suspension and measurement of the force requisite to detach the keeper. Joule thus writes about the experiments.[41]

"I proceed now to describe my electro-magnets, which I constructed of very different sizes in order to develop any curious circumstance which might present itself. A piece of cylindrical wrought iron 8in. long, had a hole 1in. in diameter, bored the whole length of its axis; one side was planed until the hole was exposed sufficiently to separate the thus-formed poles one-third of an inch. Another piece of iron, also 8in. long, was then planed, and being secured with its face in contact with the other planed surface, the whole was turned into a cylinder 8in. long, 3¾in. in exterior, and 1in. interior diameter. The larger piece was then covered with calico and wound with four copper wires covered with

Digitized by Google

silk, each 23ft. long, and $\frac{1}{11}$th of an inch in diameter—a quantity just sufficient to hide the exterior surface, and to fill the interior opened hole." . . . . "The above is designated No. 1; and the rest are numbered in the order of their description.

"I made No. 2 of a bar of half-inch round iron 2·7in. long. It was bent into an almost semi-circular shape, and then covered with 7ft. of insulated copper wire, 1-20th of an inch thick. The poles are half-an-inch asunder; and the wire completely fills the space between them.

"A third electro-magnet was made of a piece of iron 0·7in. long, 0·37in. broad, and 0·15in. thick. Its edges were reduced to such an extent that the transverse section was elliptical. It was bent into a semicircular shape, and wound with 19in. of silked copper wire, 1-40th of an inch in diameter.

"To procure a still more extensive variety, I constructed what might, from its extreme minuteness, be termed an elementary electro-magnet. It is the smallest, I believe, ever made, consisting of a bit of iron wire $\frac{1}{4}$ of an inch long, and 1-25th of an inch in diameter. It was bent into the shape of a semicircle, and was wound with three turns of uninsulated copper wire 1-40th of an inch in thickness."

With these magnets experiments were made with various strengths of currents, the tractive forces being measured by an arrangement of levers. The results, briefly, are as follows:—Electro-magnet No. 1, the iron of which weighed 15lbs., required a weight of 2,090lbs. to detach the keeper. No. 2, the iron of which weighed 1,057 grains, required 49.bs. to detach its armature. No. 3, the iron of which weighed 65·3 grains, supported a load of 12lbs., or 1,286 times its own weight. No. 4, the weight of which was only half a grain, carried in one instance 1,417 grains, or 2,834 times its own weight.

"It required much patience to work with an arrangement so minute as this last; and it is probable that I might ultimately have obtained a larger figure than the above, which, however, exhibits a power proportioned to its weight far greater than any on record, and is 11 times that of the celebrated steel magnet which belonged to Sir Isaac Newton.

"It is well known that a steel magnet ought to have a much greater length than breadth or thickness; and Mr. Scoresby has found that when a large number of straight steel magnets are bundled together, the power of each when separated and examined is greatly deteriorated. All this is easily understood, and finds its cause in the attempt of each part of the system to induce upon the other part a contrary magnetism to its own. Still there is no reason why the principle should in all cases be extended from the steel to the electro-magnet, since in the latter case a great and commanding inductive power is brought into play to sustain what the former has to support by its own unassisted retentive property. All the preceding experiments support this position; and the following table gives proof of the obvious and necessary general consequence, the maximum power of the electro-magnet is directly proportional to its least transverse sectional area. The second column of the table contains the least sectional area in square inches of the entire magnetic circuit. The maximum power in pounds avoirdupois is recorded in the third; and this, reduced to an inch square of sectional area, is given in the fourth column under the title of specific power."

Table I.

Description.	Least sectional area.	Maximum power.	Specific power.
My own electro-magnets (No. 1 . .....)	10	2090	209
(No. 2 .....)	0·196	49	250
(No. 3 .....)	0·0436	12	275
(No. 4 .....)	0·0012	0·202	162
Mr. J. C. Nesbit's. Length round the curve, 3ft.; diameter of iron core, 2⅞in.; sectional area, 5·7in.; do. of armature, 4·5in.; weight of iron, about 50lb.	4·5	1428	317
Prof. Henry's. Length round the curve, 20in.; section, 2in. square; sharp edges rounded off; weight, 21lb.	3·94	750	190
Mr. Sturgeon's original. Length round the curve, about 1ft.; diameter of the round bar, ½in.	0·195	50	255

"The above examples are, I think, sufficient to prove the rule I have advanced. No. 1 was probably not fully saturated; otherwise I have no doubt that its power per square inch would have approached 300. Also, the specific power of No. 4 is small, because of the difficulty of making a good experiment with it."

These experiments were followed by some to ascertain the effect of the length of the iron of the magnet, which he considered, at least in those cases where the degree of magnetisation is considerably below the point of saturation, to offer a decidedly proportional resistance to magnetisation; a view the justice of which is now after fifty years amply confirmed.

In November of the same year further experiments[42] in the same direction were published. A tube of iron, spirally made and welded, was prepared, planed down as in the preceding case, and fitted to a similarly prepared armature. The hollow cylinder thus formed, shown in Fig. 8, was 2·t. in length, its internal diameter was 1·42in., its internal being 0·5in. The least sectional area was 10¼ square in. The exciting coil consisted of a single copper rod, covered with tape, bent into a sort of S-shape. This was later replaced by a coil of 21 copper wires, each 1·25in. in diameter and 23ft. long, bound together by cotton tape. This magnet, excited by a battery of 16 of Sturgeon's cast-iron cells, each 1ft. square and 1½in. in interior width, arranged in a series of four, gave a lifting power of 2,775lbs.

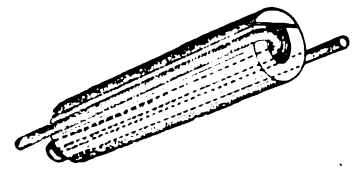

Fig. 8.—Joule's Cylindrical Electro-Magnet.

Joule's work was well worthy of the master from whom he had learned his first lesson in electro-magnetism. He showed his devotion not only by writing descriptions of them for Sturgeon's "Annals," but by exhibiting two of his electro-magnets at the Victoria Gallery of Practical Science, of which Sturgeon was director. Others, stimulated into activity by Joule's example, proposed new forms, amongst them being two Manchester gentlemen, Mr. Radford and Mr. Richard Roberts, the latter being a well-known engineer and inventor. Mr. Radford's electro-magnet consisted of a flat iron disc, with deep spiral grooves cut in its face, in which were laid the insulated copper wires. The armature consisted of a plain iron disc of similar size. This form is described in Vol. IV. of Sturgeon's "Annals."

Mr. Roberts's form of electro-magnet consisted of a rectangular iron block, having straight parallel grooves cut across its face, as in Fig. 9. This was described in Vol. VI. of Sturgeon's "Annals," p. 166. Its face was 6§ inches square, and its thickness 2$\frac{7}{8}$ inch. It weighed, with the conducting wire, 35lbs.; and the armature, of the same size and 1½in. thick, weighed 23lbs. The load sustained by this magnet was no less than 2,950lbs. Roberts inferred that a magnet if made of equal thickness, but 5ft. square, would sustain 100 tons weight. Some of Roberts's apparatus is still preserved in the Museum of Peel Park, Manchester.

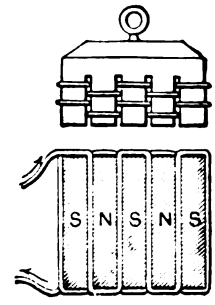

Fig. 9.—Roberts's Electro-Magnet.

On p. 431 of the same volume of the "Annals," Joule described yet another form of electro-magnet, the form of which resembled in general Fig. 10; but which, in actual fact, was built up of 24 separate flat pieces of iron bolted to a circular brass ring. The armature was a similar structure, but not wound with iron. The iron of the magnet weighed 7lbs., and that of the armature 4·55lbs. The weight was 2,710lbs., when excited by 16 of Sturgeon's cast-iron cells.

In a subsequent Paper on the calorific effects of magneto-electricity,[43] published in 1843, Joule described another form of electro-magnet of horse-shoe shape, made from a piece of boiler-plate. This was not intended to give great lifting power, and was used as the field-magnet of a motor. In 1852, another powerful electro-magnet of horse-shoe form, somewhat similar to the preceding, was constructed by Joule for experiment. He came to the conclusion[44]

[42] "Scientific Papers," p. 40, and "Annals of Electricity," Vol. V., p. 170

Digitized by Google

that, owing to magnetic saturation setting in, it was improbable that any force of electric current could give a magnetic attraction greater than 200lbs. per square inch. "That is, the greatest weight which could be lifted by an electro-magnet formed of a bar of iron 1in. square, bent into a semi-circular shape, would not exceed 400lbs."

With the researches of Joule may be said to end the first stage of development. The notion of the magnetic circuit which had thus guided Joule's work did not commend itself at that time to the professors of physical theories; and the practical men, the telegraph engineers, were for the most part content to work by purely empirical methods. Between the practical man and the theoretical man there was, at least on this topic, a great gulf fixed. The theoretical man, arguing as though magnetism consisted in a

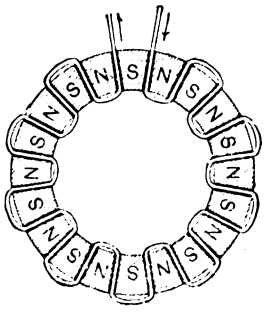

FIG. 10.—Joule's Zig-zag Electro-Magnet.

surface distribution of polarity, and as though the laws of electro-magnets were like those of steel magnets, laid down rules not applicable to the cases which occur in practice, and which hindered rather than helped progress. The practical man, finding no help from theory, threw it on one side as misleading and useless. It is true that a few workers made careful observations and formulated into rules the results of their investigations. Amongst these the principal were Ritchie, Robinson, Müller, Dub, Von Kolke, and Du Moncel; but their work was little known beyond the pages of the scientific journals wherein their results were described. Some of these results will be examined in my later lectures, but they cannot be discussed in this historical *résumé*, which is accordingly closed.

(To be continued.)

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September* 5, 1890.

The Street Railway Organisations and Electric Propulsion.—A striking sign of the times is the great interest taken in electricity by all the street railway organisations. On September 16th, the New York Street Railway Association is to meet in Rochester, and it announces that a large part of the time of the Association will be devoted to the consideration of electrical propulsion. Representatives of all the leading electrical systems will be present, and in all probability foundations will be there laid for some increase of electrical traction. The American Street Railway Association, which is the general organisation in this country, meets October 15th, 16th, and 17th, at Buffalo, New York, and, like the smaller organisation, a considerable part of the interest of the meeting will centre on reports of electrical progress. Several important electrical Papers will be read at that time, and it is probable that the discussion will not be so much upon the possibilities of improvement in the other forms of motive power as in the most expeditious means of getting rid of them and adopting electric power. Among other bits of railway news, I may mention that a 25-mile electric road, running out of the city of Buffalo, through intervening towns to Niagara Falls, is projected, and work will probably soon be begun. It will be operated by a single-power station, and in all probability some attempt will be made to introduce higher speeds than present practice admits.

A Primary Battery Mania.—We are having just now an epidemic of primary battery fever. Three or four new companies of inconsiderable size and small influence have recently been started in various parts of the country, and there are distressing symptoms of more to follow. The unfortunate part of the business is that a considerable amount of money is wheedled out of innocent investors, and in addition some harm is done to electrical interests in general, since the oft-swindled public gradually grows suspicious of everything electrical. One of the most extraordinary of these schemes proposes to work wonders through the medium of a storage battery to be charged from a primary battery.

A New Thermopile.—It transpires that the discovery of a means of producing electricity direct from heat, reported from Hartford, Connecticut, some weeks since, and about which there was so much talk, is nothing more nor less than a glorified thermopile, with presumably the inefficiency and other disadvantages that pertain to that venerable apparatus.

Meeting of the National Telephone Convention.—The National Telephone Convention meets next week at Detroit, Michigan, and in all probability the proceedings will be of unusual interest. Last year there was special activity shown in the matter of all metallic circuits, long-distance telephony, and the like, and appearances indicate that still further improvements will be shown at the present meeting. The subject of induction interferences between telephone and electric light and power lines will probably come up for vigorous discussion, although the details of any proceedings taken on this subject may not be made public. The legal decisions in the cases that have been brought to an issue in this country have been pretty uniformly against the telephone companies, although not often relieving the interfering lines from responsibility, and with the increase in electric railroading, this question becomes more and more important.

CORRESPONDENCE.

THE ELECTRIC LIGHT AT BATH.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue I noticed a letter from Charles Powell, who has imposed upon you by stating that he "recently had a run down to Bath," and that he "met the police going to the station to report lamps out, and went with them," &c. Charles Powell was actually in my employ for a month as an engine driver, and was summarily discharged by me for savagely assaulting the second engineer, who had upbraided him for his negligence, which resulted in a breakdown and temporary extinguishment of the lights. Your contemporaries have been imposed upon by the same person, and published similar information; but, unlike yourselves, they did not give the name of their informant, and had it not been for your doing this I should have been unable to expose the matter.

I may mention that when he was leaving here, he intimated to my staff that he would have his revenge for being dismissed, hence his communications to the technical press.—Yours, &c.,

Bath Electric Light Works, H. G. MASSINGHAM.
Bath, September 15, 1890.

MAGNET STEEL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I see Mr. Preece is complaining once more of the sad deterioration in the magnet steel of English makers. He cannot obtain an induction over 2,000 gausses, it seems. May I once more state that both Messrs. Jowitt and Mr. J. P. Wall supply steel which, when properly treated, has a permanent induction of over 4,000 gausses. We make a large number of magnets from Wall steel for use in our portable generators, and have no difficulty whatever in getting a permanent induction of from 4,000 to 5,000 gausses. In fact, no magnet of our own make has given less than 3,700 gausses. The secret of success lies in properly hardening the steel, and I have no doubt our smith would be happy to show Mr. Preece how it is done.—Yours, &c., SYDNEY EVERSHED.

Buxton, September 17, 1890.

MAGNETIC BRASS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have read with interest your note in last week's *Electrician* respecting magnetic brass, as I had some trouble from the decidedly magnetic properties of the brass bobbins used for the current coil of my ohm meter. In the first astatic instrument we made these bobbins were cast in one piece, and the needles were strongly attracted to the edges of the bobbin cheeks. I naturally looked for flats on the pivot or the point of the axle, or a crack in the jewel-cup, and only after investigating every impossible and apparently possible cause in vain, did it occur to me that the brass was magnetic. However, on replacing the castings by bobbins of rolled brass the defect vanished. I found a small bar of metal cut from one of the delinquent castings was strongly magnetic, although it showed no trace of polarity.

In an experimental instrument I had previously noticed apparent magnetic permeability in a *rolled brass* frame closely surrounding an astatic system of needles, so that it is necessary to examine all brass before putting it into sensitive instruments.—Yours, &c., SYDNEY EVERSHED.

Buxton, 17th September, 1890.

COMPARING CAPACITIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I think Dr. Muirhead's Inductive Capacity Test (see *The Electrician*, September 5th), using a Saunders' key, a splendid one, and the key is certainly a "long-felt want supplied." The test will recommend itself as an efficient check on the ordinary methods of testing. The times of charging are *very* wide, but the result shows up the beauties of the test. In Table I., a little under two seconds; and for the cable, two seconds appeared to be the best times for application of the particular currents used.

I would ask how the true capacity of the cable was arrived at, because if it is the factory test, the figures given in the table would represent *about* the true capacity of the cable when laid, as the effects of pressure and temperature must then be taken into account.—Yours, &c., H. CASENHEM.

MORLEY MEMORIAL COLLEGE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: May I call the attention of your readers to the advertisement on page xvii. of this paper? We are anxious to make known these classes to heads of firms, that they may facilitate their *employés* joining them; that more people may be benefited by the higher education now placed within the reach of all who wish to improve themselves. You will notice that the classes are not exactly free, because we do not desire to pauperise our working friends, not even with education, and being sure that they would prefer to pay part of the expenses; but the fees are so small that it places education within the reach of the *very poorest*, so that none can in future years say that they wished to educate themselves but could not afford to do so. Last year our numbers rose to over 800. We have room for 1,000 students, and hope this year to have that number as the College becomes more known.

Thanking you for your kindness in helping our work, I am, yours, &c., EMMA CONS, Hon. Sec. and Trustee.

TRADE NOTES AND NOTICES.

[Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.]

BELFAST.—The Corporation are endeavouring to obtain the sanction of the Local Government Board to borrow £50,000 for electric lighting purposes.

VACANT APPOINTMENT.—The Jamaica Institute, Kingston, Jamaica, require a secretary and librarian, who shall not be a member of the Civil Service. He must be competent to perform the duties set out in the printed conditions—amongst which is the encouragement of literature, science, and art in the island. The salary is £500 per annum. Applications must be accompanied by testimonials, and reach the Secretary of the Institute by November 30th next, from whom printed conditions can be obtained on application.

MESSRS. W. SOUTTER AND SONS.—We have received from this old-established firm of art metal workers an elaborate catalogue of very artistic designs for electric light brackets, electroliers, pendants, ceiling lights, wall mirrors, table lamps, bell pushes, bells, and switches, &c. On the frontispiece of the catalogue (which is large folio book) is an engraving of the very large works of the Company at Birmingham. Many of the designs in the book show great taste. Amongst the brackets may be mentioned Nos. 1665, 1670, 1764, 1506, 1524, 421, 1587, 1581, 1507, 1520, 1641, 1648, and 1635. No. 1666 is a three-light passion-flower electrolier, and is a very chaste design. The ceiling lights and wall mirrors are cheap and worthy of notice, and include an excellent selection. The catalogue is well got up, and reflects credit both on compiler and printer.

"ELECTRICITY IN EVERY-DAY LIFE."—With reference to our note of last week, respecting the issue of a brochure by Messrs. Goolden and Co., we understand that this is issued for private circulation only, and not for sale. A similar book will, however, be issued shortly for public sale.

WOODHOUSE AND RAWSON UNITED (LIMITED).—We are in receipt of some well-got-up circulars from this Company, giving illustrated particulars of Lincrusta-Walton bell pushes, specially designed for use on the Lincrusta-Walton paper, the diamond waste oil filter, electric bell dry battery, and a card list of prices of Hardtmuth's electric light carbons, for which the Woodhouse and Rawson Company are agents.

MR. SCHMIDT.—We are in receipt of an illustrated circular giving the prices and particulars of The Instantaneous and Continuous Screw Vice, made by Mr. Schmidt.

MESSRS. HOLDEN AND BROOKE (LIMITED).—We have to acknowledge the receipt of a large quarto catalogue, containing 100 pages of descriptive matter, and prices of injectors and fittings made by this firm. A large number of illustrations are given, and the catalogue contains some useful tables. Flattering testimonials from a large number of users of Messrs. Holden and Brooke's manufactures are set out; amongst the users being a large number of electrical firms. On page 28 sectional drawings are given, showing the arrangement of the high-speed electric light engines, and the automatic and supplementary injector. The catalogue is admirably arranged and well printed.

MESSRS. MARSHALL, SONS AND COMPANY.—This firm have been awarded six separate highest awards for their engines, boilers, saw-bench, &c., exhibited at the New Zealand International Exhibition this year.

THE NEW YORK INSULATED WIRE COMPANY.—This Company send us their new price list (No. 17, August, 1890), which gives particulars and prices of "Grimshaw" Cables, Wire and Tapes. Wright, gauge and resistance tables are included, and the book is a handy size for the pocket.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

August 16, 1890.

12,874. C. R. BONNE. London. Improved electric switch. (The Actien Gesellschaft, Mix and Genest, Germany.)

August 18, 1890.

12,914. A. J. JARMAN. London. Improvements in switches for controlling and regulating double or compound electric motors, especially applicable to traction or marine propulsion.

12,915. A. J. JARMAN. London. Improvements in brush holders for dynamo-electric motors and generators.

12,957. D. H. DAVIES and J. M. TOURTEL. London. Improvements in electric lighting by means of coin feed apparatus.

12,958. D. H. DAVIES and J. M. TOURTEL. London. Improvements in apparatus for effecting by insertion of a coin the production of electric light for a certain time.

August 19, 1890.

12,979. H. B. COX. London. Improvements in thermo-electric generators.

12,997. W. B. BRAIN, A. J. ARNOT, and F. BAKER. London. An improved electrical rock-drill coal digger or earth cutter.

Digitized by Google

13,002. H. H. Lake. London. Improvements relating to induction coils or transformers chiefly designed for use in welding or otherwise working metal by electricity (E. Thomson, United States).

13,003. D. Pepper, jun. London. Improvements in the manufacture of electrodes for primary and secondary batteries.

13,006. H. H. Lake. London. Improvements in welding or otherwise working metals by electricity and in apparatus therefor (E. Thomson, United States).

13,013. D. Pepper, jun. London. Improvements in the manufacture of electrodes for primary and secondary batteries.

13,024. G. O. Rennerfelt. London. Method of, and apparatus for, producing by means of electrolysis decomposed products of melted haloid salts, and other combinations of metals.

13,042. C. J. Van Depoele. Liverpool. Improvements in or appertaining to electric railway systems.

13,044. P. E. Bardonnant and P. Jupfont. Liverpool. A new or improved method and apparatus for effecting economy of electric force in electric writing. (Date applied for under Patents Act, 1883, Sec. 103, 20th February, 1890, being date of application in France.)

13,049. F. E. Macmahon. London. Improvements in electric telegraphs in part applicable for signalling on racecourses and elsewhere.

August 20, 1890.

13,107. K. Kurmayer, S. Cappilleri, H. Grunwald, and C. Holzappel. London. Improvements in electric arc lamps.

August 21, 1890.

12,123. G. Hookham. Birmingham. Improvements in electricity meters for alternating or interrupted currents.

13,129. A. W. Slater. Blackheath. Improvements in safety fuses or cut-outs for electrical circuits.

13,161. A. Lucas and E. Sundboig. London. Improvements in means and apparatus for adjusting electric suspending lights and for other like purposes.

13,171. L. Hoepl and E. Courtin. London. Improvements in fittings for incan lescent electric lamps.

13,175. W. Peto. London. Improvements in miners' electric safety lamps.

13,187. R. F. Moore. London. Improvements in electro-motors.

August 22, 1890.

13,190. R. Kennedy. Kilmarnock. Improvements in exciting electro magnets and electro-magnetic machinery.

13,199. J. Graham. London. Improvements in electric telephone switch apparatus.

13,212. R. Drysdale. Birm'ngham. Improvements in electric accumulators.

13,223. The Mining and General Electric Lamp Company, Limited, and W. Moscrop. London. Improvements in portable electric lamps, more especially intended for miners' use.

13,256. J. T. Gent, A. W. Staveley and I. H. Parsons. Improvements in coin-freed electrical apparatus.

13,260. M. von Dolivo, Dobrowolsky and P. Mamroth. Trading as Allgemeine Electricitäts Gesellschaft. London. Improved means for the distribution of electricity.

SPECIFICATIONS PUBLISHED.

1889.

7,005. Schanschieff. Galvanic batteries. (Price 6d.)

10,640. Crampton and Essinger. Electric arc lamps. (Price 8d.)

12,185. Howard. Distributing electricity. (Price 11d.)

12,236. Swinburne. Alternating, &c. electric currents. (Price 8d.)

12,237. Swinburne. Electric transformer. (Price 8d.)

12,389. Houghton. Electrical contact maker, &c. (Price 6d.)

12,563. Lowne. Electrical ships' logs. (Price 11d.)

13,154. Mather and Sumpner. Constructing electrical coils. (Price 6d.)

NEW COMPANIES REGISTERED.

GLASGOW AND DISTRICT PULSION TELEPHONE COMPANY.—Registered in Scotland with a capital of £6,100, in 6,000 ordinary shares of £1 and 100 founders' shares. Object: To acquire and make binding upon the company, and to carry into effect, an agreement dated July 2 last, made between the Primary Syndicate (Limited), of 72, King William-street, London, and James Weir Cathcart, of 51, Pall-mall, London, on behalf of this Company, and to accept and execute the licences referred to in that agreement; to purchase or otherwise acquire any patents or patent rights or licences or any invention comprised in or referred to in said agreement, and any invention analogous to or capable of being used in connection with the invention, or which the Company may consider desirable to obtain for the purposes of its business in respect of any such invention, and any trade marks, registered designs, or such other privileges as the Company may deem expedient: to experiment with, exhibit and use, work and turn to account any inventions, licences or privileges acquired by the Company within the counties of Lanark, Renfrew, Stirling, and Dumbarton, as may be found expedient. The Directors shall not be less than three nor more than five in number, and the first Board shall be appointed by the subscribers to the memorandum of agreement and Articles of Association of the Company.

NORTH BRITISH BOILER AND MACHINERY INSURANCE COMPANY.—Capital, £75,000, in £1 shares. Objects, to insure against damage arising from explosion of steam boilers and the breaking down of steam engines, with the buildings and machinery of the works in which these are set, the policy of the Company covering loss of every description to the extent insured; to periodically inspect and report on the condition of steam boilers and steam engines, and advise as to their management, and as to the most recent developments of engineering science; to advise as to boilers, engines, and other engineering structures; surveying the manufacturing of all kinds of plant having relation to, or required in, engineering structures comprising the testing of the various metals used in connection therewith; to carry on the business of general consulting engineers in all its branches, to insure employers against claims made against them at the instance of their *employés* under the Employers' Liability Act and at common law; to purchase the goodwill or any interest of any trade or business of the same nature; to carry on the business of engineers and boiler-makers and repairers of engines and boilers. Directors not to be less than three nor more than eight in number. The first Directors are to be Ralph Moore, C. and M.E., Glasgow; Bailie Robert Sharp, iron and steel merchant, Coatbridge; Robert Clark, Armiston Coal Company, Gorebridge; Robert Highgate, of Pollok, Nitrab and Highgate, Firpark Iron Works, Shettleston, Glasgow, and Britannia Iron Works, Manchester; J. C. Adamson, J.P., Airdrie Iron Company, Airdrie; and Prof. Alexander MacLay, B.Sc., C.E., Glasgow and West of Scotland Technical College.

WHITFIELD, HODGSONS AND BROUGH (LIMITED).—Capital £10,000, in £10 shares. Object, to acquire the business of Charles Whitfield, mechanical engineer, of the Union-street Ironworks, Kettering. Not less than three nor more than four Directors. The first are C. Whitfield, J. E. Hodgson, T. E. P. Hodgson, and W. P. Brough.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 12th amounted to £4,728.

DIRECT SPANISH TELEGRAPH COMPANY (LIMITED).—The Board derided on Wednesday to recommend the payment of the dividend at the rate of 10 per cent. on the Preference Shares, and a dividend at the rate of 6 per cent. (free of income-tax) upon the ordinary shares for the half-year ended June 30th last. The Report of the Directors will be issued this day (Friday).

ELMORE'S FRENCH PATENT COPPER DEPOSITING COMPANY (LIMITED).—The prospectus of this Company was issued on Saturday last. The Company has a capital of £200,000, in 100,000 shares of £2 each, of which 66,750 shares were offered for subscription at a premium of 10s. per share. Of the 100,000 shares, 13,000 shares were applied for by the Directors and their friends. The Directors are Sir Richard J. Meade, K.C.S.I., C.I.E. (chairman), Major Charles Jones (vice-chairman), Mr. E. J. Carson, Mr. William Elmore, Mr. Charles Glendining Philips, and Sir J. D. Mackenzie, Bart. (Managing Director). The consulting metallurgical chemists are Francis E. Elmore, Esq., and Alexander S. Elmore, Esq.; and the secretary is Mr. James Shurmer. The Works are situate at Bellegarde, near Lyons, and the London office is at 20, Bucklersbury, E.C. This Company is formed to acquire the patents for France (numbered 192,985, of 1888, and 195,277, of 1889) relating to the discovery made by Messrs. F. E. Elmore and A. S. Elmore, for manufacturing, amongst other things, copper articles direct from rough copper bars. The patents are sold to this Company by Elmore's Foreign and Colonial Patent Copper Depositing Company (Limited) for £83,500 payable in cash, and £66,500 payable in shares, together with the premiums received from the issue of the shares now offered for subscription, the vendors paying all preliminary expenses up to the first allotment of shares. No founders' shares are created. After completion of the above purchase there will remain the sum of £50,000 for working capital. The lists opened and closed on Tuesday last. The Memorandum of Association is a very exhaustive one, under which the Company has power to undertake an extremely varied assortment of businesses, including those of bankers and financial agents.

FIVE PER CENT.—The *Financial News* of yesterday contained an interesting article on the subject of investments yielding 5 per cent. Included in the list by our contemporary are "The Globe Telegraph and Trust Company, Limited," "The Anglo-American Telegraph Preference," and "The Direct Spanish Telegraph Preference," yielding 5¼, 6¼, and 5¼ per cent. respectively, at the prices of 8⅞, 88, and 92.

GENERAL ELECTRIC POWER AND TRACTION COMPANY.—The statutory general meeting of this Company will be held at Winchester House, Old Broad-street, on Tuesday, the 23rd inst., at 12 o'clock.

THE UNITED ELECTRIC LIGHT AND POWER COMPANY (AMERICA).—The stockholders of this Company have filed a consent to the execution of a mortgage on the property of the Company not exceeding $5,000,000.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated receipts of this Company for the half-month ended September 15th, amounted to £2,384, compared with £2,038 in the corresponding period last year, an increase of £346.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 12, 1890, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,698.

WINFIELD'S (LIMITED).—The annual general meeting of Winfield's (Limited) was held on Thursday afternoon last at the Company's Works in Cambridge-street, Birmingham, presided over by Mr. Wilson, Vice-Chairman of the Company, who, in moving the adoption of the report, said: Although the profit which had resulted on the last year's working was not great, they believed they were thoroughly justified in adopting a hopeful and confident tone. The amount had been fairly and honestly earned, and was an indication that the business had turned the corner. The profit had practically been earned during the last six or seven months. They had cut down dead expenses very extensively, consistent with the efficient conduct of the business, and had not been unmindful of the importance of introducing new and special articles. They were cautiously and safely laying down lines of a new manufacturing policy, which they could not discuss publicly, but which would be most helpful to them in the future. The profit earned (£3,592. 15s. 9d., after writing off £2,027 for depreciation) they proposed to carry to the credit of the concurrent year's trading, and thus strengthen and conserve the resources of the Company. They had thought it prudent to take their largest shareholders into their confidence before they submitted this proposal to the Company, and they unanimously concurred in the suggestion, and the auditors also approved it. The Directors now felt the time had come when they must make an appeal to the shareholders for an additional amount of working capital. They were under considerable obligations to their bankers, and if it could be obtained it would preferable to work upon their own capital than upon borrowed money. The report and balance sheet were then adopted, and the retiring Directors were re-elected, as also were the joint Auditors.

THE NON-CONDUCTOR OF ELECTRICITY.

VULCANISED FIBRE,

PATENTED.

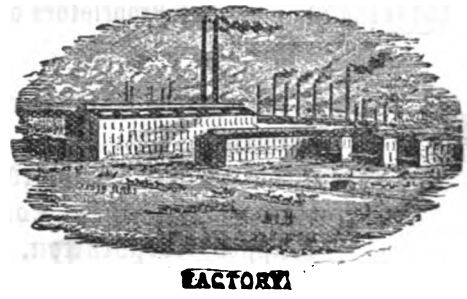
This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 2ft. 6in., varying in thickness from 1-60in. to 1in.



FACTORY.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

MOSSES & MITCHELL, 70, Chiswell-st., London, E.C.

JABLOCHKOFF'S

DISTRIBUTION PATENT

(BEING A PATENT FOR "PRODUCING AND DIVIDING ELECTRIC LIGHT," No. 1996 of 1877.)

THE ELECTRICAL ENGINEERING CORPORATION, LIMITED

(STATTER'S) Are Proprietors of the above Patent, and Warn the Public against Infringement. (UNITED).

The following are Licensees:—

Brush Electrical Engineering Company, Limited.
Crompton & Co., Limited.
S. Z. de Ferranti.—London Electric Supply Corporation, Limited.
W. T. Goolden & Co.
Hammond & Co.
Wilson Hartnell.
Johnson & Phillips.
Laurence, Paris & Scott, Limited.
Nalder Brothers & Co.
Paterson & Cooper.
Ernest Scott & Co.
Siemens Brothers & Co., Limited.

3, PRINCE'S MANSIONS, VICTORIA STREET, WESTMINSTER. PERCY E. SCRUTTON, *Secretary.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 645.—Vol. XXV. FRIDAY, SEPTEMBER 26, 1890. Price Fourpence.

NOTES.

The list of electric lighting notices for 1890-91, which will be found in another column, shows that considerable activity still exists in this direction. The 474 notices of last year resulted in the granting of 31 Provisional Orders; and if the same proportion should continue to hold good, the 263 notices of this summer may be expected to yield about 17 Orders next August. As there are some 50 Companies concerned in the issue of these notices, they may reasonably anticipate obtaining one Provisional Order between three of them. The vast majority of the notices are, of course, mere *ballons d'essai*, but they no doubt serve a useful purpose, inasmuch as they keep electric lighting before the Local Authorities and oblige them to come to a definite decision with regard to it. Although most of the Companies now in the field were also prominent last summer, there are several new comers, such as Latimer Clark, Muirhead, and Co., and the Sheffield Telephone Exchange and Electric Light Company. The House-to-House Company still continues its shower of notices. Last year 20 and this year 14 have been served by this Company, its metropolitan notices having been mostly repeated. It is to be hoped that this persistence may ultimately lead to some tangible result.

The paragraph in *The Times* announcing that "a new form of electrical generator and motor has been invented by Mr. J. Vaughan-Sherrin, by means of which the propulsion of boats, tricycles, and Bath-chairs is effected without accumulators," has attracted the attention of several of our contemporaries; but the *Spectator* thinks that "it will be necessary to obtain legislation before the new vehicles can legally come into use on the roads, unless, indeed, they are content to move at a foot's pace, and to be preceded by a man with a red flag." This erroneous idea was prevalent among the Metropolitan Police when Mr. Radcliffe Ward began to make experimental runs with his omnibus; but he had provided himself with a licence under a recent, but little known, Act, which was not in operation when Profs. Ayrton and Perry experimented with an electrical tricycle in the streets of London. In the absence of further information, we can only say that, considering the obstacles which are only now being overcome in tramway work, the difficulties of a practical electrical carriage on a small scale are enormous. As it is unlikely that any great improvement has been made in reducing the weight of the motor and its gearing, the invention probably relies on some *new* battery.

The Paper by Mr. Glazebrook on the "Recent Determinations of the Absolute Resistance of Mercury" deals with a subject of wider interest than is suggested by its title. The value of the absolute resistance of mercury does not concern the average electrical engineer any more than the absolute resistance of sodium; but a glance at the contents shows that it treats of a subject with which every electrician should be more or less acquainted. It is a sketch of the recent determinations of the ohm, and being written by one who has not only been engaged in carrying out such determinations, but who has spent so much time in comparing the standards, and in minutely watching and recording any relative changes that appear in their values, it carries the greatest weight. It is, however, a pity that it is so brief, and apparently addressed only to the members of the B.A.U. Committee and others who are concerned in this important work. The value of Mr. Glazebrook's Paper would have been much enhanced to most practical men by footnotes referring to the publications or works in which further information may be found. Few engineers have time to keep up with the work that is done by such men as Kohlrausch and Lorenz, but many of them will follow with interest the results which are obtained. In this country writers do not seem to consider that the bibliography of a subject concerns their readers as much as it concerns themselves; but a German author will generally give a list, and often a very long one, of the authorities whom he has consulted. The Cantor lectures by Prof. S. P. Thompson, on "The Electro-magnet," are an example of the use not only of copious references, but of the manner in which such references should be made.

It appears that the true value of the ohm which has been approached, asymptotically as it were, during the past ten years, can differ but very little from the "weighted" mean of the numerous determinations. The result given in Prof. J. Viriamu Jones' Paper, which is modestly called "Suggestions towards a Determination of the Ohm," 106·307 centimetres, with a probable error of ± 0·012, is nearer the mean of the ten values alluded to by M. Glazebrook than are most of the values themselves; and any new figure which may be hereafter put forward, which differs by 0·05 from that mean, will carry little, if any, weight. The time is, therefore, at hand when a complete account should be prepared of all the methods which have been adopted, with a thorough discussion of the comparative merits of the observations; an account, in fact, of which Mr. Glazebrook's Paper might be an abstract, and of which Prof. J. V. Jones' Paper might be one chapter.

According to M. Boucherot, in a recent number of *L'Electricien*, the insulation resistance of electric circuits may be obtained in a very simple manner from three observations made with a suitable voltmeter. The volts between the earth and the positive and negative leads are successively measured and added together: the ratio of the sum thus found, to the excess of the voltage of the line above that quantity, can be shown by calculation to equal the ratio of the resistance of the voltmeter to the insulation resistance required. The same formula can be applied to a three-wire system, if by the voltage of the line is understood the total potential between the positive and negative leads. The method seems well adapted to systems of distribution in which low pressure and constant potential are used, and its simplicity and quickness are great points in its favour. Its application, however, must be very limited, as the measurement cannot be at all sensitive unless the resistance of the voltmeter approximates in value to the insulation resistance under test.

A new measuring instrument, bearing the distasteful name of Mho-heure-metre, has recently been made in Paris by M. Frager. The power expended per second in a circuit of resistance, R, and absorbing V volts, is V^2/R, and the time integral of this measures the energy. If V is constant the energy depends on the time integral of $1/R$; and it is this latter quantity which M. Frager's instrument measures. It is difficult to see the purpose served by the new instrument; although its construction, which has not yet been explained, may possibly show merit. If the volts supplied are constant, the energy absorbed may be obtained from the indications, but any ordinary coulomb meter would do as well; while if the volts vary, although neither instrument measures the energy supplied, the coulomb-meter indicates something which is well understood, while the new instrument only gives a quantity unknown, to most electricians.

The occasions on which a practical electrician need trouble himself about the value of H, the horizontal component of the earth's magnetic force, are fortunately very few. Measuring instruments are generally placed in an artificial field produced by strong permanent magnets, and their sensibility determined by the effect produced by the passage of a known current. Moreover, as sensitive apparatus is usually constructed, a knowledge of H would be of but little assistance in deducing the constants, since the complex winding of the coils renders calculation impossible. The usual method of measuring H, that of Gauss, is also so long and tedious, and the apparatus required for good results so expensive, that the determination is avoided whenever possible. If, however, a simple and short method for measuring this quantity could be found out, it is not unlikely that useful applications would result; and it is therefore interesting to find that Prof. Stroud, of the Yorkshire College, Leeds, has been able to devise a method which possesses many advantages over the well-known one of Gauss.

Prof. Stroud's apparatus, which is described in the June number of the *Proceedings* of the Royal Society, consists of a piece of fine pianoforte wire, bent into the form of a circle, the two ends being soldered together. This ring is magnetised like a Gramme armature, with opposite poles at the ends of a diameter, and suspended bifilarly in a vertical plane, with the line of poles horizontal. At the centre of the circle is suspended a small magnetised needle, whose deflection is observed when the plane of the circle is placed at right angles to the magnetic meridian by twisting the bifilar arrangement. The formula obtained for H involves the ratio of two observed angles, the weight and radius of the wire circle, and the dimensions of the bifilar suspension. It does not depend in any way on the distribution of magnetism in the wire; nor is it necessary for the suspended needle to be exactly at the centre of the circle. The corrections necessary are of a much simpler and more certain kind than those required in Gauss's method; while there is no need to go through the tedious operation of determining a time of vibration. The instrument can be made at very small cost; and when the dimensions and other constants of the instrument have been once determined, the time occupied in finding H is only a few minutes. How accurate the method can be made is as yet somewhat doubtful. The correction for torsion of the suspending fibres is rather serious; and the dimensions have all to be measured very carefully, a very difficult matter when some of the lengths are as small as those of a bifilar suspension. The method is, however, one of great promise, and the measurements given show that the instrument, when skilfully used, may be relied on to give results true to one-tenth per cent.

Bromley.—The Local Board have instructed their clerk to take the steps necessary to obtain an electric lighting order.

The Telephone at Manilla.—The Telephone Company at the Port of Manilla has decided to open a floating telephone station in the harbour.

Fire.—We are desired by Messrs. Cathcart and Peto to state that the recent fire at their Hatton-garden Works will in no way interfere with their business.

Appointment.—Mr. E. A. O'Keeffe has been appointed Senior Demonstrator and Lecturer at the City and Guilds of London Technical College, Finsbury, in the place of Mr. W. Robinson.

Personal.—We are informed that Mr. W. B. Sayers has been appointed manager to Messrs. Mavor and Coulson, of Glasgow, who have a number of important installations on hand.

The Westinghouse Strike.—The strike of the Westinghouse Electric Company's *employés* for shorter hours with ten hours' pay and other concessions, has ended in a practical victory for the Company.

Heriot-Watt College, Edinburgh.—The 1890-91 session of this College commences on Wednesday, October 1st. The College is completely equipped for providing higher technical and commercial education.

Editorial Change.—We learn that Herr Arthur Wilke will cease to edit the *Electrotechnischer Anzeiger* from October 1st, and will devote himself exclusively to conducting the new weekly electrical journal, the *Elektricitäts-Zeitung*.

The Electric Lighting of the Paris Boulevards.—On Thursday evening, last week, the electric light on the Boulevard des Capucines was temporarily extinguished, owing to a "burn-out" in a section of the Popp Company's underground system.

Newcastle.—The Newcastle and District Company now supply something like 6,000 ten-candle lights, and hope to supply before the winter is over illumination to the extent of 10,000 lamps. The Newcastle-on-Tyne Electric Supply Company is also busy.

Digitized by Google

The Production of Oxygen.—In a recent number of the *Bulletin de la Société Industrielle de Mulhouse*, M. Scheurer-Kestner estimates that about 36 franc's worth of coal is used in producing a kilogramme (700 litres) of oxygen by the electrolysis of water.

Electric Lighting in Gibraltar and Malta.—Mr. Preece left the Thames yesterday morning in the P. & O. ss. "Mirzapore," to visit Gibraltar and Malta, with the object of reporting to the Government on the best mode of introducing the electric light into these fortresses.

Royal Victoria Hall.—The autumn series of science lectures at the above hall begins with two "People's Lectures" (under the auspices of the London Society for the Extension of University Teaching), by J. D. McClure, Esq., on "Nebulæ" (September 30th), and "The Sun" (October 7th).

Electro-Harmonic Society.—The concerts of this Society will recommence on October 3rd, and will be continued on November 7 and December 8, 1890, and January 30, February 27, and April 10, 1891. They will, as before, be held in the Banquet Room, St. James's Hall Restaurant.

Holborn Board of Works.—At the last meeting of this Board, the Committee of Works recommended that the electric light should be supplied to the whole of the public rooms and offices in the Town Hall, &c. The Clerk was directed to communicate with the Metropolitan Electric Supply Company as to terms.

The Telephone at Birmingham.—Telephone transmitters are to be set up in Christ Church, New-street, Birmingham, so that subscribers to the telephone, if they desire, can hear the service and the sermon at their private residences. The transmitters will be arranged at the end of the choir stalls, on the top of the lectern and the reading desk of the pulpit.

City and Guilds of London Institute.—Prof. Ayrton's special course of lectures for outside students will be given every Monday and Wednesday at 3 p.m., commencing Monday, October 6th, and the subject will be "The Construction of Direct and Alternate-Current Dynamos and Motors, and the Methods of Testing their Power and Efficiency."

The Association of Edison Illuminating Companies.—The following are some of the subjects discussed at the Minneapolis meeting of this Association: Lightning Protection—results of experiments; Insurance of Edison Central Stations; a National Code of Insurance Rules; Edison Patent Litigation; Central Station Steam Piping; Re-organisation of Edison Interests; Grounding the Neutral Wire in Three Wire Systems.

Leeds.—At a meeting of the Sub-Highways (Tramways) Committee of the Corporation, held last week, Mr. C. H. Wilkinson, agent for the Thomson-Houston International Company, attended and laid before them a scheme for working the Roundhay section of the Leeds Tramways. It was proposed to equip the section for two years, and at the end of that time to make any re-arrangement that might seem to be desirable, the equipment to be the same as that put down at Boston.

Interurban Telephonic Communication in France.—As soon as a Bill now awaiting the sanction of the Senate has become law, interurban telephonic communication will assume large proportions in France. Bordeaux, Dieppe, Elbeuf, Limoges, Saint-Quentin, Tours, Troyes, Fontainebleau, and several other towns will be telephonically connected with Paris; Grenoble and Saint-Etienne with Lyons; Nice with Marseilles; Montpellier with Cette; Béziers with Narbonne, &c.

Telegraphs in India.—According to an extract contained in the current issue of *The Board of Trade Journal*, the length of telegraph line and cable in British India is 33,462 miles, of which 1,568 miles represent the extensions of the year 1888-89. The number of messages during that period was 2,978,998, or an increase of 176,669 over the previous year. The receipts were Rs632,247, yielding a surplus of Rs198,024 on the revenue account, equal to 4·45, as against 5·46, per cent. in the preceding year, on the capital outlay. The additions to the capital expenditure during the year amounted to Rs174,362, or Rs60,593 less than in the previous year.

Electric Heating.—One of the latest applications of electricity is the heating of pressing irons, which has been introduced in a clothing factory at Minneapolis. The method of conducting the electricity into the pressing iron is as follows:—A spring rod stands upon each table, and to it the electrical wires are connected, running thence into the pressing iron. The current is made to pass through a wire resistance, which is so arranged within the pressing iron as not to come in contact with any portion of the shell of the iron. The wire is raised to incandescence by the current, and the heat thus generated warms the pressing iron to the required degree.

The Telegraph Department at Chin-Lushai.—In the military despatches on the Chin-Lushai operations, mention was made of the excellent work done by the Telegraph Department; but, says the *Indian Engineer*, the civil officers engaged deserve yet further notice, for their labours were of the most trying kind. Field lines of a length of 420 miles were laid, the principal section being from Demagiri to the Upper Koladyne, 104 miles, and from Pouk to the Boinu river, six miles west of Haka, 192 miles. Mr. E. O. Walker laid the former section; and the difficulties he had to overcome were very great, the line running through a dense forest and across a succession of hills from 2,000 to 5,000 feet in height.

Electric Tanning.—M. Müntz, Professor at the Institut Agronomique, has recently published a highly favourable report on the Worms and Balé process of tanning by electricity. All the hides so tanned had, says M. Müntz, the appearance of hides tanned by the ordinary process. Tests with acetic acid showed that the hides were thoroughly well tanned after a maximum of four days in the vats. Further chemical tests showed that the tannin was as well combined with the leather as in the ordinary method. We may mention in this connection, that a large firm of tanners in Paris are sending out, with every consignment of hides, a certain proportion of electrically tanned ones, intimating that any of the electrically tanned skins which are not found up to the mark will be immediately exchanged for some tanned by the ordinary process. No electrically tanned skins have as yet been returned.

Telephone Contracts.—The following letter from Mr. A. Erskine Muirhead appeared in the Glasgow *Evening Citizen* of Saturday last:—

"I have been a subscriber to the Telephone Exchange for some years; but recently having introduced to the notice of the telephone company and the city generally some French telephones, and at the request of a number of firms agreed to run wires and fix those telephones when the patent expires, it was quite to be expected the telephone company would be annoyed, seeing the rate proposed by me to erect wires and sell the telephones outright was not more than the annual rental charged by the National Telephone Company. They at very short notice cut off my telephonic communication with their system, though I had signed a contract in which six months' notice was required by either side. As they keep these contracts, when I applied for redress they denied my ever having signed such a contract, though their rules, as printed in their own directory, say, 'Each subscriber must sign a contract specifying the terms and conditions under which the service is supplied.' I am the sole exception, out of their 2,000 Glasgow subscribers, who has not signed a contract."

Electric Tram Accident at Florence.—A fatal accident occurred on Wednesday on the electric tramway between Florence and Fiesole. The cars ran off the track, five persons being killed on the spot and twenty others injured. In connection with this accident Mr. E. Manville writes:—"The reports published on the above regrettable accident are liable to produce an impression that the fact of the tramway being propelled by electricity was the cause of the accident. But from details already received it is clear the accident was due only to an inexperienced driver omitting to shut off the current from the motor when going down hill, and exactly the same results would have followed had the car been propelled by a steam locomotive, or indeed any form of mechanical traction involving the use of independent motors."

An American Invention.—John Bull, says our esteemed contemporary, the *Electrical Review* of New York, is green with envy over the rapid strides taken by American inventors in the field of invention. The English journals at every issue contain some slur intended to detract from the value of the great inventions in power, lighting, telegraphy, or the multiplicity of applications found for the subtle fluid by the ingenious American. It is, doubtless, very hard for our English cousins to admit that

Digitized by Google

they are beaten in the contest of brains, but they can scarcely fail to realise the situation, and it would be more creditable to bow gracefully to the inevitable. Just now they are directing their slings at the phonograph, and assailing its commercial usefulness. It has not taken the public on this side of the pond long to learn how to employ this marvellous instrument. The thousands of instruments in active use by business men in the despatch of their daily routine is a safer criterion of the commercial value of the invention than the slurs of quasi-scientific scribblers, who, if they laboured until the crack of doom, could give birth to nothing more useful than a few tomes of platitudinous twaddle.

An Edison Electric Generator.—One of the latest and most curious outcomes of Mr. Edison's inventive genius is an apparatus for generating electricity by causing the magnetic circuits of a series of electromagnets to be alternately made and broken. To effect these interruptions of the magnetic circuits Mr. Edison employs the agency of heat. The electromagnets, which are magnetised nearly to saturation, are attached to the ends of a number of arms consisting of sheets of nickel secured to end pieces. These arms, mounted in openings in the top plate of a short cylindrical furnace, project radially from its centre, the top plate extending beyond the sides of the furnace so as to keep the magnets cool. Inside the furnace is a slowly revolving shield, covering one half of the openings in the top plate. One half of the nickel arms are thus cooling while the others are being heated; in other words, one half of the arms will be contracting and the other half will be expanding. Now, as the magnetic circuits are pivoted at their centres, these expansions and contractions cause the circuits to be alternately closed and interrupted. At the points where the magnetic circuits are broken, coils are wound in which currents are induced by the alterations in the value and distribution of the magnetic flux. *Parturiunt montes, nascetur ridiculus mus.*

The Disengagement of Heat and Light in Electrical Discharges.—In a recent number of the *Beiblätter der Physik*, G. Staub describes how he determined the ratio of the total energy (E) emitted by a gas to that which is perceived as light (L). He introduced a Geissler tube into an ice-calorimeter, from the bottom of which the mercury was removed. The ice and water transmitted all the rays of light, and only absorbed those of heat. He then blackened the Geissler tube, and thus retained the visible rays also in the ice-calorimeter. If the quantity of heat in the first case is Q and in the second E, $L = E - Q$. The width of the Geissler tube was altered as well as the pressure in it, and condensers and also breaks were interposed in the circuit. The results of the experiments were as follows. With the help of electrical discharges in Geissler tubes, light of considerably greater useful effect may be obtained than in the glow-lamp. The maximum for one of Blattner's was 10 per cent., and for a Geissler tube with condensers 32·8 per cent. The useful effect increases with the density and quantity of electricity which passes through the tube. It decreases as the pressure and diameter of the capillary tube increases. If the Geissler tube is filled with hydrogen, the optical effect is less than in air, other things being equal. These results agree with the experiments on glow-lamps and flames, in so far that the higher the temperature the higher in general is the useful effect.

Municipal Telegraphy and Strikes.—The dependence of the police in large cities for the efficiency of their system upon the telegraph is, says the *Western Electrician*, illustrated in the following story concerning the big strike on the New York Central Railroad. When the strike of the New York Central road was declared, some four weeks ago, the police wires on the east side above Fourteenth-street did not respond. The operator rushed into the inspector's office in great excitement with the news. The wires were tried again without response. Four linemen were sent out to find and repair the break; and orders were sent over the Western Union wires to forty detectives to report at once to police head-quarters. These men were stationed where they could get telephones, and were instructed to keep the central office informed of the actions of the strikers. At 8 o'clock the linemen reported that they were unable to locate the break in the police wire. In the meantime it was telephoned from the Murray Hill Hotel that the signal station switches at Fifty-seventh-street were threatened. The inspector sent out the linemen again, and an hour later they came back unsuccessful. The circuit was ultimately completed by using a Western Union wire from Fourteenth to Thirty-fifth streets, and the anxiety of the police inspector was relieved.

The Storage Battery in the Chicago Telephone Exchange.—For some months, says the *Western Electrician*, the Chicago Telephone Company has been ringing its subscribers' signal bells by means of current from the Chicago Edison Company's system. The apparatus consists of a small commutator driven at about 700 revolutions by a water motor. By this arrangement alternating current necessary for the operation of the bells is obtained directly from the Edison wires. The Company is now introducing a system through which the primary batteries working on all local circuits will be replaced by storage batteries charged from the Edison house circuit. Each group of storage cells is divided into two sets of five each. The cells of each set are charged in series, the charging current coming to them through a lamp resistance. By means of switches, either of the two sets of a group may be cut into or out of the lamp circuit and thrown into service on the local wires. By the use of the storage batteries, it is said, the local service is much improved. Much valuable space is saved by the difference in the room taken up by gravity cells and accumulators In addition to the above adaptation, Mr. O'Connell, the Electrician to the Company, also proposes to employ storage cells in connection with subscribers' telephones. His plan is to remove the primary battery and instal a small accumulator at any telephone where the Edison lighting wires may be tapped. Connections are to be made in such a manner that when the telephone is in use the released hook-lever will throw the Edison current into the storage cell through a lamp resistance. The accumulator will ordinarily be connected in the same manner as the primary battery was, and the Edison current will only be flowing while the subscriber is talking. Hanging the telephone on the hook breaks the circuit to the Edison mains.

Electric Transmission of Power for Railway Tunnelling Purposes.—*Engineering* of September 19th contains an interesting description of the works in connection with the construction of the Santa Rosa—Mendoza section of the Buenos Ayres with Valparaiso railway line. This section of the line crosses the Andes by a series of tunnels, the highest of which is at an altitude of 10,466 feet above the level of the sea. The greater portion of the tunnelling is through very hard rock, and it was found necessary to employ drilling machinery to expedite the work. As the cost of fuel would have been great and there was not sufficient water power close to the entrances to the tunnel, it was decided to utilise the water found in the valley below, and to transmit the power by electricity to the tunnel faces on the mountain sides above. Two installations have been made, one on the Argentine and the other on the Chilian side of the Andes. On the Chilian side a head of water of 600 feet and on the Argentine side a head of 400 feet can be obtained. The water thus obtained at considerable pressure is used for driving Girard turbines. On the Chilian side there will be twelve 80 horse power turbines, working at 700 revolutions per minute, each turbine driving direct on to a 54 kilowatt (400 volts × 135 amperes) dynamo. From this installation the power is conveyed to Juncalillo, about two miles distant, from six of the dynamos to six 60 horse-power motors, whilst the power of four dynamos is carried to four 60 horse-power motors at Calavera. In each case the motors make 600 revolutions per minute and drive air compressors, capable of compressing air to six atmospheres. The power from the Argentine side will be carried about two miles to Las Cuevas. The cables, made by Siemens Bros. and Co., are covered with a special insulating preparation and encased in lead and further protected by an outer covering of plaited jute. Four installations of electric light have been provided, each absorbing 10 horse-power. Telephonic communication will be established between the two generating stations. As this is probably the first instance in which electrical transmission has been used for tunnelling purposes on so large a scale, it will be interesting to watch the results.

THE BRITISH ASSOCIATION MEETING AT LEEDS.

BY DR. OLIVER LODGE, F.R.S.

Once more has Section A been overladen with the weight of its own material, and full discussion has been of necessity choked. There is nothing of a grievance in this statement; it is the result of the great activity in all departments of Physics at the present time, and it is easier to point to the evil than to find a remedy. Already it is necessary to practically divorce Mathematics from the rest of the subjects, and take it by itself at a time when the main body of the Section is sitting elsewhere; and this is by no means a satisfactory or desirable occurrence. The Pure Mathematicians attend during many physical communications; and it is only reasonable that Physicists should keep in some sort of connection with the progress of Pure Mathematics. In old days the overlapping of the two sets of minds on the mathematical field-day sometimes produced brilliant results.

With the chair occupied as it was this year by an eminent Mathematician, who, though a specialist in one sense, is known to be interested in a wide range of subjects outside his special domain, it was to be hoped that some memories of the meeting at Bradford would be revived; but the press of business ordered it otherwise, and a great part of the members were called away on electro-chemical duty during the mathematical session.

Yet some bifurcation seems absolutely essential, and an opportune proposal is understood to come from the Meteorologists suggesting a sub-section for their department. By splitting off Astronomy, and Spectroscopy, Terrestrial Magnetism, Meteorology, and Photography, into a sub section, meeting regularly on several days but arranging so as to read their Papers of most general interest on, say, Monday, when the main Section might either abstain from sitting or take its more formal reports, considerable relief might be afforded, and a fairly mathematical Saturday might again be possible. The other proposal is to divide into General Physics on the one hand and Electricity on the other. It is characteristic of this particular portion of the century that such a proposal can be seriously contemplated, but it seems to me highly undesirable thus officially to widen a breach which the populace is already too willing to detect and emphasise. Moreover, an electrical sub-section would soon become an omnium gatherum of some of the highest flights of scientific speculation on the one hand, and some of the trivialest forms of "cut-out" on the other. A mass of patent devices and practical detail, highly useful in their own way but scientifically considered of little significance, would tend to accumulate in such a sub-section, whereas their more appropriate place is Section G.

Whatever has for its main interest the practically useful and commercially advantageous seem to me to belong by rights to the Engineering and Applied Science Section; and some slight relief would sometimes be afforded to Section A if this proposition were admitted and acted upon.

I admit at once that the scientific engineer might, if he chose, entirely repudiate any such contention, and taking his stand on the undoubted fact that pure mechanical engineering is a science irrespective of any possible uses in the arts, might repel the insinuation that he was mainly concerned with practical utility, and assert that he dealt with abstract mechanical science. But from what one knows of the past associations of the section, such an objection is not likely to be really made; and Applied Electricity is already assimilated by it just as much as applied Heat and Mechanics.

And a highly interesting department of knowledge is thus constituted. Applied and pure science are to be separated not because one is less exciting than the other, but because the attitude of mind appropriate to one is inappropriate to the other, and wherever you try to combine or alternate them they clash.

As to general interest, there can be no doubt, indeed, that the applications of science, the developments wherein abstract science begins to touch the needs or increase the power of humanity, have by far the greatest interest for the bulk of mankind. And if the disciple of pure science feels a little sorry when a great opportunity, like a Presidential Address for instance, is thrown away in pointing to and eulogising those conspicuous facts which every newspaper teems with and every commercial traveller knows, it is not because he does not appreciate Atlantic cables and Forth bridges, electric traction, arc lamps, telephones, the United States, Wheatstone's bridge, petroleum oil, and natural gas; but because these things are already so dinned into the public ear by their own well-beloved organs that to prelude what is assumed to be a great scientific gathering by a further reverberation of the big drum seems scarcely dignified or suitable; seems, indeed, calculated to mislead the public as to what real science is, and to excite in the minds of its devotees a grating sensation, somewhat as though a "sky-sign" advertisement had intruded itself on the foreground of a cathedral view.

One of the most prominent subjects of discussion during the present meeting in Section A has been the most probable approximation to the C.-G.-S. unit of resistance; in other words, the most probable value of the old British Association unit in terms of the true ohm. Mr. Glazebrook had tabulated the measurements of different workers during the last few years with scrupulous care, and discussed the different methods which had been employed, with the object of deciding on the amount of accuracy to be hoped for from each. After long consideration of the figures so tabulated, and hearing from Mr. Glazebrook a full statement of the conclusions to which he felt himself led, the Electrical Standards Committee ultimately, on his advice, adopted the number ·98656 as the closest present practicable approximation to the ratio of the old British Association unit to the ohm; and they accordingly instructed him to employ this factor in issuing or certifying true ohm standards based upon the old units. The last figure in the above number is, however, quite uncertain, and the penultimate figure may be wrong by one unit. Such an error, which is only one part in ten thousand, is of no moment whatever for practical purposes, and is getting rather near to the limit at which accuracy in absolute physical measurements is possible.

Indeed, without the most scrupulous care it is not easy to know precisely what the value of the British Association unit itself is. At Cambridge there are a number of copies of the standard, and in a few physical laboratories old and authentic copies are preserved. At intervals of a few years those in England are collected together and rigorously compared with each other by means of Carey Foster's method and Fleming's bridge, great pains being taken to ascertain the temperature of each coil and also to determine its temperature coefficient. Some of these coils retain a satisfactory constancy among themselves, others exhibit a kind of secular change, notably one very important coil F (important because used largely by Lord Rayleigh), which has diverged from the general average by as much as seven parts in ten thousand, so that to make it agree with the others it has to be altered in temperature nearly half a degree. The process of comparing coils with each other is one of such comparative ease and extreme accuracy that a divergence of this amount is very conspicuous. Although the change may be described as secular it is not necessarily to be supposed gradual; it may have occurred at definite epochs while some operation was being performed upon it; while, for instance, it was immersed in an ice bath.

Not the general mean of all the coils, therefore, but the mean of those which keep practically unaltered among themselves, is taken as the value of the old B.A. unit; and on the basis of this and the factor given above, something very near a true ohm can be now issued or certified at the Cavendish Laboratory.

But outside Cambridge matters are different. On the Continent, for instance, or in America, no one knows with any precise accuracy what the British Association unit is. Copies can, of course, be purchased from instrument makers, but there is no guarantee that these shall exactly agree with the mean of those under test at Cambridge; and the discrepancy between different copies made at different times may easily be as great as the uncertainty nowadays attaching to an absolute determination. It is customary, therefore, to appeal to a totally different kind of standard, one that may be set up in any locality and at any future time, and to state the net result of all the determinations in terms of this. This is the object of

Digitized by Google

the mercury standard; it is not an easy or convenient standard to replace a wire coil, but it is a standard which, having been once thoroughly determined in terms of the British Association unit, may henceforward at any time with due care be constructed, and the old values redetermined by means of it, even though all present standards were destroyed by fire. Applying the above given factor to all the exact determinations of the specific resistance of mercury, arithmetic gives the number 106·3 as the length of a column of mercury at 0°C., 1 square millimetre in cross-section, which most nearly has the resistance of a true ohm. The range of probable inaccuracy lies between 106·25 and 106·33, the range of possible error being scarcely any wider than this; and the value most in accord with Mr. Glazebrook's instinct being 106·29. Independent and highly elaborate determinations, made in America, France, and Germany, all lie practically within these limits; and there can be little harm done if Government should see fit to make use of the labours of the Committee at this stage, or soon after the Paris Congress has sat next year, and confer authority on 106·3 as a legal and world-wide standard. No further addition to our knowledge can then be commercially significant. If only 106·25 had had the good fortune to be adopted four years ago at the previous Paris Congress, as urged strongly by the British delegates, on the strength of the measurements of Lord Rayleigh, and as supported by both France and America, all this trouble and indecision would have been spared. Failing to carry the ·25, through the opposition of certain representatives, who, by adding up a number of determinations and taking an unweighted mean, arrived at the number 106, it would have been happier if the Congress had declined to come to any decision in the matter; for a legal ohm which was never legal, and was always incorrect, has been an incubus and common nuisance for four years. Fortunate we are to get rid of it before its allotted period of 10 years has expired.

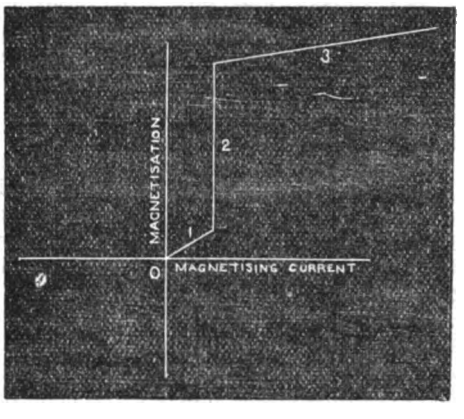
Prof. Viriamu Jones, of Cardiff, was able to bring the results of his own recent and very careful determination of the absolute specific resistance of mercury at 15½°C. by the most direct possible method (a combination of Lorenz's method with Carey Foster's), employing exact engineering appliances and workmanship. Of course it agrees with the others within the usual limits (it is, in fact, 106·307 when reduced to 0°C.), and he feels enthusiastically sanguine that now is the time to undertake a final and abnormally accurate determination, aiming at a sixth significant figure.

The British Association has almost from the beginning taken such a leading part in the introduction of absolute measurement into electrical science, its long-established committee on Electrical Standards being one of the weightiest and best known of its committees, and having a great influence all over the world, that a couple of mornings was none too much to give to a thorough explanation of these matters in the Section; and the meeting will be remembered as one largely occupied with questions of refined accuracy. A general and lighter discussion on electrical units in general, which had been announced and prepared for, had from this cause to be postponed, first to Wednesday, and thence by press of work *sine die*; but a future time can doubtless be found for it, either at Cardiff or at Edinburgh, and, meanwhile, opinion can be matured and suggestions made by circular or correspondence. Doubtless it would have been some relief to the Section to have a light skirmish by way of diversifying the proceedings of the heavy-armed troops; but it is better to finish a thing thoroughly when begun, and the Leeds meeting of Section A has been characterised by good solid work, very little time being afforded for frolic or diversion.

The most brilliant Paper communicated to the meeting, and the one likely to be most fruitful of consequences (so it seems to the writer), was the one on the "Induction of Magnetism," by Prof. Ewing. Ever since the time of Ampère, physicists have been familiar with the idea that a magnetic substance consists of an assemblage of minute magnets, which by the act of magnetisation are made to face on the average in one direction, instead of continuing to lie higgledy-piggledy, as they did when the substance was not magnetised. And this view of magnetisation, that it consists in facing round already magnetised molecules, rather than in exciting magnetism in previously inert molecules, has been experimentally proved in several ways.

But when it came to entering into detail concerning magnetic induction (the term "induction" being here used in what Sir W. Thomson considers its only proper signification, viz., to express the simple old operation analogous to electrostatic induction, the magnetisation of iron by immersion in a magnetic field), there was room for considerable uncertainty as to the kind of process going on. Everyone knows that when a substance is subjected to magnetising processes, some of the magnetisation excited is only temporary, while some continues permanently after the magnetising forces are withdrawn; a fact which may be expressed by saying that the molecules are strained out of their old positions into new ones, and when released they spring back part way toward their old positions, but do not completely recover unless the strain has been very small, or the iron excessively soft. The whole process is so analogous to what is known of the behaviour of solids in general that it has been natural to think of it as a kind of elasticity, accompanied by a kind of permanent set, as soon as the elastic limits are overstepped. *And so no doubt it is.* The molecules are jammed into their positions by something analogous to solid friction, but with a certain freedom or elastic yielding for small ranges of disturbances.

The behaviour of a set of magnetised molecules had been worked out theoretically by Weber and Maxwell on the elastic solid hypothesis; but the correlative hypothesis that instead of being subject to arbitrary mechanical force they might be perfectly free molecules, subject only to their own mutually perturbing magnetic forces, although suggested, had not been theoretically attacked or developed. Prof. Ewing has attacked it experimentally with brilliant results. Even with so crude a model as an assemblage of pivoted compass needles in a plane he has been able to imitate a great deal of the known behaviour of magnetic substances very satisfactorily.



Plotting the magnetisation developed in bodies against the magnetising force applied, everyone knows the curve obtained—the characteristic curve of a dynamo, in fact. This curve looks very much as if it were the smoothing out of three distinct almost linear portions, which I will call 1, 2, and 3. In portion 1 the susceptibility is small, and we are within the elastic limits, so that if the force be withdrawn everything subsides back to the origin. But at a certain point instability sets in; magnetisation increases with enormous rapidity, and if the force be withdrawn now, the magnetisation returns, not to O, but to a point on the vertical line above O, the height of which point indicates the permanent set. This rapid sort of viscous yield of the material continues until another critical point is reached, the beginning of portion 3, when again elasticity supervenes, and no further permanent magnetisation can be got by increasing the strain, only a slight increase of temporary effect; the iron is said to be nearly saturated.

All this Prof. Ewing finds his flock of compass needles able to imitate. First, when joggled in any irregular manner, they set themselves in some regular pattern having no resultant magnetic action, neutralising each other so far as outside space is concerned. Then, when a current is passed

Digitized by Google

round them they deflect a little in such a way that they can swing back to their old position when it stops. Increasing it further, they begin one after another to topple round into some fresh position, wherein they combine to produce a resultant outside magnetic effect, giving the second portion of the curve. Finally, after they have all thus revolved, they can be deflected a little more towards the exact line at right angles to the magnetising current, but only in a temporary or elastic manner, springing back into their newly-acquired stable position when the current is stopped.

It is unnecessary to follow the process of reversal of magnetisation in detail; it can be easily imagined. Suffice it to say that all the known phenomena called hysteresis can be imitated by the model, and many other things too, less obvious on their surface.

This conception of molecules subject only to known mutual forces and subject to no obscure constraints either elastic or viscous, free from solid friction and every other vague force, is a tremendous simplification in the dynamics of magnetism. Neither does it limit itself to magnetism alone, for, as both Osborne Reynolds and Fitzgerald said at the meeting—as Ewing indeed began to hint in his Paper—it gives a hope of explaining similarly all the properties of solids. For, as I have above said, the molecules of a magnetic substance do behave elastically, do yield viscously, and do get set by solid friction into new positions. The model does not deny these propositions, but it takes us underneath the vague statements, and shows us, at least for magnetic substances, what elasticity and viscosity and solid friction really are. It reduces the behaviour of solids to the action of free molecules acting on one another by simple and calculable polar forces. And for non-magnetic substances, as Fitzgerald hinted, and as Maxwell (I think he said) began to work out, there may be crystalline or some other polar forces to take the place of the magnetic force in Ewing's model.

If, as Ewing surmises, when a substance enters the liquid or pasty condition, every molecule begins to spin on its axis, all polarity should at once disappear, and the peculiar properties of a solid body should likewise disappear with it.

It is not to be supposed that all magnetic phenomena are completely explained; many can be thought of which the model does not yet seem to touch; but an immense step has been made towards understanding the structure of a solid; and with the cessation of vagueness, and the emphasising of a definite calculable action among the molecules, much progress in solid dynamics may be expected.

The theory of free molecules possessing velocities of translation (a gas) has long been known. The theory of stationary molecules, subject to simple mutual constraints, already by Boscovich and others begun, may now be developed. The intermediate theory, expressive of the properties of liquids, seems likely to lag a little behind the other two.

Another very interesting communication was an account by Mr. H. G. du Bois, in excellent English, of some researches he had been conducting in Prof. Kundt's laboratory on the passage of light through metals. A very thin film of metal is electrolytically deposited on a glass plate prepared to receive it by an infinitesimal spray or evaporation from an electrified metallic point. By the use of a point-anode held close above the plate, films of graduated thickness are deposited in somewhat lenticular form, but everywhere thin enough to be just transparent. Places with sufficiently flat surfaces are selected on the film, and all the rest is covered up with black varnish. Some of the flat surfaces being on a slope, a prism of excessively small angle is obtained, and the light in passing through this is deflected by a measured amount. The experiments are delicate and difficult, but the results exhibit surprising concordance. Using the term "index of refraction" in its ordinary elementary sense, the result is that copper, silver, and gold have an index less than unity, while iron and most other metals have an index of about the value two or three, differing for different kinds of light in a normal manner.

Prof. Kundt seems to suppose this to mean that light travels through the first three metals at a pace greater than its speed in vacuo; but, as Sir W. Thomson pointed out, no conclusions based on ordinary laws of refraction can be held valid for these extraordinarily thin films, whose thickness is less than the wave length of light. The ordinary theory of refraction, and the idea of an index of refraction, tacitly assume that the thickness of substance is great compared with a wave length; and a special theory for very thin films would have to be worked out. Moreover, the disturbance due to rapid absorption and consequent anomalous dispersion is likely to be so great in opaque substances like metals that no simple theory can be applicable. Sir William indeed doubts the advisability of using the prism method at all in such cases as this. He would prefer films of uniform thickness, the retardation (or acceleration) of light in passing through them being measured by some interference method. In this way results would be obtained which, though far from obviously interpretable, would be as amenable to theory as any that could be got; and the gratuitous complication introduced by the varying thickness of a prism would be avoided.

Experiments on the optical properties of metals, though severely difficult both to carry out and to interpret, are obviously of great moment towards a full understanding of the properties of ether, and the way in which it is modified by the presence of an electric conductor.

Sir William Thomson read two connected Papers on the laws of alternating currents in wire conductors. The first was a continuation and development of the investigation into which he was led by considering the formula for a ballistic galvanometer, and the mode in which the whole of the wire was ultimately effective in conveying its share of current, although at first sight the outside conveyed an abnormal portion. His conclusions were completely in accord with experiment as to the equal conveying power, but unequal dissipating or heating power, of different metals. The analogies which hold between distribution of current in conductors of various shapes subject to rapid alternations, and the distribution of density when the same conductors are statically charged, are interesting, and with perfect conductors, as Rowland has shown, are complete.

The second Paper was an examination into the question whether conductors of too great thickness might be not only *in*effective for the conveyance of alternating currents, but actually *anti*-effective in respect of dissipation of energy and production of unnecessary heat. The question put mathematically whether such anti-effective copper was possible was answered in the affirmative, to the surprise of many present. It seems that just as stray lumps of copper in the neighbourhood of an alternating circuit, by having Foucault currents induced in them, will dissipate energy (notwithstanding that they manifestly decrease the total impedance of the circuit near which they are), so also will masses of copper not stray, but pretending to form part of the effective conducting circuit. Doubtless the effect is more marked when the circuit forms a coil, but it exists even in a simple pair of parallel conductors. Discussion of these important Papers was impossible, owing to the lateness of the hour and the still crowded state of the agenda paper.

Prof. Fitzgerald brought forward a case in which practical stability could be secured with an essentially unstable class of forces by supposing a continuous oscillation of particles under the action of mutual forces and under conditions securing not static, but kinetic stability.

He also subsequently made a further small contribution to the incubating Hydrodynamic theory of the Universe, by pointing out that the tendency which a vortex filament ether has to tie itself into knots could be postponed indefinitely by supposing the filaments were very far apart in proportion to their diameters; this hypothesis being shown not to interfere with its power of transmitting energy. At present the vortex theory of the ether labours under a great many difficulties, for not only does such an ether decline to be perfectly transparent to liget now, but it threatens to gradually change its properties with time, containing within itself the seeds of its own entanglement. Problems like this, however, are not to be solved in a few years; and, though present prospects of the theory look dark, some further discovery may suddenly change the aspect of affairs, and verify what at present can only be regarded as a brilliant speculation.

The present writer discussed the theory of the mechanical forces acting on electric resonators and other conductors con-

Digitized by Google

veying transient currents, and tried to estimate the magnitude of the effect looked for by Mr. Boys (*see* September *Phil. Mag.*), and also the magnitude of the thermal effect first observed by Mr. Gregory, using Hertz's theory. The fact that a small electric oscillator radiates to a moderate distance with greater intensity than terrestrial sunlight while it lasts was regarded with some interest; but it is to be remembered that were steady sunshine as intense as is the intermittent artificial radiation, not only would metals exposed to it get heated by Foucault currents in the way they do, but a continuous torrent of sparks would be apt to pass between contiguous pieces of metal, especially when some period of solar vibration happened to agree with their own. The energy of solar radiation, however, is spread over a considerable range of wave length, the greatest portion of it being embodied in extremely short waves somewhat below the red end of the spectrum, whereas the energy of an artificial radiator is embodied in very much larger waves, which are mostly all of the same size; it, has, therefore, a more concentrated spark-producing character.

An account of some experiments by Prof. Trowbridge, in America, on photographing the oscillatory discharge of air-condensers at Harvard, was also read; but the present writer threw doubt on the conclusions deduced from Prof. Trowbridge's observations that the effective capacity of an air condenser depends on the rapidity of its vibrations, *i.e*, that its dielectric coefficient is not a constant; pointing out that the capacity of the leads was able to produce something very like the anomalous results which had been detected by the author of the Paper. On the other hand, if the conclusions of Prof. Trowbridge withstand this criticism and turning out to be valid, it will be a matter of considerable interest and importance.

The communication from Prof. Fitzgerald, entitled, "An episode in the life of J," was an outcome of the well-known discussion begun at Bath, on the propagation of electrostatic potential, and the most appropriate form of Maxwell's equations of the electro-magnetic field. As already known, Maxwell's equations appear to leave the question of the propagation of electrostatic potential vague, as something depending on ethereal volume elasticity, a quantity about which nothing definite is at present known. Maxwell seemed to suppose it infinite; Thomson has recently suggested that it may be zero; while Helmholz seemed to provide opportunity for everything by calling it k, and making the propagation of electrostatic potential explicitly depend upon it.

Fitzgerald and others have argued, however, that electrostatic potential is not propagated *per se* at all, but that it is the consequence and residue of a subsident electro-magnetic field; and hence, if it can be said to be a travelling entity or to have any velocity of propagation, it must be said to travel at the same rate as an electro-magnetic disturbance, viz., with the velocity of light; but that the best mode of regarding the matter is not to attend explicitly to the electrostatic potential (Maxwell's function Ψ) until everything has settled down and become static. That electrostatic ideas, in fact, are not appropriate to the conception of kinetic phenomena. The discussers at Bath were led to perceive that Maxwell's occasionally introduced function J, which is connected with Ψ in a definite manner, was much more convenient, and should be explicitly employed in preference to it. Fitzgerald is now able to point out the reason why Maxwell dropped J at an early stage in considering periodic disturbances, and to put his finger on the mistake, viz., that the linear relation for it $\frac{d^2 J}{dt^2} = 0$ is erroneous, and that the true relation is $\mu K \frac{d^2 J}{dt^2} = \nabla^2 J$, which at once gives a wave propagation travelling with the velocity of light, and eliminates from the subject every question connected with the compressibility of the ether and Helmholtz's constant k. Hertz has virtually independently revived the J function under the name H, and has shown that it is most useful in working out his oscillator results.

Although there was no time for discussion, Sir William Thomson expressed practical agreement with Fitzgerald; and since Mr. Heaviside had already informally expressed himself regarding Helmholtz's theory as "Maxwell's run mad," there can be little doubt but that the matter is settled, and will be henceforth quite straightforward.

Lord Rayleigh described a beautiful method by which he had examined the effect of various amounts of contamination on the surface tension of water. It has long been known that waves of different length travel over the surface of liquids with different velocities, not at all like the waves in the interior of simply-constituted substances, whose every size of wave travels at one pace. Large water waves travel quicker the bigger they are; so that Atlantic rollers speed along at a prodigious pace, quite eclipsing the steamers and competing closely with express trains. The speed varies, in fact, directly as the square root of the wave length. With minute waves or ripples, Sir William Thomson has taught us, it is quite otherwise. Their propagation depends not on gravitation, but on surface-tension, and they travel quicker the smaller they are, so that infinitesimal waves flash across the surface with immense velocity—a velocity inversely as the square root of their lengths. Of course the two classes, waves and ripples, merge into each other, there is no sharp line between them, and there is accordingly a ripple-wave of small size which is the slowest possible. But it was the ripples proper of which Lord Rayleigh wished to make use, in order, by help of their observed velocity, to measure the tension of the surface on which they were formed. The problem then was to produce a regular succession of very minute ripples, and measure accurately their velocity of travel. The method adopted was to cause a point attached to the prong of a tuning fork to throw the surface into crispations at a known frequency, and to measure the wave-length of the ripples so caused. To measure them it was necessary to render them stationary, either actually by reflection, or optically by some intermittent-vision device. The optical method was preferred, vision of the surface being obtained between the pairs of overlapping slits attached to the prongs of another synchronised fork. Thus the ripples might be seen as if stationary, and their number to the inch counted. But before doing this, there is another requirement to be attended to. The theory of waves in its simple form applies only to disturbances of infinitely small amplitude; at least, to amplitudes much smaller than the wave-length. To be at all accurate for these minute ripples, therefore, the permissible amplitude must be too small to be ordinarily visible, and here comes in the most beautiful part of the method. The water surface is illuminated by a convergent beam which, after reflection, comes to a focus at a point above the water. At this focus the eye of the observer is placed, and accordingly sees the water surface, if steady, as a uniform sheet of light. But the slightest shiver or irregularity of reflection, by concentrating the light in some places and removing it from others, becomes exceedingly conspicuous. With all these appliances then working properly, the ripples are seen like fine shading or narrow stripes, looking like the interference bands of optics.

By this series of ingenious contrivances the surface tension could be quickly measured for a variety of surface contaminations, starting with clean water and adding known proportions of oil, of soap, or of other materials.

A clean water surface is obtained by a delightfully simple process. A clean dish is first filled with fresh tap-water, which already is almost absolutely free from grease, and then by an expanding metal hoop (which itself must, of course, be perfectly clean) a small portion of the central surface is stretched to a large area, so that any residue of contamination is thinned out a hundred times and becomes utterly inappreciable. This is not the place to quote results, but it seems that the surface tension of pure water has by several observers been exaggerated. Instead of 80 dynes per centimetre (or ergs per square centimetre), it is only 74. With oil added till camphor particles are just killed, it is 53; with as much olive-oil as it cares to take, 41; and saturated with soap, it is 25.

Prof. Ramsay communicated some initial results of an ingenious method of examining the physical properties of saturated vapours at high pressures, near their critical temperature, which he had devised in consultation with Prof. Fitzgerald. It consists in obtaining Kundt's dust figures in a small-bore tube of an Andrews's press full of the vapour, by

Digitized by Google

stroking the tube till it squeaked. The wave length shown by the dust pattern, combined with the pitch of the note, gives the velocity of sound in the vapour, and thus gives the ratio of its adiabatic to its isothermal elasticity, or the ratio of its two specific heats. The fact that a saturated vapour can transmit sound at all is interesting, for one group of them, like chloroform, liquefy on adiabatic compression, while another group of them, like steam and ether, liquefy on adiabatic expansion; hence in the sound wave it is by no means clear what is happening. Absence of nuclei is one mode of avoiding the apparent difficulty. Hurry is another. But so far as I know a complete theoretical investigation into the circumstances has yet to be made.

Sir William Thomson described what he considered, and what doubtless is, the best method of measuring the magnetic susceptibility of feebly magnetic or diamagnetic bodies. There are many objections to Faraday's old qualitative plan of suspending bodies between conical poles, and observing their axial or equatorial set; anything metrical obtained by this method, with say, ellipsoidally shaped bodies, is apt to lead, and in practice has led, observers to ridiculously futile results. The method now laid down consists in taking a magnetic field, varying from one uniform value at one place to another very different uniform value at another. The body to be experimented on is to be cut in some regular slab form, and suspended with one boundary in one of these regions and another boundary in the other. The force with which it is drawn in or pushed out of the strongest region is then to be observed. Afterwards, by measuring the two field intensities, and the dimensions of the piece, the susceptibility of its material can be calculated.

The question was raised as to how feeble the magnetic intensity might be without preventing the getting of good observations; and Mr. Boys said he could make a spring balance which would do for delicate measurements of this sort, by rolling a quartz fibre into a spiral; and that by the use of a torsion arm an inch long, suspended by his finest fibres, he could detect a force of the million millionth of the weight of a grain. These infinitesimal methods of Mr. Boys tend to revolutionise all physical measurement, and to render possible an examination into the properties of substances over a very surprising range.

It may perhaps be remembered in this connection that the writer has observed that substances magnetic for feeble forces sometimes become diamagnetic for strong forces, especially when the substance is not homogeneous; and that all substances, or at least a great many, show traces of permanent magnetism when they have been subjected to strong fields.

Prof. Barrett exhibited the now well-known Gore effect in iron and steel, and told us more about his discovery of recalescence. It appears as if recalescence were going to abandon Section A altogether, and turn out to be a mere chemical process, viz., a sudden combination of iron and carbon when a certain temperature is reached in the cooling process, with consequent evolution of heat, expansion, and everything else that has been observed. Similarly, during heating, dissociation of iron and carbon at nearly the same stage will occur, with consequent cooling and momentary contraction. The one effect which appears to resist this barbarous chemical explanation is the sudden loss of magnetic polarity at the same critical point; and for a comprehension of this I hope we may have to look to Prof. Ewing's model, without help from Section B.

Mr. Trouton wishes to give us yet another physical constant to measure, which he calls the *co-efficient of abrasion* of bodies. At present the hardness of minerals is tested and recorded in a very primitive fashion by seeing which of them get scratched against which. To get a numerical measure and to avoid the arbitrariness of abrasion by a foreign body, Mr. Trouton proposes to grind two surfaces of the same material over each other at a known speed for an observed time under a measured intensity of pressure, and to collect and weigh the abraded material. The co-efficient of abrasion, which will not, indeed, be exactly "hardness," but which will be a definite thing, can then be defined as $\frac{p\ s}{m}$; where m is mass of substance rubbed off an area A, under a total pressure p A, during the time the surfaces have travelled a distance s over one another.

Mr. Trouton also described some further experiments he had made on the index of refraction of bodies to large-waved radiation; using the method of interposing a slab of the substance in the stationary waves caused by a reflector and observing the shift in the position of the nodes and loops thus caused. But there are many difficulties in the making of these experiments, partly owing to diffraction phenomena caused by the necessarily small size of the reflectors and slabs employed (small, that is, compared with the size of the waves), partly owing to reflection from the faces of the slab; for though it may be thought that reflection from the back will practically annul that from the front, it is not altogether so (owing, apparently, to absorption), and disturbing reflections do exist. Another difficulty is the perennial one of not being able to determine the position of the nodes with sharpness. For it must be remembered that even in a parallel beam of this kind of evanescent radiation the intensity of direct and reflected portions will not be the same. That which has travelled furthest has been longest subjected to damping influence, and accordingly, superposed upon the stationary waves, a set of progressive waves will be advancing uninterfered with by reflection.

Another more abstruse difficulty attending all the hitherto made slab or prism or lens determinations is the one mentioned above in connection with du Bois' experiments on metal films, viz., that the thickness of the substance is far too nearly comparable with the wave length of the radiation employed for ordinary optical theories to apply with ease and certainty.

The electrolytic discussion in Section A on Saturday, and in Section B on Monday, was, as it happened, of mainly chemical interest; and to give any intelligible account of it, it would be necessary to introduce the subject in a somewhat elaborate manner, and the result might not be well adapted to the nature of this article. The discussion is to be printed *in extenso* in the annual volume of the Association, under the editorship of Prof. Thorpe, and at some later date I shall hope to have something to say about it.

An excellent and very practical arrangement for obtaining lantern photographs in an easy and expeditious manner was exhibited by Profs. Barr and Stroud, who seem to have brought this sort of thing to perfection. But the details are easy to understand, and the apparatus will be purchasable before long, so that there is no need to dwell upon it.

A good many more Papers were read, but I did not hear them all; for though the Section at present declines to adjourn for lunch, I have at length learned that at a certain hour of the day nothing but lunch is worth discussing, and, moreover, that lunch cannot be taken effectively in a vitiated atmosphere, with the noise of a Paper which one is endeavouring not to heed surging in one's ears. If the Section suspended itself at one, there would be no hardship in sitting again from two to four, or even till five; but three hours' continuous session is enough for ordinary mortals, and after four hours' session communications cease to be effective; they become, indeed, anti-effective.

MAGNETISM IN IRON AND OTHER METALS.*—XXXI.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 483.*)

§ 115. Effects of Temperature within the Atmospheric Range.—None of the three magnetic metals is sufficiently affected by temperature to have its magnetic susceptibility very materially altered by any change of temperature that is liable to be experienced within the atmospheric range. In the case of iron, especially, the effects which atmospheric fluctuations of temperature exert upon the magnetic quality are too slight to require to be taken account of in specifying the magnetic properties of a sample, or in stating the results of experiments. Even when iron is raised to 100°C. the influence of the heating is by no means considerable. This is shown in Fig. 88, which gives two pairs of

* All rights are reserved.

Digitized by Google

curves of I and H, one referring to iron wire in the soft annealed state, and the other to the same wire after it had been hardened by stretching beyond the limit of elasticity.* The full line in each pair is a curve of magnetisation taken at atmospheric temperature (7° or 8°C. in this case), and the dotted line is a curve of magnetisation taken while the wire was maintained at a temperature of 100°C. by enclosing it in a tube through which a current of steam was kept up. The curves cross at much the same value of I for both conditions of the metal, though at very different values of H.

§ 116. **Effects of Varying Temperature, the Magnetic Force being Constant.**—In the experiments which have been noticed above, the temperature was kept constant and the magnetic force was varied. If we keep the force constant and vary the temperature, a rather complex series of effects will be observed. In the first place, there is in general an effect which is not reversible—that is to say, which would not be undone if the temperature were brought back to its initial value. The first effect of any heating is like the effect of vibration: it produces a permanent change in the magnetisation; but whether that change will be an increase or a decrease will depend on the previous history of the magnetised piece. The reason of this should be apparent when we come to discuss molecular theories of induced magnetism: in effect it is this, that at any (not on account of complications proceeding from magnetic hysteresis, it is not possible to infer, from results of experiments of the one kind, where the reversal should occur in the other.

That the first effect of any change of temperature on the magnetism of iron or steel is not reversible has been shown by many experiments, probably first by those of Wiedemann.* If the magnetism that is dealt with is residual, and there is no acting magnetic force, a cyclic process of heating and cooling, or of cooling and heating, results in a reduction of the magnetism. If, on the other hand, the magnetism that is dealt with is that which has been reached by applying a magnetising force which is kept in action while the temperature is changed, then a cyclic process of heating and cooling or of cooling and heating results in an increase of magnetism. In either case it is, in general, only after many repetitions of the temperature cycle that the change of magnetism becomes cyclic. In the earliest cycles we find, superposed upon what may be called the legitimate or differential variations of magnetism, a progressive shaking in of magnetism if that is induced, or a progressive shaking out of magnetism if that is residual. By repeating the temperature cycle often enough we may get rid of the progressive changes, and may then study the differential effects of heating and cooling. One or two experiments of this class will be briefly referred to.

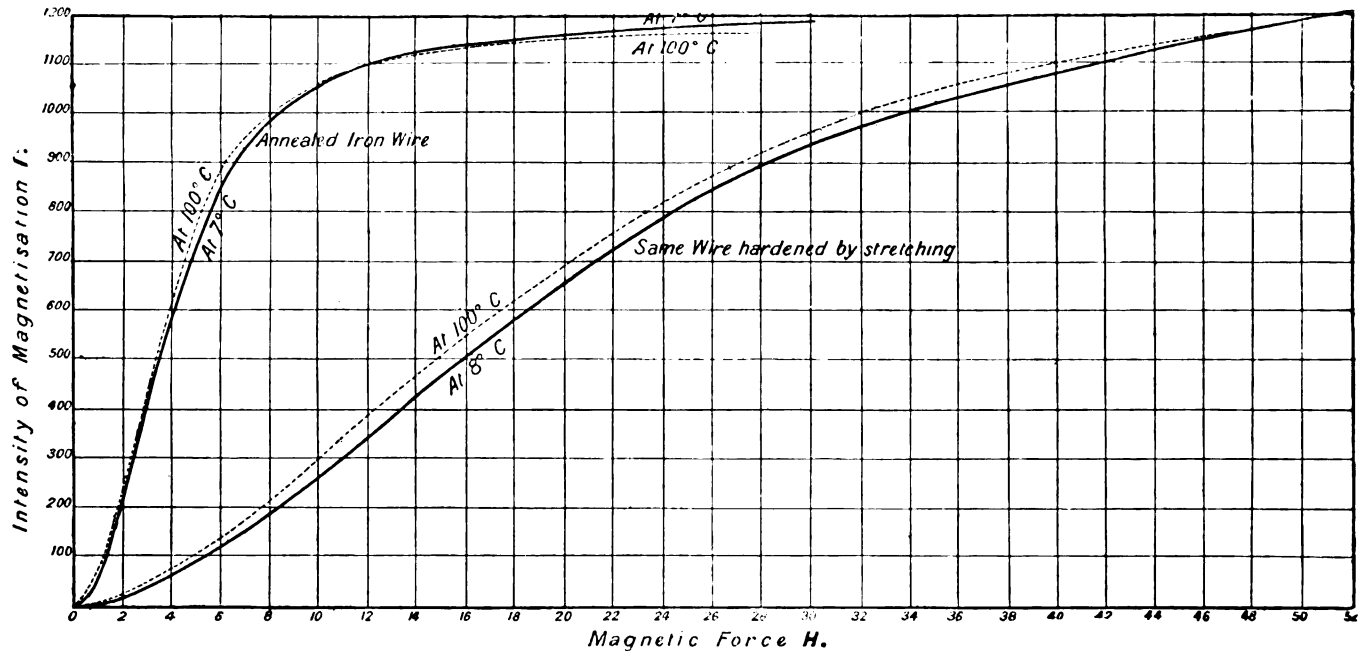


Fig. 88.—Effects of heating to 100° C. on the magnetic susceptibility of soft and hard iron.

extreme) stage in the process of magnetisation there are groups of molecules verging on instability, which are precipitated into instability when the temperature begins to change. This effect is distinct from—and may be much greater than—the reversible changes of magnetism which are caused by alternate heating and cooling. But when any alternation of heating and cooling is sufficiently often repeated, a cyclic *régime* is established; the magnetism will then fluctuate between two values, but whether the higher or the lower value will correspond to the hotter state will depend on whether the magnetism is below or above a certain value. In other words, the effects of temperature, when tested in this way (by repeated alternate heating and cooling), become reversed when the magnetisation is sufficiently strong. When there is but little magnetisation heating augments, and cooling reduces the amount of magnetism, whether that be either residual, or induced by the action of a constant magnetising force; when there is much magnetisation the reverse happens. The reversal of effect which is observed in experiments of this class is evidently to be anticipated in connection with the crossing of the magnetisation curves in experiments of the class described above. But,

* Phil Trans., 1885, p. 637.

§ 117. **Experiments in Alternate Heating and Cooling of Magnetised Iron.**—In the first of these† a hardened iron wire was tested, surrounded by a tube, on which a magnetising coil was wound, and through which currents of steam or of cold water could be alternately passed. The resulting magnetic changes were observed by means of a magnetometer. The wire was at first demagnetised, and then from time to time its magnetism was increased a step by passing a weak current through the magnetising coil; but after each such step the current was stopped, and the only force in action was the vertical component of the earth's field. The first series of heatings and coolings (between 100° C. and 6° C.) made I fluctuate between about 2·14 (cold) and 2·23 (hot). At this stage heating increased I. Later the fluctuations of I were from 3·51 (cold) to 3·56 (hot); the effect still had the same sign. Later still it became reversed; the fluctuations of I were between 8·69 (cold) and 8.67 (hot), and later still the reversed effect was more marked, the range being from 9·09 (cold) to 9·04 (hot).

A similar experiment with a piece of annealed iron wire‡ showed that the reversal of effect took place in that case when

* "Galvanismus," II., § 522 *et seq.*
† *Phil. Trans.*, 1885, p. 633. ‡ *Loc. cit.*, p. 635.

Digitized by Google

I was about 20. At an early stage I ranged from 4·77 (at 6°C.) to 4·95 (at 100°C.); at a later stage (after reversal) I ranged from 37·53 (at 6°C.) to about 36·77 (at 100°C.). In both cases the reversal occurred at a very early point in the process of magnetisation.

In another case * the magnetisation of the specimen was examined at intermediate points, during heating and during cooling, to see whether there was hysteresis in the relation of magnetism to temperature. The specimen—a long iron wire—was fixed inside a glass tube which could be connected at one end to any one of three small boilers capable of supplying a steady current of steam, of alcohol vapour, and of sulphuric ether vapour, or to a cistern supplying cold water. Steam and cold water (at 14°C.) were alternately passed through the tube many times until the magnetic state of the wire was observed to change from one to the other of two nearly steady values. Then readings of the magnetometer were taken during the passage through the tube of (1) cold water, (2) ether vapour, (3) alcohol vapour, (4) steam, (5) alcohol vapour, (6) ether vapour, (7) cold water. This completed a cycle of temperature changes in which two intermediate points (35°C. and 78½°C.), were fixed during the process of heating and cooling. The method was adopted in order to secure that the iron should be exposed sufficiently long to an atmosphere of definite temperature to give it time to take that temperature throughout, and so avoid any possibility of error proceeding from the sluggishness with which changes of temperature take place. The stream of vapour was kept up in every case until the magnometer reading became steady.

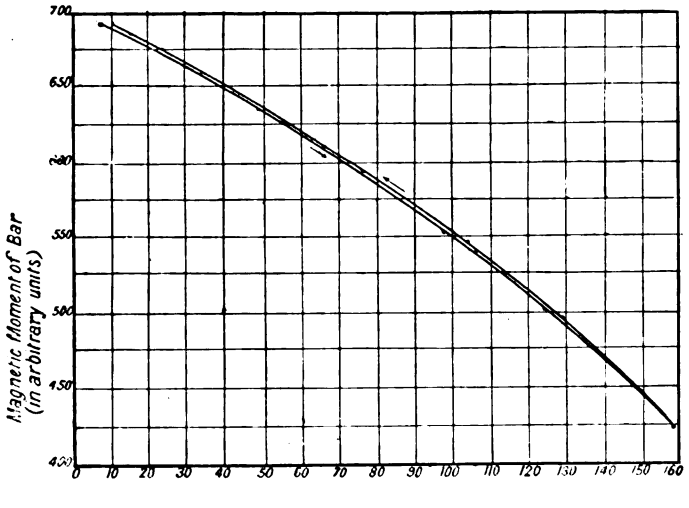

Fig. 89.—Effects of heating and cooling a steel bar magnet.

The iron was magnetised to begin with sufficiently strongly to make the heating cause a diminution and cooling an augmentation of magnetism. The only magnetic force in action during the heating and cooling was the earth's vertical field. In the following statement of observed results the numbers are proportional (on an arbitrary scale) to the intensity of magnetisation. The arrows show the sequence of the changes:

	Water.		Ether vapour.		Alcohol vapour.		Steam.
Temp.	14°C.		35°C.		78½°C.		100°C.
	17,416	→	17,382	→	17,304	→	17,262
	17,418	←	17,382	←	17,304	←	

The whole change is about 0·9 per cent. of the whole magnetism. It is clear from the readings at 35°C. and 78½°C. that the changes occur without any perceptible hysteresis; the magnetisation at intermediate points is, as nearly as can be judged, the same during heating as during cooling.

Fig. 89 shows the result of another experiment of the same class,† in which a steel bar magnet was heated and cooled in a bath of oil, through a considerably wider range of temperature (between 10°C. and 158°C.). The temperature of the oil was altered very slowly—so slowly that it took more than 17 hours to complete the cycle of changes shown in the figure—in order to let the bar's temperature be sensibly uniform with that of the oil, which was observed by means of two thermometers. Several heatings and coolings preceded the cycle in which the observations were made. Here, as in the former case, there is no sensible hysteresis in the relation of magnetism to temperature.

(To be continued.)

ON THE ELECTRO-DYNAMICS OF STATIONARY BODIES.*

BY H. HERTZ.

(Continued from page 484.)

Electric and Magnetic Polarisation.—As far as our equations relate to an isotropic medium they give at any given moment the value of a physical quantity in terms simply of the actual state of things existing at the moment considered.

This form of the equations is very useful from a mathematical point of view, because it shows at once the sequence of any phenomenon. This form is also perfect from a philosophical point of view, because it is possible to make the left-hand side of the equations represent the future state, while the cause of this future, *i.e.*, the actual state, is represented on the right-hand side.

The analogous equations relating to non-isotropic bodies are far from exhibiting this perfect form, since their left-hand side does not consist of a derivative of a single physical quantity, but is a function of these derivatives. However, as these functions are linear it is easy to put the equations into the desirable form.

Another means conducting to the same end consists in the introduction of new quantities, which may be called components of polarisation. These quantities are,

$$\left.\begin{aligned} L_p &= \mu_{11}L + \mu_{12}M + \mu_{13}N \\ M_p &= \mu_{21}L + \mu_{22}M + \mu_{23}N \\ N_p &= \mu_{31}L + \mu_{32}M + \mu_{33}N \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (7)$$

$$\left.\begin{aligned} X_p &= \epsilon_{11}X + \epsilon_{12}Y + \epsilon_{13}Z \\ Y_p &= \epsilon_{21}X + \epsilon_{22}Y + \epsilon_{23}Z \\ Z_p &= \epsilon_{31}X + \epsilon_{32}Y + \epsilon_{33}Z \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (8)$$

Except for crystalline bodies, the quantities having two different suffixes are each zero; and probably for all substances quantities having the same two suffixes (such as ϵ_{12} and ϵ_{21}) are equal to each other.

We shall call the resultant of L_p, M_p and N_p the magnetic polarisation, and, similarly, the resultant of X_p, Y_p and Z_p we shall call the electric polarisation. For isotropic media the forces and polarisations lie in the same direction, and their ratio, according as we are considering magnetic or electric phenomena, is either the magnetic constant μ or the dielectric constant ϵ. For free ether the forces and polarisations are identical. If we introduce these quantities into the first members of our equations we shall see that the variation of each component of the polarisation depends directly on the forces at the instant considered. As the forces are themselves linear functions of the polarisation components we can easily introduce the latter into the second members of the equations. We shall then have replaced the directed quantities serving to specify the electro-magnetic state, viz., the electric and magnetic forces, by other directed quantities defining the polarisation. These latter serve the same purpose as the former, but are more useful to consider. Since the equations are simplified by the introduction of the polarisation components besides those of the forces, we shall make the assumption that with massive bodies it is necessary to have given two directed magnetic quantities and two directed electric quantities in order to completely specify the electro-magnetic state of the medium.

* An abstract of a paper published in the "Nachrichten von der Kœniglichen Gesellschaft, der Wissenschaften," for March, 1890 and reprinted in *La Lumière Électrique*, July, 1890.

Digitized by Google

In order to further simplify our equations let us put—

$$\left.\begin{aligned} u &= \lambda_{11}(X-X') + \lambda_{12}(Y-Y') + \lambda_{13}(Z-Z') \\ v &= \lambda_{21}(X-X') + \lambda_{22}(Y-Y') + \lambda_{23}(Z-Z') \\ w &= \lambda_{31}(X-X') + \lambda_{32}(Y-Y') + \lambda_{33}(Z-Z') \end{aligned}\right\} \quad . \quad (9)$$

Here, as before, with the exception of crystalline bodies, coefficients having different suffixes are each zero, and also for all known bodies, $\lambda_{13}=\lambda_{32}$, $\lambda_{31}=\lambda_{13}$, $\lambda_{12}=\lambda_{21}$.

Our general equations (1) and (6) then take the definite form—

$$\left.\begin{aligned} A\frac{dL_p}{dt} &= \frac{dZ}{dy} - \frac{dY}{dz} \\ A\frac{dM_p}{dt} &= \frac{dX}{dz} - \frac{dZ}{dx} \\ A\frac{dN_p}{dt} &= \frac{dY}{dx} - \frac{dX}{dy} \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

$$\left.\begin{aligned} A\frac{dX_p}{dt} &= \frac{dM}{dz} - \frac{dN}{dy} - 4\pi A u \\ A\frac{dY_p}{dt} &= \frac{dN}{dx} - \frac{dL}{dz} - 4\pi A v \\ A\frac{dZ_p}{dt} &= \frac{dL}{dy} - \frac{dM}{dx} - 4\pi A w \end{aligned}\right\} \quad . \quad . \quad (11)$$

and the electro-magnetic energy per unit volume of any body whatever is given by the expression

$$\frac{1}{\pi}(X X_p + Y Y_p + Z Z_p) + \frac{1}{8\pi}(L L_p + M M_p + N N_p). \quad (12)$$

These expressions are true for bodies of all kinds, whether crystalline or not.

From what we have established in the preceding sections, we conclude that u, v, and w are the components in electrostatic measure of the electric current.

Electricity and Magnetism.—Let us consider the electro-magnetic phenomena occurring within a material system which is completely separated from the influences of external bodies. Differentiate the three equations (11) by x, y, and z respectively and add; we obtain

$$\frac{d}{dt}\left(\frac{dX_p}{dx}+\frac{dY_p}{dy}+\frac{dZ_p}{dz}\right) = -4\pi\left(\frac{du}{dx}+\frac{dv}{dy}+\frac{d\omega}{dz}\right) \quad . \quad . \quad (13)$$

Let us integrate each side of this equation throughout the space bounded by any closed surface completely enveloping the system. Let $d\tau$ be an element of volume, and $d\omega$ an element of the surface whose normal makes with the axes the angles (n, x), (n, y), and (n, z). Then, by a theorem well known to mathematicians, we have

$$\int\left(\frac{dX_p}{dx}+\frac{dY_p}{dy}+\frac{dZ_p}{dz}\right)d\tau = \int [X_p \cos(n,x) + Y_p \cos(n,y) + Z_p \cos(n,z)]\, d\omega \quad . \quad . \quad (14)$$

and

$$\int\left(\frac{du}{dx}+\frac{dv}{dy}+\frac{d\omega}{dz}\right)d\tau = \int [u\cos n, x) + v\cos(n,y) + \omega\cos(n,z)]\, d\omega \quad . \quad . \quad (15)$$

and as at the surface the values of u, v, ω, are zero, we have

$$\frac{d}{dt}\int\left(\frac{dX_p}{dx}+\frac{dY_p}{dy}+\frac{dZ_p}{dz}\right)d\tau = 0.$$

So that if we integrate with respect to t we obtain

$$\int\left(\frac{dX_p}{dx}+\frac{dY_p}{dy}+\frac{dZ_p}{dz}\right)d\tau = 4\pi e \quad . \quad . \quad (16)$$

where e is some quantity independent of time t. This quantity e here introduced is evidently a function of the electrical state of the system, and is such that its magnitude cannot be increased or diminished by any electro-magnetic phenomena occurring either within or without the system under consideration. This property of invariability points very strongly to the belief that a quantity of a definite substance contained within the system is represented by its value; and in conformity with this view we shall call e the quantity of electricity contained within the material system. As the quantity e may be either positive or negative we may suppose it to represent the excess of electricity actually contained within the system over the quantity normally comprised within it.

Whatever form the quantity e may actually take, each element of volume $d\tau$ contributes to the total value an element whose magnitude is given by the expression

$$\frac{1}{4\pi}\left(\frac{dX_p}{dx}+\frac{dY_p}{dy}+\frac{dZ_p}{dz}\right)d\tau$$

and we shall call the quantity thus represented the "true" electricity of the element. The "true" volume density within a body is thus equal to

$$\frac{1}{4\pi}\left(\frac{dX_p}{dx}+\frac{dY_p}{dy}+\frac{dZ_p}{dz}\right) \quad . \quad . \quad . \quad . \quad (17)$$

while at the bounding surface of a body the "true" surface density is equal to

$$\frac{1}{4\pi}[(X_{p,2}-X_{p,1})\cos(n,x) + (Y_{p,2}-Y_{p,1})\cos(n,y) + (Z_{p,2}-Z_{p,1})\cos(n,z)]$$

For free space the quantities representing the forces and polarisations coincide, so that we may replace the above expressions by others in which the suffixes p are removed. To distinguish the new expressions for surface and volume density, we shall suppose them to relate to "free" electricity. In air and open space the amount of "free" electricity is the same as the amount of "true" electricity, but in material bodies the latter exceeds the former by a quantity which, in accordance with old notions, may be styled "bound" electricity.

In accordance with the foregoing reasoning, the quantity of "true" electricity on a surface (whether closed or unclosed) is obtained by integrating the expression

$$\frac{1}{4\pi}\int [X_p \cos(n,x) + Y_p \cos(n,y) + Z_p \cos(n,z)]\, d\omega$$

over the surface considered. We shall say that this expression is equal to the total number of lines of force cut by the surface in the direction of the normal drawn positively. This definition is in accordance with Faraday's suppositions that the lines of force point always in the direction of the acting force, and are in density proportional to the magnitude of the force. We shall complete the suppositions and at the same time make them more accurate by assuming that the lines of force in any body proceed in the direction not of the *force* but of the *polarisation*, and that their density is proportional to the magnitude of the polarisation. It follows from these definitions that 4π times the quantity of true electricity contained in any given volume is equal to the difference between the number of lines of force arriving at the bounding surface and those leaving it. Each end of a line of force represents a certain quantity of "true" electricity, and we can specify the quantity of this electricity by the number of free ends of the lines.

If some space situated in the neighbourhood of the surface, over which the integral is calculated, is quite devoid of "true" electricity, the value of the integral is entirely independent of the particular shape and position of the surface throughout the space in question, and depends simply on the contour of the surface. In such cases we shall say that the value of the integral is equal to the number of lines of force enclosed by the contour, without reference to the shape of the surface bounded by it.

The rate at which the quantity of "free" electricity e increases within a given space can be obtained from (13) and (16), and is given by the expression

$$\frac{de}{dt} = -\int\left(\frac{du}{dx}+\frac{dv}{dy}+\frac{d\omega}{dz}\right)d\tau$$

$$= -\int [u\cos(n,x) + v\cos(n,y) + \omega\cos(n,z)]\, d\omega \quad . \quad . \quad (18)$$

by (15).

Now, if the region at the bounding surface is non-conducting, the conductivities λ are zero, and from (9) it follows that $u=v=\omega=0$; so that from (18) we see that $\frac{de}{dt}=0$, and that in consequence the quantity of "true" electricity within the space considered remains absolutely constant. Electricity cannot, therefore, escape from a body surrounded by a medium

Digitized by Google

for which the quantities λ are zero. It is for this reason that we call such a medium non-conducting. If at any part of the bounding surface a body exists for which the quantities λ are not zero, variation of the electricity is possible; and hence such a body is called a good conductor in contrast with bad conductors within which electrical movement is only possible under the influence of electro-dynamic phenomena. The division of bodies into good and bad conductors only then refers to "true" electricity; with respect to "free" electricity, all bodies can be considered conducting, since polarisation currents are transmitted by them.

The quantity of a substance within a given volume can only vary by the entrance or exit of a certain quantity of it through the bounding surface of the space considered; and each element of the bounding surface must pass a quantity, whose amount is perfectly determinate. In accordance with this axiom we may assume that the quantity of electricity per second (the electric current) crossing unit surface of each element is equal to

$$u\cos(n,x)+v\cos(n,y)+w\cos(n,z) \quad . \quad . \quad (19)$$

and the integral of this taken over any surface is equal to the current flowing across this surface. We must remark that, even admitting the material nature of electricity, the special way in which we have obtained the electric current constitutes a great assumption. We can, in fact, to the system of currents found, superpose any closed system of currents without varying in the slightest degree the rate of increase or decrease at a given point.

If a part of the system can pass from the electrified to the non-electrified state, and *vice versâ*, under the sole influence of electro-magnetic phenomena, the amount of true electricity in each of the non-conductors is zero, and in consequence the quantities represented by the expressions (16 and 17) are each equal to zero for such bodies.

The same considerations that we have put forward for electrical phenomena can equally well be applied to magnetic phenomena. In fact, in the foregoing expressions we have merely to replace X, Y, and Z respectively by L, M, and N. Thus, the "true" magnetic volume and surface densities are given by the expressions

$$\frac{1}{4\pi}\left(\frac{d\,L_p}{d\,x}+\frac{d\,M_p}{d\,y}+\frac{d\,N_p}{d\,z}\right) \quad . \quad . \quad . \quad . \quad (20)$$

and,

$$\frac{1}{4\pi}\{(L_{p,2}-L_{p,1})\cos(n,x)+(M_{p,2}-M_{p,1})\cos(n,y)+(N_{p,2}-N_{p,1})\cos(n,z)\} \quad . \quad . \quad . \quad . \quad (21)$$

Again, the number of magnetic lines of force traversing a surface is given by the surface integral

$$\int\{L_p\cos(n,x)+M_p\cos(n,y)+N_p\cos(n,z)\}\,d\omega \quad . \quad (22)$$

and by leaving out the suffixes p we get expressions which refer to "free" magnetism.

The distinction of bodies into good and bad conductors does not, however, occur for "true" magnetism, since equations (10) do not contain any conduction terms to correspond with equations (11). With regard to "free" magnetism, all bodies can be considered conducting as in the analogous electrical case. If a system, or a part of a system, can pass from its magnetic to its non-magnetic state, and *vice versâ*, by purely electro-magnetic means, the expressions (20) and (21) for volume and surface density can each be equated to zero.

(To be continued.)

THE EFFECT OF DIRECT AND ALTERNATING PRESSURES ON THE HUMAN BODY.*

BY J. SWINBURNE.

As there seems to be some doubt as to the relative effects of alternating and direct currents, a bridge which measured the resistance of the patient under various pressures was made up. Fuller readings, which agreed with the first as nearly as such very uncertain readings can be expected to agree, were afterwards taken by putting on different pressures and measuring the current; the resistances being calculated. The alternating currents were measured with a non-inductive wattmeter arranged as an ammeter, the pressure being taken with a hot wire voltmeter. The tests were taken from hand to hand, the hands being dry or wet with dilute acid in the case of direct currents, and dry in the case of alternating. It seemed to make little difference in the case of alternating currents whether the hands were wet or dry. There was no need to measure the resistance from hand to foot, as that obviously would depend on the boots worn.

Human Resistances; Hand to Hand.

Current.	Name.	Hands.	Volts.	Resistance.
Alternate	A	Dry	18	950
Continuous	,,	Dry	50	8,000
Continuous	,,	H_2SO_4	50	3,010
Alternate	B	Dry	10	1,330
Alternate	,,	Dry	18	1,110
Continuous	,,	Dry	50	6,6[illegible]0
Continuous	,,	H_2SO_4	50	1,930
Alternate	C	Dry	18	620
Continuous	,,	Dry	50	5,4[illegible]0
Continuous	,,	H_2SO_4	50	1,[illegible]80
Alternate	D	Dry	18	1,090
Continuous	,,	Dry	50	10,000
Continuous	,,	H_2SO_4	50	16,000
Continuous	E	Dry	50	6,700
Continuous	,,	H_2SO_4	50	1,100
Alternate	,,	Dry	18	1,300
Alternate	F	Dry	18	750
Continuous	,,	Dry	50	3,320
Continuous	,,	H_2SO_4	50	1,710
Alternate	,,	Dry	54	670

In the above table the direct pressure is always 50 volts. Any of those tested could have taken more than this; but even with 50 volts the discomfort is extreme if the contact is made and broken. The maximum current taken was ·04 ampere by E, whose resistance is low. He could have taken more if available. All the resistances are much lower than those obtained by the usual method of measuring with a bridge and one or two cells. Probably polarisation then interferes.

When the direct current from 50 volts is concentrated in one finger it feels hot, though especially as the current is reduced, there can be no appreciable heat generated.

The most curious thing is the very low effective resistance to alternating currents. The alternating pressure could be regulated by steps of 4·5 volts. Out of the five subjects tested not one except F could stand more than 18 volts alternating, the maximum effective current taken being ·03 ampere. F seems abnormal. He took 54 volts and nearly a tenth of an ampere. D, who has the highest resistance, was the only lady tested. Though, with the exception of F, none of us could take more than 18 volts alternating with a good contact, I have several times touched 600-volt alternating terminals lightly. They were given by a Siemens machine used for "flashing" lamps. Before I took charge of the factory containing it I am told several of the girls had shocks from the same machine. Spring switches, which demanded both hands to give any current, obviated danger to them afterwards. I have also had a very severe shock from a 100-volt Ferranti. Though 18 volts was as much as we could take, there was no difficulty in letting go.

These results bear out those of Messrs. Lawrence and Harries* as to the relative resistance to alternating and direct currents, but the figures are entirely different. They never found anyone take over 10 milliamperes, while F took 90 milliamperes alternating, and E, a workman, took 44 milliamperes direct, and could have taken far more if available.

* Paper read before the British Association in Section A, Leeds September, 1890.

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 5 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1890 Edition consists of about 850 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

Orders for the 1890 issue should be forwarded AT ONCE *to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.*

ELECTRICAL BOOKS AND PUBLICATIONS.

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

ELECTRICAL PROGRESS.

The industrial applications of electricity are at the present day so various and important that the pseudo-scientific novelist who is endowed with a sufficiently vivid imagination may be certain of producing a saleable work by the simple process of magnifying to the power of six the present applications of electricity and dating his lucubration 1990, or by partially inverting the process and drawing harrowing pictures of what would happen if electricity were suddenly to disappear from our everyday life. Without, however, rising to the height of all the superlatives usual on such occasions, a glance at some of the recent advances of industrial electricity and a brief mention of one or two of its more promising future developments may not be out of place at a season of the year when those whose business it is to supply materials for discussions at the meetings of scientific societies are silent and presumably engaged in recruiting their exhausted frames for the Session of 1890-91.

Across the Atlantic electric lighting shows distinct signs of the near approach of the crystalline stage. Outdoor wiring, indeed, it is generally admitted, still affords room for improvement, and perfection is not yet claimed even for American dynamos; but it is felt that the work of distributing current for the purposes of light and power is fast settling down into a few regular grooves, and that nothing very novel need be looked for in that direction. A glance at the voluminous Papers read at any of the numerous electrical conventions shows tolerably plainly that the improvement of details and not the introduction of novelties has now become the chief business of American electric light engineers. Even with us central stations are beginning to lose the interest of novelty; and the last fine crop of Provisional Orders, making all due allowances for non-performance, cannot but result in still further hastening the process. What exactly will be the outcome of the sudden fervour with which our Local Authorities have adopted the motto of "the electric light for the people" remains to be seen; but, that street lighting on a comparatively extensive scale will be indulged in in many of our most important towns seems highly probable. The glare, flickering, and glorious uncertainty of "pioneer" arc lighting would have been sufficient to have destroyed the reputation of a much finer means of illumination; and it is by no means surprising that the British mind, while forced to admit the beauty of incandescent lighting, still draws the line at the arc lamps. But arc lighting with the best modern lamps,

Digitized by Google

carbons, lanterns, and dynamos, and employed in the lavish style that only a municipality performing a public duty may aspire to, should not take long in conquering a place for itself and becoming the recognised light for the main streets and open spaces of our dimly-lighted cities. The battle of the systems (then largely on paper) which raged so furiously but two years ago, has now subsided; and the many doughty champions who formerly confronted one another across the arena at 25, Great George-street have possibly in many instances considerably modified their views, and are busily engaged in carrying out high and low tension work according as local circumstances and peculiarities favour the one or the other. In the States, house lighting is practically carried out on either the alternate-current transformer or the three-wire system; and the limitations of these two methods are now, as with us, pretty well ascertained. Neither storage-batteries nor continuous-current transformers have, on the other hand, met with much vogue across the ocean. Tardy, therefore, as has been our commencement of serious central lighting work, it has been left to English electrical engineers to put to the test the capabilities of distribution by means of storage-battery sub-stations at Chelsea, and to ascertain the value of continuous-current transformers at St. Pancras. The former system has already shown itself equal to the fulfilment of the elementary requirements of constancy of pressure and freedom from breakdown, and it only remains for a few more facts to be ascertained as to its economy for it to take its appropriate place amongst the recognised methods of distributing the electric current. Distribution by means of continuous-current transformers is at the present moment completely *in futuro*, and it has yet to exhibit its superiority in some one particular over the systems at present in use. It has thus the distinction of being still an open question, and one which has not already been discussed to exhaustion in the technical press and at electrical societies.

But if the distribution of electricity for light and power has become a comparatively prosaic routine performance, we are not left entirely without compensation, for again our progressive cousins are showing us the way, to their honour and our advantage. The conditions in this country are not over favourable to electrical experiments of any description. What better could happen, therefore, than that the many knotty problems connected with electric traction should be partially solved for us across the Atlantic? In a few years it will doubtless have been satisfactorily settled for us by practical experience whether we should employ two small motors or a single large machine; and an efficient slow-speed motor geared direct to the axle will probably have been evolved. With such points disposed of, and the City and South London line and the Liverpool Overhead Railway in fair running order, it is possible, provided that a satisfactory closed or open conduit system has been devised, that we may buckle to and move forward in the matter of electrical propulsion.

Owing doubtless to the attention which has of recent years been paid to the development of telegraphy, telephony, the distribution of electricity for the purposes of light and power, and electric traction, the minor applications of electricity have until quite lately scarcely received their due attention. All this is now, however, rapidly being altered; and no doubt as the larger applications become more or less worked out increased energy will be expended in developing the potential possibilities of electricity in other directions. Electric bleaching, electric tanning, and electric welding have, as the saying is, "come to stay;" and even electric heating, although under present conditions it can scarcely be termed economical, may, it is quite conceivable, under special conditions, have advantages outweighing its disadvantages. An electric heater, it must be remembered, can be almost instantly lit and extinguished, and probably in the event of any accident it would be put out by the very occurrence of the accident. Further advantages arise from its almost absolute cleanliness and the complete absence of deleterious gases, and these manifest advantages have already led to its adoption on several American railways. The electrical dissipation of fog, of which something was heard in these columns a few months ago, is not indeed as yet an accomplished fact, but we believe that something similar has been tried with a certain measure of success in the case of the fumes given off in lead factories where considerable loss of lead occurs in this way.

The application of electricity to agriculture and horticulture in which so much interest was excited by the well-known experiments of Sir William Siemens in 1880-81, has lately had attention again drawn to it by the remarkable results obtained in Russia by Specnew. Sir William Siemens, it will be remembered, investigated the effect of exposing various plants placed inside a glasshouse to the electric light during the night time, and found that while a naked arc light produced anything but satisfactory results, the interposition of a mere thin sheet of clear glass between the plants and the source of light was most striking. Peas sown at the end of October produced a harvest of ripe fruit by the middle of February; strawberry plants planted about the middle of December produced excellent fruit two months afterwards, and equally satisfactory results were obtained with wheat, barley, and oats. "It is with great diffidence, and without wishing to generalise," says Sir William Siemens, "that I feel bound to state as the result of all my experiments, extending now over two winters, that although periodic darkness evidently favours growth in the sense of elongating the stalks of plants, the continuous stimulus of light appears favourable for healthy development at a greatly accelerated pace through all the stages of the annual life of the plant, from the early leaf to the ripened fruit. The latter is superior in size, in aroma, and in colour to that produced by alternating light, and the resulting seeds are not, at any rate, devoid of regerminating power."

Specnew's experiments, which extended over five years, were of a different order. He first of all investigated the effect of submitting different seeds to the direct action of an electric current, and he then carried out two series of experiments on a large scale. In one set of experiments he placed zinc and copper plates of 3½ square feet in the soil and connected them overhead by insulated wires, forming in this way a zinc | earth | copper cell. The plots between the plates he planted with various seeds. In the other series of experiments he employed a number of insulating rods crowned with comb collectors. All Specnew's experiments showed that electricity had a beneficial effect, and the increased yield due to electro-culture as compared with that due to ordinary culture on identically the same soil amounted in some instances to over 200 per cent. Specnew, although he did not make economy his primary object, seems to have obtained those results at a cost comparable, say, with that of ordinary fertilising agents, £10 per acre being the cost of his insulating rod apparatus. The minor applications of electricity bid fair, therefore, to assume large proportions; and the danger seems to be not that they will be neglected, but that too much will be expected of them. The law of the conservation of energy is now fortunately well understood and is always with us. Were it not so we should doubtless see many a limited company floated in the city of London for the purpose of obtaining 100 horse-power electrically by the expenditure of 10 mechanically.

ELECTRIC LIGHTING NOTICES FOR 1890-91.

The following is a list of the Local Authorities who have been served with notices by Electric Lighting Companies for the ensuing year. In places marked with an asterisk (*) the Local Authorities have decided themselves to apply for an Order or Licence, or are considering the advisability of doing so.

Place.	No. of Applications.	Names of Applicants.
METROPOLITAN AREAS.		
Acton	1	House-to-House Electric Light Supply Company.
Battersea	1	House-to-House Electric Light Supply Company.
Camberwell ...	3	Electric Installation and Maintenance Company. House-to-House Electric Light Supply Company. London Electric Supply Corporation.
Chelsea	4	Kensington and Knightsbridge Electric Lighting Co. London Electric Supply Corporation. New Cadogan and Belgrave Electric Supply Co. Westminster Electric Supply Corporation.
Chiswick.....	1	House-to-House Electric Light Supply Company.
City of London	3	House-to-House Electric Light Supply Company. Laing, Wharton, and Down Construction Syndicate. Metropolitan Electric Supply Company.
Fulham	4	Brush Electrical Engineering Company. House-to-House Electric Light Supply Company. London Electric Supply Corporation. Stamford Hill, Tottenham and Edmonton Electric Light and Power Supply Company.
Hackney.....	1	House-to-House Electric Light Supply Company.
Hammersmith...	1	House-to-House Electric Light Supply Company.
Hampstead.....	2	House-to-House Electric Light Supply Company. Metropolitan Electric Supply Company.
Hornsey	1	House-to-House Electric Light Supply Company.
Kensington.....	2	Kensington and Knightsbridge Electric Lighting Co. Westminster Electric Supply Corporation.
Lambeth	3	House-to-House Electric Light Supply Company. London Electric Supply Corporation. Metropolitan Electric Supply Company.
Paddington.....	4	Kensington and Knightsbridge Electric Lighting Co. London Electric Supply Corporation. Paddington and Bayswater Electric Light and Power Company. Westminster Electric Supply Corporation.
Shoreditch	1	House-to-House Electric Light Supply Company.
St. George's (Hanover-sqre.)	4	Chelsea Electricity Supply Company. New Cadogan and Belgrave Electric Supply Co. Kensington and Knightsbridge Electric Lighting Co. St. James and Pall Mall Electric Light Company.
St. George-the-Martyr (Southwark)	1	London Electric Supply Corporation.
St. John and St. Margaret (Westminster)	1	Westminster Electric Supply Corporation.
St. Luke's	2	House-to-House Electric Light Supply Company. London Electric Supply Corporation.
St. Marylebone	1	Westminster Electric Supply Corporation.
St. Pancras ...	1	Metropolitan Electric Supply Company.
Wandsworth ...	2	House-to-House Electric Light Supply Company. Metropolitan Electric Supply Company.
Whitechapel ...	1	House-to-House Electric Light Supply Company.
Willesden	1	House-to-House Electric Light Supply Company.
Woolwich	2	Woolwich District Electric Light Company. London Electric Supply Corporation.
PROVINCES.		
Alnwick	1	Northern Counties Electric Light and Power Supply Company.
Altrincham.....	1	Manchester House-to-House Electricity Company.
Astley Bridge...	1	Lancashire and Cheshire House-to-House Electricity Company.
Aylesbury	1	Latimer Clark, Muirhead and Co.
Barrow-in-Furness	2	Lancashire and Cheshire House-to-House Electricity Company. Municipal Electric Light and Power Corporation.
Batley	1	Yorkshire House-to-House Electricity Company.
Birmingham ...	2	Birmingham Electric Supply Company. Birmingham House-to-House Electricity Co.
Blackrock	1	Irish House-to-House Electricity Company.
*Bolton	2	Lancashire and Cheshire House-to-House Electricity Company. Municipal Electric Light and Power Corporation.
Boston.....	1	Latimer Clark, Muirhead and Co.
Bowdon	1	Manchester House-to-House Electricity Company.
Bradford-on-Avon	1	Latimer Clark, Muirhead and Co.
Bristol	3	Bristol Electricity Supply Company. Laing, Wharton, and Down Construction Syndicate. Western House-to-House Electricity Company.
Broadstairs.....	1	Municipal Electric Light and Power Corporation.
*Bromley	1	Laing, Wharton, and Down Construction Syndicate.
Buxton	1	Municipal Electric Light and Power Corporation.
*Canterbury. ...	3	Brush Electrical Engineering Company. Canterbury Electricity Supply Company. South of England House-to-House Electricity Co.
*Cardiff	5	Barry and Cardiff Electric Light and Power Supply Company. Brush Electrical Engineering Company. Electric Installation and Maintenance Company. National Electric Supply Company. Western House-to-House Electricity Company.
Chesterfield ...	1	Laing, Wharton, and Down Construction Syndicate.
Cirencester.....	1	Latimer Clark, Muirhead and Co.
Colchester	1	Latimer Clark, Muirhead, and Co.
ComptonGifford	1	Devon and Cornwall Electricity Supply Company.
Cork	1	Irish House-to-House Electricity Company.
Coventry.....	2	Midland House-to-House Electricity Company. Municipal Electric Light and Power Corporation.
Crosshill	1	Scottish House-to-House Electricity Company.
Croydon	1	South of England House-to-House Electricity Co.
Darkley	1	Irish House-to-House Electricity Company.
Daventry	1	Latimer Clark, Muirhead and Co.
Derby	1	Laing, Wharton, and Down Construction Syndicate.
Devonport	1	Devon and Cornwall Electricity Supply Company.
Dewsbury	2	Latimer Clark, Muirhead and Co. Yorkshire House-to-House Electricity Company.
Didsbury.....	1	Manchester House-to-House Electricity Company.
Dorchester	1	Latimer Clark, Muirhead and Co.
Drogheda	1	Irish House-to-House Electricity Company.
Dudley	2	Midland House-to-House Electricity Company. Municipal Electric Light and Power Corporation.
Dukinfield (Lancs.)	1	Municipal Electric Light and Power Corporation.
Dundalk	1	Irish House-to-House Electricity Company.
Dundee	1	Scottish House-to-House Electricity Company.
Eastbourne ...	1	Eastbourne Electric Light Company.
East Cowes.....	1	Municipal Electric Light and Power Corporation.
East Stonehouse	1	Devon and Cornwall Electricity Supply Company.
Edinburgh	4	Latimer Clark, Muirhead and Co. National Electric Supply Company. Scottish Electric Supply Company. Scottish House-to-House Electricity Company.
*Exeter	2	Devonshire Electric Light and Power Supply Co. Exeter Electric Light Company.
Farnworth	1	Lancashire and Cheshire House-to-House Electricity Company.
Folkestone	1	South of England House-to-House Electricity Co.
Glasgow	1	Scottish House-to-House Electricity Company.
Gloucester	2	Municipal Electric Light and Power Corporation. Western House-to-House Electricity Company.
Govan	1	Scottish House-to-House Electricity Company.
Govanhill	1	Scottish House-to-House Electricity Company.
Gravesend	1	South of England House-to-House Electricity Co.
Guildford	1	South of England House-to-House Electricity Co.
Greenock	1	Scottish House-to-House Electricity Company.
Halifax	2	National Electric Supply Company. Yorkshire House-to-House Electricity Company.
Hampton Wick	1	Municipal Electric Light and Power Corporation.
Hanley (Staffs.).	2	Birmingham House-to-House Electricity Co. Brush Electrical Engineering Company.
Harborne	1	Birmingham House-to-House Electricity Co.
*Harrogate	2	National Electric Supply Company. Yorkshire House-to-House Electricity Company.
Hartlepool	1	Municipal Electric Light and Power Corporation.
Hawick	1	Scottish House-to-House Electricity Company.
Hebden Bridge	1	Latimer Clark, Muirhead and Co.
*Hertford	1	Hertford Electric Light and Power Supply Company.
Heywood (Lan.)	1	Municipal Electric Light and Power Corporation.
Hillhead	1	Scottish House-to-House Electricity Company.
Huddersfield ..	1	Yorkshire House-to-House Electricity Company.
Hyde	1	Midland House-to-House Electricity Company.
Ilkley	1	Yorkshire House-to-House Electricity Company.
Ipswich	1	Brush Electrical Engineering Company.
Jarrow.....	1	Municipal Electric Light and Power Corporation.
Kearsley	1	Lancashire and Cheshire House-to-House Electricity Company.
Keighley	1	Yorkshire House-to-House Electricity Company.
Kidderminster	1	Midland House-to-House Electricity Company.
Killiney and Ballybrook ...	1	Irish House-to-House Electricity Company.
Kingston-on-Thames	1	Municipal Electric Light and Power Corporation.
Kingstown	1	Irish House-to-House Electricity Company.
Kinning Park...	1	Scottish House-to-House Electricity Company.
Leamington ...	2	Midland Electric Light and Power Company. Municipal Electric Light and Power Corporation.
Leeds	3	Electric Installation and Maintenance Company. National Electric Supply Company. Yorkshire House-to-House Electricity Company.
Leith	1	Scottish House-to-House Electricity Company.

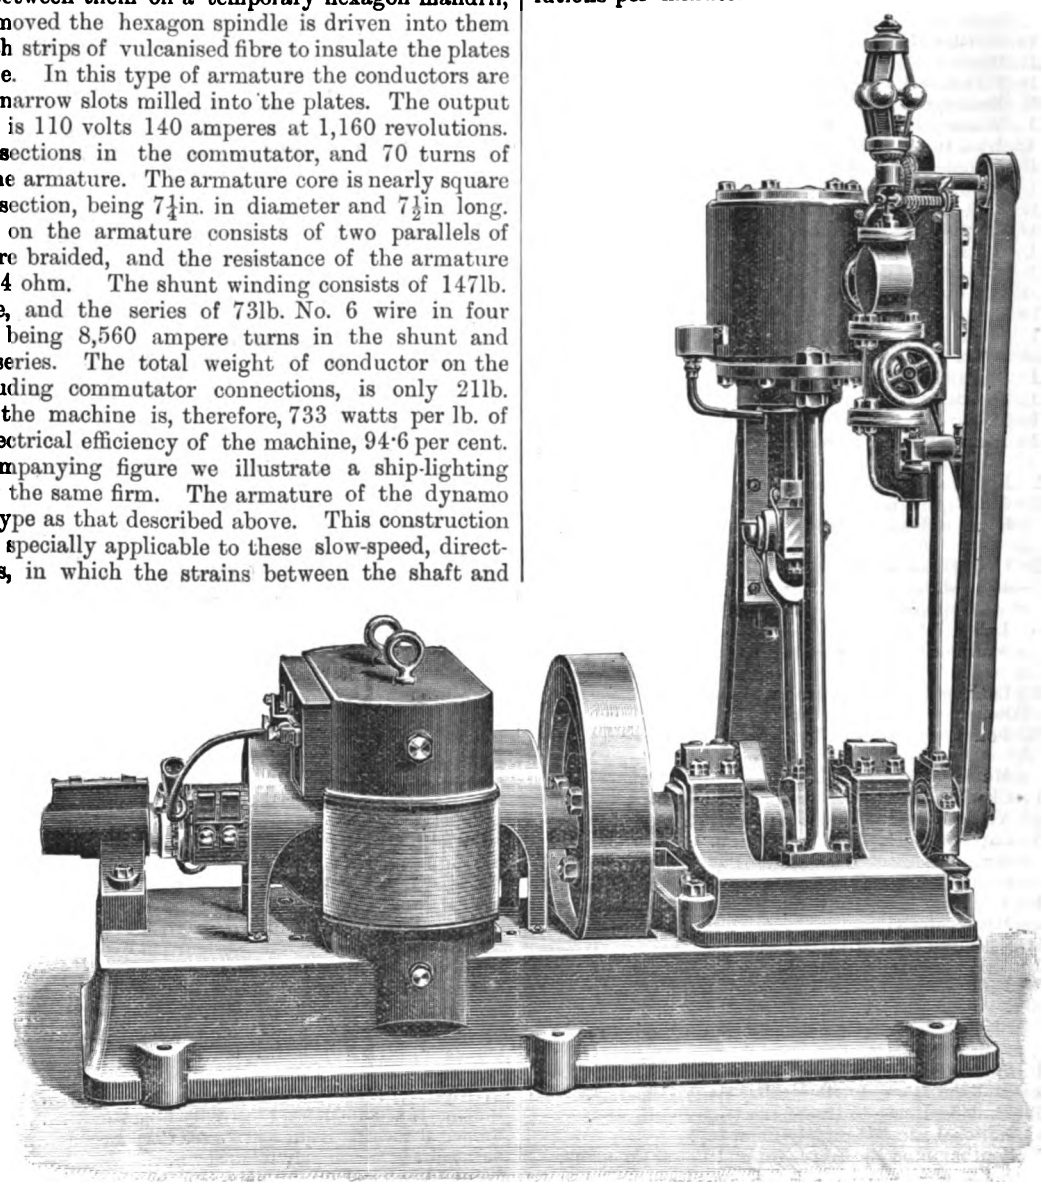
THE EDINBURGH EXHIBITION.—V.

MESSRS. LAURENCE, SCOTT AND CO.'S EXHIBIT.

Messrs. Laurence, Scott and Co., of Norwich, show on the stand of their agents for Scotland, Messrs. Norman and Son, of Glasgow, among other things one of their "D" dynamos, driven by a long stroke engine, by Messrs. Ransomes, Sims and Jefferies, of Ipswich. The magnets of this machine are of the "Kapp" type, made of specially soft cast-iron. The drum armature is built up on the system which Messrs. Laurence, Scott and Co. have used for several years. The plates are stamped with hexagon holes placed together, with the insulating material between them on a temporary hexagon mandril, which being removed the hexagon spindle is driven into them very tightly with strips of vulcanised fibre to insulate the plates from the spindle. In this type of armature the conductors are wound in deep narrow slots milled into the plates. The output of the machine is 110 volts 140 amperes at 1,160 revolutions. There are 70 sections in the commutator, and 70 turns of conductor on the armature. The armature core is nearly square in longitudinal section, being 7¼in. in diameter and 7½in long. The conductor on the armature consists of two parallels of ·12in. round wire braided, and the resistance of the armature when hot is ·024 ohm. The shunt winding consists of 147lb. of No. 17 wire, and the series of 73lb. No. 6 wire in four parallels, there being 8,560 ampere turns in the shunt and 5,520 in the series. The total weight of conductor on the armature, including commutator connections, is only 21lb. The output of the machine is, therefore, 733 watts per lb. of copper. The electrical efficiency of the machine, 94·6 per cent.

In the accompanying figure we illustrate a ship-lighting plant shown by the same firm. The armature of the dynamo is of the same type as that described above. This construction of armature is specially applicable to these slow-speed, direct-driven machines, in which the strains between the shaft and the armature conductor are so much greater and more trying than in an ordinary belt-driven machine. The output of the dynamo is 60 volts 75 amperes, at the slow speed of 260 revolutions per minute. Messrs. Laurence, Scott and Co. always test these ship-lighters before leaving their works for six hours at "load and a half," and for twelve hours at full load. The engine itself is by Messrs. Sabberton Bros., of Norwich. The crank is of forged steel, slotted and fitted with balance weights; the connecting-rod, also of forged steel, is six cranks long. All the bearings and wearing surfaces are very large, and fitted with suitable lubricating arrangements, to enable it to run continuously at a high speed. The cylinders are 6in. diameter, and 6in. stroke, and the engine will run well up to 1,100 revolutions per minute.



4½-kilowatt Ship Lighting Plant.

SOME NEW VACUUM JOINTS AND TAPS.*

BY W. A. SHENSTONE.

In making joints in ordinary vacuum apparatus it is usual to provide a cup, and to grind a glass stopper to fit the tube to which it is attached. The cup is filled with glycerine or mercury which acts as a seal to the joint thus formed. The objection to this is, that if the position of the stopper is shifted, the mercury enters the apparatus, and in many cases is very objectionable, and in some cases it would altogether vitiate the results. The author had recently been engaged in the production of pure oxygen, and had occasion to make and break joints without admitting anything to the apparatus. He devised a form of joint in which the plug was upside down, and on suggesting this to Mr. Cundall who was working with him, he found that he had hit on the same idea, and had begun to construct one. He exhibited a specimen of such a joint (Fig. 1).

He had also felt the want of a joint which would withstand pressure in either direction. Any pressure on the interior of such a joint as he had described would cause it to leak if not to blow out, as the seal was in one direction only, consequently it could not be used with manometers. He had thought of a tap which could be worked from within or without, and had considered electro-magnetic methods for working it. He had

* Abstract of a Paper read before the British Association in Section A, Leeds, September, 1890.

Digitized by Google

eventually arranged a double seal, and exhibited a joint made in this way (Fig. 2). It was provided with a means of making or breaking the joint, which was a ready way of introducing the mercury to the inner seal. A flat was filed on the taper plug (Fig. 3) and a groove was cut on the inner side of the tube which had been ground to fit it. When these two cuts were turned to be in line, a passage was formed by them, and when turned round this was shut off. Another pattern was exhibited, in which the mercury was introduced to the inner seal by means of a branch tube, which could be sealed off after use.

In ordinary glass plug taps a difficulty often arose owing to the air, which was contained at the bottom of the hole into which the glass plug was ground. This could not be got over by introducing anything into the hole before the plug was put in place. If the well were filled with mercury, when the plug was put in, it displaced the mercury, and some of it would remain between the ground surfaces of the plug and the hole, interfering with the working. The improvement which he had effected was merely to drill a hole from the bottom of the plug through the axis to the cross hole, thus placing the cavity below the plug in communication with the passage through the

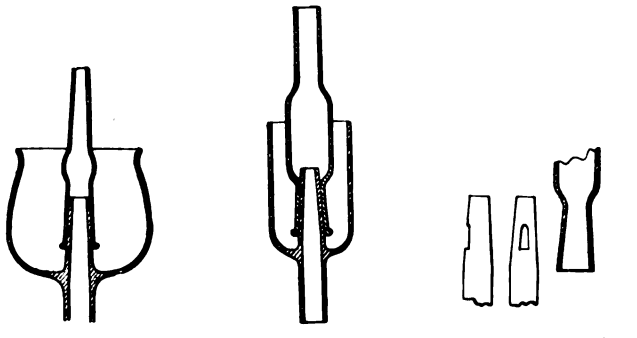


FIG. 1. FIG. 2. FIG. 3.

plug. When air or gas passed through the tap it filled the cavity as well as the tubes to which the tap was connected, and when these were exhausted, the cavity below the plug was also exhausted.

DISCUSSION.

Mr. SWINBURNE said that a difficulty arose in the use of ground-glass taps in finding a good lubricant. For most purposes, and for all vacuum purposes, one could not use hydrocarbons. He had found silicate of soda to be the best thing to use, but would ask Mr. Shenstone if he could suggest anything better.

Mr. SHENSTONE in reply said that he was aware of the difficulty and had used silicate of soda, but he had found that it acted on the glass; and after a vacuum apparatus had been set up for a few weeks spots of a white appearance were to be found on the surface of the plug, and these tended to increase, and eventually the two surfaces of the glass would unite together. He had found that pentoxide of phosphorous or syrupy phosphoric acid was a good lubricant, and he had not discovered any bad results from its presence.

REPORT OF THE COMMITTEE ON ELECTRICAL STANDARDS.*

The work of testing resistance coils at the Cavendish Laboratory has been continued. A table of values found for the coils is appended:—

LEGAL OHMS.

No. of Coils.				Resistance in legal ohms.	Temperature.
Nalder	1577	C.L.C.	189	·99981	16·9
Nalder	1578	C.L.C.	190	1·00089	16·9
Nalder	1579	C.L.C.	191	1·00041	16·9
Edison Swan	16	C.L.C.	192	·99846	13·9
Elliott	229	C.L.C.	193	1·00028	16·9
Elliott	230	C.L.C.	194	1·00021	16·9
Simmons		C.L.C.	195	·99992	16·8
Nalder	1626	C.L.C.	196	1·00045	15·3
Nalder	1627	C.L.C.	197	1·00056	15·3
Nalder	1628	C.L.C.	198	1·00058	14·8
Nalder	1580	C.L.C.	199	1·00072	15·3

* Read before the British Association in Section A, Leeds, September, 1890.

It would be of considerable advantage in the testing if all the coils were made of a uniform size. The original standards of the Association measure 6¾in. from the bottom of the case to the underside of the horizontal portion of the copper connecting rods, while the vertical portion of these rods is 8in. in length. These dimensions should be adopted in all coils sent to be tested; if this be done, the baths, &c., made to hold the standards hold the coils equally well, and the additional convenience in testing is very great great.

The original standards of the Association have again been several times compared among themselves. The results of the comparisons appear to show that while the coils A, B, C, D, E, and Flat have remained constant relative to each other, the three platinum silver coils F G and H have changed. The change in F was referred to at the end of the Report in 1888, and is now very large. The coil has increased in resistance by about ·0006 B.A. unit; G, on the other hand, has fallen by about ·0002 B.A. unit, and H by about ·0001 unit. The evidence for these various statements is given in an appendix to the Report by the secretary. It is, perhaps, worth remark that in each case the change either took place during the time that the coil was immersed in ice, or was found to have happened when the coil was next measured after its removal from the ice. The legal ohm coils have not varied relative to Flat.

The investigations into the resistance of copper have been continued by Mr. Fitzpatrick. The committee desire again to thank the gentlemen who have rendered him assistance in various ways.

Mr. Fitzpatrick has examined various specimens of copper supplied him as wire. He has also examined copper prepared for him as pure by Messrs. Sutton, as well as some which he prepared himself electrolytically from carefully purified copper sulphate. These last two specimens lead to practically the same value as that obtained by Matthiessen for the specific resistance of copper, viz., 1767×10^{-9} B.A. units at 18deg.; the specific gravity of these specimens is about 8·90. Two wires supplied to him have, however, a distinctly lower resistance: the value for one being 1731×10^{-9}, and for the other 1724×10^{-9}; a difference in the one case of 2 and in the other of 2·4 per cent. The specific gravity of the first of these wires is 8·940, and of the other 8·946, and Mr. Fitzpatrick assigns the increased conductivity to increased density rather than to greater purity.

Matthiessen gives his results for the resistance of copper at 0deg. The observations were, however, made mostly at a temperature of 18deg. or 20deg., and reduced to 0deg. by the use of a temperature coefficient. So that the value at 18deg. found from that at 0deg. by the same coefficient will probably represent the result of Matthiessen's work more accurately than the one he gives himself. Various other points of importance are discussed in Mr. Fitzpatrick's appendix. He hopes to be able to give the results for some copper prepared by chemical means by Mr. Skinner and himself. He has also made a number of measurements on silver, but these are not yet complete.

Dr. Muirhead and the Secretary have both been working independently at the construction and measurement of a standard air condenser. Two such condensers have been made for the Committee by the Cambridge Scientific Instrument Company, on a plan suggested by Dr. Muirhead, and mentioned in the last Report. The capacity of each of these is about ·02 microfarad. Some slight alterations are required to one of these, the other is completely satisfactory. Its capacity has been repeatedly found, and remains constant to at least within 1 in 2,000, which is about the limit of accuracy attained. Its insulation resistance is good, the loss by leakage being about 1 in 1,000 of the total charge per one minute. It has been found possible to compare readily with this standard various mica condensers having capacities of 1, ·5, ·1, and ·05 microfarad. The accuracy of these determinations is about 1 in 2,000. A full account of the construction of the condensers, and of the method of making the various tests, is given in an appendix by the Secretary, while Dr. Muirhead has contributed some notes on his own condensers and tests.

Another appendix contains an account of a very careful and interesting comparison between the standard mercury ther-

Digitized by Google

mometers of the Association and a platinum resistance thermometer constructed by Mr. E. H. Griffiths. The resistance thermometer was graduated by means of Regnault's numbers for the vapour pressure of water at various temperatures between 0° and 100°. The curve of corrections obtained in this way is exactly parallel to that given by the Kew comparisons; there is throughout the range a constant difference of 0°·02 between them. This amount is within the limits of error on the mercury thermometer.

The question of the best value to adopt for the dimensions of a mercury column having a resistance of one ohm has been raised by some members of the committee during the year. There is no doubt that the column of 106 centimetres adopted by the Paris Conference in 1884 is too short. After a discussion of the results of the most recent observations, the following resolutions were adopted by the committee :—

(1) The committee recommend for adoption as a standard of resistance sufficiently near to the absolute ohm for practical purposes the resistance of a column of mercury 106·3 cm. in length one square mm. in section at a temperature of 0°C.

(2) That for the purpose of issuing practical standards of resistance the number ·9866 be adopted as the ratio of the B.A. unit to the ohm.

Thus the new unit may be obtained from the B.A. unit by increasing it in the ratio ·9866 to unity, or, to put it differently, the specific resistance of mercury in B.A. units is taken as $\cdot 9535 \times 10^{-4}$ and the length of a column of mercury which has a resistance of 1 B.A. unit as 104·97.

The specific resistance of mercury in ohms in thus :—

$$\cdot 9407 \times 10^{-4}.$$

In conclusion, the committee wish to ask for reappointment to enable them to continue the work of constructing and issuing standard instruments. Of the grant of £50 made at Newcastle only £12. 17s. has been drawn. In order to check any further change in the values of the B.A. units, and to render it less necessary to employ the original standards in all the comparisons which are made, it is desirable that the committee should possess three or four copies of the B.A. unit; while, to enable comparisons to be made between the new air condensers and condensers of capacity comparable with a microfarad, a resistance box going up to several hundred thousand ohms is required.

The committee are of opinion that they should be in a position to purchase these resistances; they, therefore, recommend that they be reappointed with a grant of £100, that Prof. Carey Foster be the chairman, and Mr. R. T. Glazebrook secretary.

THE COUPLING AND CONTROL OF DYNAMOS IN CENTRAL STATIONS.—III.*

(*Concluded from page 470.*)

Alternating Currents.—The usual arrangement is to have a number of independent dynamos and a number of independent circuits leading to separate districts. One or more of the circuits is connected to each machine. As the number of lamps on each circuit diminishes, more circuits are put on to each machine, and the number of machines in use is reduced. The machines thus do not run in parallel at all. One argument against parallel running, which is especially used in the States, is that faults are constantly occurring on the high-tension circuits. If all the circuits are connected together, a fault on any positive lead in conjunction with a fault on any negative lead causes a short circuit, which may have more or less disastrous effects according to the arrangements of the circuits and dynamos, while, on the separate circuit system, faults on positive and negative leads of the same dynamo are needed before there is any accident. Against this it is to be urged that an armature of any machine going wrong puts a district out, and high-tension alternating armatures do go wrong very easily. It would, therefore, seem better to secure the advantages of both these systems. It is not at all necessary that the circuits should be metallically connected; one leading feature of alternating currents is the ease with which they can be managed. If the dynamos themselves give high pressures, as is usually the case, one or more external circuits may be connected to each dynamo, but the whole of the dynamos may be coupled to work in parallel without any metallic connection whatever. This arrangement is shown in Fig. 1. Three dynamos, A, B, C, are connected directly to circuits. A has two external circuits, B one, and C three. An earth on the positive of one of the circuits of, say 1, in conjunction with one on the negative of a circuit on, say 4, causes no stoppage, as there is no metalli connection between the circuits. If a leak came on the positive of 4 and negative of 6, there would be a stoppage; but by transferring 4 or 6 to another machine, a start can be made at once. The dynamos are also connected to a transformer D. This is wound with as many circuits as there are dynamos in parallel. Three only are shown. The transformer need not be large; its utmost capacity need only be enough to enable it to give the output of one dynamo for a few minutes. Ordinarily this transformer has no load except what little may be necessary to keep the dynamos in step. If one dynamo, say C, breaks down, the transformer takes power from A and B, and supplies to the circuits belonging to C. If C had an armature short circuit, or a break in its exciting current, its fuse will have blown, and it will be disconnected. The transformer need only be able to supply power till an attendant has put the circuits 4, 5, and 6 on another dynamo, so the current density allowed may be very high. This high-current density occurs only in the coil acting as secondary. As all the other coils act as primaries in parallel, their current densities are low.

If the dynamos are wound for low tension, and transformers are used to give the high pressure for the mains, there is less difficulty. All the dynamos may feed into one large transformer, or into a bank of several, the primaries, or low-pressure circuits, all being connected together. It is strange that transforming up is not used more. At first it was to have been used at Deptford, but the scheme was altered. The arguments against it are that the transformers waste power and cost money. As to loss of power

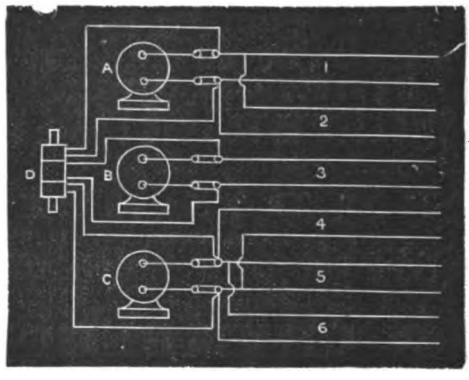

FIG. 1.

the efficiency of a large station transformer can be raised above 99 per cent. including the loss in the iron, by use of the open circuit, and very nearly as high with a closed circuit, if the arrangement is such that the transformers can be cut in or out so that those in use are always at full load. The loss in efficiency is also counterbalanced by gain in the dynamo. An armature wound for 2,000 volts has small wire and a great deal of insulation. The insulation is not only costly, sometimes running up to about £30 for mica alone, but it takes up room that could be much better occupied with copper conductor. The whole dynamo can thus be made more efficient by winding it for low pressure, and its increased efficiency probably compensates, or almost compensates, for the loss of power in the transformers. In many cases it is also possible to arrange the whole station on the low-pressure side of the transformers. The switches, couplings, fuses, and instruments then demand neither troublesome insulation nor careful handling, and this alone is an enormous advantage. The cost of large transformers is also very trifling. They can be made for less than sixpence per 8 candle-power lamp, which is nothing in comparison with the saving in using them.

In transforming up, if there are a number of external circuits, as in Fig. 1, to avoid chances of breakdown through faults, a large transformer, or a bank of them, may be arranged with several high-pressure circuits, as shown in Fig. 2. In this case the switches and gear are not all on the low-pressure side, but the arrangement has the advantage of allowing the transformers to be cut in and out, and it also admits of regulation of the pressures on the high-tension circuit by cutting turns in or out. Circuits 1 and 2 are shown regulated that way. The transformers E F G may, of course, be of any form, and are shown merely diagrammatically. Circuit 5 is shown as regulated by a step-up transformer. This arrangement has been patented several times. Mr. Kapp has patented a step-up transformer for insertion in a feeder. He did not propose to use it in conjunction with a transforming-up arrangement, and altered

* Abstract of an article by James Swinburne in *Industries*.

Digitized by Google

the numbers of turns in it secondary instead of its primary, which is not quite so convenient. The dynamos in Fig. 2 may or may not be coupled to run in parellel. The high-tension circuits can also be arranged on the three-wire system without any complications.

Another arrangement is shown in Fig. 3. The dynamos are all connected in parallel, and there is one transformer for each circuit. The regulating gear and switches are then all on the low-pressure side, but each circuit or feeder is regulated independently. This arrangement demands a larger number of transformers, and is, therefore, slightly more expensive, and all the transformers are always in circuit, which is not a good arrangement. Of course, this arrangement can work without the dynamos running in parallel. Step-up transformers can also be used to regulate, instead of having spare turns on the large transformers. This avoids high-tension switches to some extent.

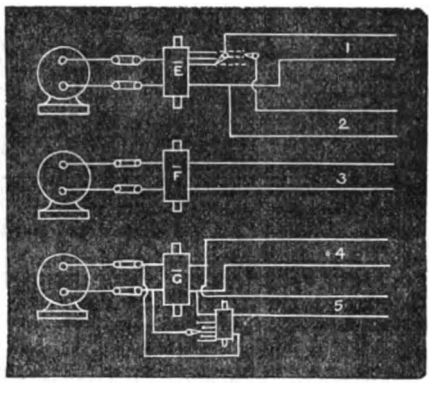

Fig. 2.

Turning now to the question of government, if each alternator is run from a single engine, and the machines are not run in parellel, the engines may have speed or electrical pressure governors. There is nothing to add here to what has been said in connection with direct currents. If, however, an electric governor is used, which acts on the exciting current of the exciter, there is a strong tendency to hunting, as, when the exciter field is altered, there is often a considerable time before the main dynamo feels it. I have used governors which would act when employed to regulate the main field, but hunted intolerably when set to control the field of the exciter. It is usual to supply a separate exciter for each dynamo. This seems to be a thoughtless survival from the early days of alternating currents. There is no reason why two engines and dynamo, with a spare at hand, should not supply exciting power for all the alternators in a station. Such an arrangement would be very much safer and considerably cheaper.

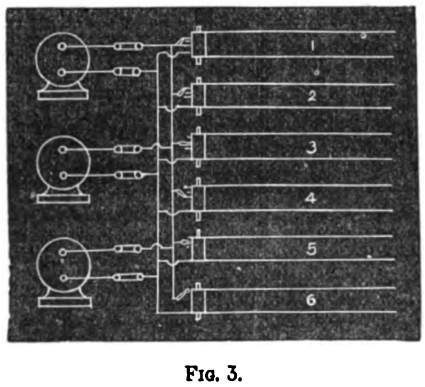

Fig. 3.

The question of the coupling of alternators in parallel is commonly dealt with in a somewhat random and general way. Under the circumstances, I also may be allowed to treat the subject somewhat dogmatically, and to give my own theory of the matter as if it were acknowledged to be correct.

The parallel running of ordinary alternators, or their availability as motors with varying loads, depends not on whether the armature has iron or not, or whether the pressure falls as the current increases when run on resistances, but on the armature reactions and the resistances of the armature. If the field of the machine is also altered, the problem is apparently more complicated, but is really simpler. As self-exciting dynamos, and probably motors, will without doubt soon come into much more general use, and as they go far towards solving the problem, I will deal with various modes of exciting as if they were as common as in the case of direct currents. As the principles underlying working dynamos in parallel and synchronising motors on parallel supply circuits are the same, they may be explained together. The case of an alternate-current supply circuit may be taken. A machine without friction may be imagined, and when its field magnets are separately excited so as to give an electromotive force exactly equal to that of the mains when it is connected, so as to be co-phasedly synchronised, it runs as a motor, taking no current. At each instant the electromotive force of the machine is exactly equal to the electromotive force of the mains, so no current passes. If power is applied to the machine, it becomes a generator; if load is put on it becomes a motor. On putting on some load the machine begins to lag. As soon as the machine lags, a current passes through the armature. If the electromotive force of the machine were still the same as that of the mains it is clear that it would develop no power as a motor, because at some parts of the period it would be supplying power to the mains, and at other parts of the period the mains would be supplying power to the armature. The electromotive force of the machine does not, however, remain equal to the main electromotive force, merely differing from it in phase, but it is decreased by the reaction of the armature current on the field magnets. This weakening of the field by the armature reaction allows the mains to do more work on the machine than the machine does on the mains, so that the machine acts as a motor, and power can be taken from it. If the load is altered, the machine will increase or decrease its lag, so that its effective field is reduced to just the right value to allow the machine to absorb electrically the power taken from it mechanically. As lag is necessary in order to weaken the effective field, so the current in the armature is no longer co-phasedly synchronised with the electromotive force of the mains. The result of this is that the current is not at the maximum value at the same instants as the electromotive force is; so that the power taken by the motor is less than the product of the effective electromotive force of the mains and the effective current of the machine. The electromotive force and current may be so much out of step that the power of the motor is small though the armature current is large. The availability of the machine as a motor thus depends on the resistance of the armature and on its reaction on the field.

For instance, if the machine has very little armature resistance, a very small reduction of its electromotive force will allow a large armature current to pass. If, on the other hand, the armature resistance is high, the armature must have a large reaction on the field so as to reduce the effective electromotive force of the machine considerably when it lags. If, at the same time the load is put on, the field of the motor is artificially weakened by reducing the excitation, the electromotive force of the machine may be reduced enough to allow current from the mains to act in step with the main electromotive force. For instance, if the supply circuit is of 100 volts, and if an ordinary separately excited 100-volt machine is connected and excited so as to give 100 volts with the same vibration frequency, or periods per second, as prevails in the mains, and if this machine is loaded as a motor with 100 horse-power, it will lag until the field is weakened enough to let sufficient current pass to give the power. This current will be more than 746 amperes, though the machine, if fairly efficient, does not need much more than 746 watts to give out 1 horse-power. But if the machine as a dynamo can give 746 amperes with the loss of five volts in the armature, due to the resistance, and if the machine is excited so as to give 95 volts on open circuit at the normal speed, and is then thrown into the circuit at an instant when it is in step, and a load of 95 horse-power taken out, it will remain in step, for the electromotive force of the machine is always just enough below the main electromotive force to allow the right current to pass. The effective current is then 746 amperes. The main circuit thus supplies 100 volts and 746 amperes, or 100 horse-power. Five horse-power is lost in overcoming the resistance of the armature, and 95 is available at the pulley. The losses by friction and Foucault currents are here neglected for the sake of simplicity. In practice a little less than 95 horse-power would be obtained for external use. If the field has not been weakened by reducing the excitation, the effective current—that is to say, the current as measured by an electro-dynamometer—would be considerably more than 746 amperes, let us say 1,500 amperes. The power given to the motor would, of course, however, be much less than 150,000 watts, as the current would be out of step with the electromotive force. The armature loss in the case already taken was 5 per cent., or 5 horse-power with 746 amperes; with 1,500 it would be 20 horse-power. The mains would thus supply 115 horse-power, of which 20 would be spent in the armature of the machine. In order to stand an armature loss of 20 horse-power without excessive heating, the machine, must be made much larger, and the electrical efficiency of the armature is much lower, 82·6 instead of 95. Thus, by lessening the ampere turns on the field of the motor as the load increases it is possible to make it work as efficiently and give as large an output as a motor as when employed as a generator.

Digitized by Google

If the machine is to be worked as a generator in parallel with the main circuit, the same reasoning holds good. If the machine is excited so as to give 100 volts at no load and is thrown into circuit at an instant when it is in step, if the engine supplies just enough power to overcome friction there will be no armature current, as the electromotive force of the machine will, at every instant of the period, be exactly equal and opposite to that of the mains. If the engine supplies just a little too much power the machine will begin to lead, and an armature current will pass, which will strengthen the fields by reaction, and the machine will at some instant act as a generator, because its electromotive force is now a little higher, as the armature current has strengthened its field. Similarly, if the steam of the engine were completely shut off, the machine would lag until it worked as a motor. If now the steam is turned on until the dynamo supplies 100 horse-power to the mains, the machine will increase its lead until the armature current strengthens the field enough to give the output. The armature current will not be in step with the electromotive force, so the current will be more than 746 amperes. If it is 1,500 amperes, which is not unlikely, the armature loss will be 20 horse-power.

It may be well to remark that the theory here given is not rigidly correct. In various theoretical investigations of armature reactions I have divided the action of the armature current into two portions capable of separate treatment, which I have called the "back induction" and "cross induction" respectively. These terms have now come into general use, so need not be defined. In the theory as explained above, I have only taken the back induction into account, and have, for the sake of simplicity, neglected the complications arising from cross induction. It is thus possible, by altering the field excitation of such dynamos, to make them work well as generators or motors on supply circuits. Instead of depending on the reaction of the armature to strengthen or weaken the effective field, the field excitation may be regulated so that the current and electromotive force of the machine are always in step or very nearly so.

Take first the case of a separately excited motor. The field magnets have an additional set of coils, and these are put in series with the main armature current, which is redressed or rectified by a commutator. These coils are arranged so as to demagnetise or weaken the field as the current increases, so that it is not necessary for the machine to lag in order to take a large load.

The redressed current might be used to demagnetise the fields of the exciter, but it is more prompt and better to act on the fields of the alternating machine itself. If the dynamo is made to excite itself with special exciting coils on the main armature, as in the case of some of Prof. Elihu Thomson's machines, it is especially useful for parallel working. If a machine made in this way is used as a motor without series demagnetising circuits round the field-magnets, it begins to lag as soon as load is put on, and the armature current then reacts on the pole-pieces and lessens the effective fields. As the exciting coils now pass through the same field, this will also lessen the magnet excitation directly, and as soon as the effective field is weakened by the armature reaction the ampere turns round are also reduced because the electromotive force in the exciting circuit is lessened. A very small lag will thus weaken the field considerably, so that a large load may be put on without the lag being great enough to make the machine inefficient. A series demagnetising circuit may be used in addition. If the ampere turns of the field-magnet are not adjusted to the load with perfect accuracy the machine adjusts itself by lagging or leading very slightly. Of course, cast-iron field-magnets are apt to give trouble, as they do not always follow the change of excitation quickly enough.

Machines with fields excited chiefly by special exciting circuits on the main armatures and partly by series circuits are useful for working in parallel as generators. The series circuits are then arranged to magnetise instead of demagnetise. If power is applied to a motor instead of taken from it it becomes a generator, and the direction of its main current is reversed, both in the armature and the series coils on the fields, so that a motor with a backward series circuit becomes a generator with a forward series circuit. If one machine, when used as a generator, begins to lead because too much power is supplied to it by its engine, its field is strengthened by the series currents, and this increases the armature electromotive force enough to make it give a large output corresponding to the power supplied to it. If machines excited from special armature circuits without series circuits are run in parallel they will keep in step, because the least loading or lagging alters the field excitation.

The compound form is best, because the whole station will then supply the mains at constant pressure if all the engines are mechanically governed for constant speed of one of them—that is to say, the whole steam supply is regulated to keep the speed of all the engines constant, the engines taking the steam in proportion to their size. Instead of keeping the speed constant, an electric governor can keep the electromotive force of the whole station constant. With alternate machines, as at present commonly used, it is necessary to alter the field excitation by hand or by automatic gear. Self-exciting compound machines have advantages corresponding to compound machines in direct-current work compared with shunt or separately excited machines. The analogy between these alternate machines and compound or separate armature circuit direct-current machines must not be pushed too far. In direct-current machines the electromotive force adapts itself by slight alterations of speed, and the armature reaction depends on the position of the brushes; in alternate machines the speed is unalterable, and the armature reaction depends on lead and lag. These compound machines may need to be coupled like direct-current compound machines to avoid any tendency to reversal. At present engineers nearly always use separate exciters, one for each alternator. Most likely, in a very few years, the various ways of exciting alternators, and the properties of the various windings, will be as well understood as in the case of direct-current dynamos.

THE ELECTRO-MAGNET.*

BY PROF. SILVANUS P. THOMPSON, D.SC., B.A., M.I.E.E.

(Continued from page 564.)

Generalities concerning Electro-Magnets.

Materials.—In any complete treatise on the electro-magnet it would be needful to enumerate, and to discuss in detail, the several constructive features of the apparatus. Three classes of material enter into its construction: first, the iron which constitutes the material of the magnetic circuit, including the armature as well as the cores on which the coils are wound, and the yoke that connects them; secondly, the copper which is employed as the material which conducts the electric currents, and which is usually in the form of wire; thirdly, the insulating material employed to prevent the copper coils from coming into contact with one another, or with the iron core. There is a further subject for discussion in the bobbins, formers, or frames upon which the coils are in so many cases wound, and which may in some cases be made in metal, but often are not. The engineering of the electro-magnet might well furnish matter for a special chapter.

Typical Forms.

It is difficult to devise a satisfactory or exhaustive classification of the varied forms which the electro-magnet has assumed; but it is at least possible to enumerate some of the typical forms.

1. *Bar Electro-Magnet.*—This consists of a single straight core (whether solid, tubular, or laminated), surrounded by a coil. Fig. 3 (*The Electrician*, September 12th, p. 527), depicted Sturgeon's earliest example.

2. *Horse-shoe Electro-Magnet.*—There are two sub-types included in this name. The original electro-magnet of Sturgeon (Fig. 1) really resembled a horse-shoe in form, being constructed of a single piece of round wrought iron, about half an inch in diameter, and nearly a foot long, bent into an arch. In recent years the other sub-type has prevailed, consisting, as shown in Fig. 11, of two separate iron cores, usually cut from circular rod, fixed into a third piece of wrought iron, the yoke. Occasionally this form is modified by the use of one coil only, the second core being left uncovered. This form has received in France the name of *aimant boiteux*. Its merits will be considered later. Sometimes a single coil is wound upon the yoke, the two limbs being uncovered.

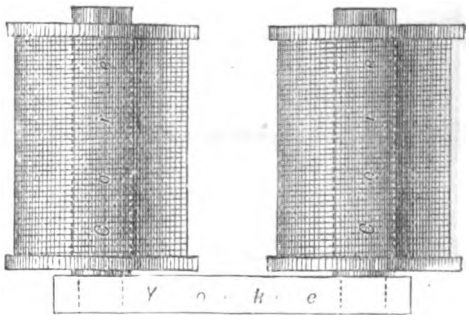

FIG. 11.—Typical Two-Pole Electro-Magnet.

* A series of four Cantor Lectures delivered before the Society of Arts, January—February, 1890.

Digitized by Google

3. *Iron-clad Electro-Magnet.*—This form, which has many times been re-invented, differs from the simple bar magnet in having an iron shell or casing external to the coils, and attached to the core at one end. Such a magnet presents, as depicted in Fig. 12, a central pole at one end surrounded by an outer annual pole of the opposite polarity. The appropriate armature for electro-magnets of this type is a circular disc or lid of iron.

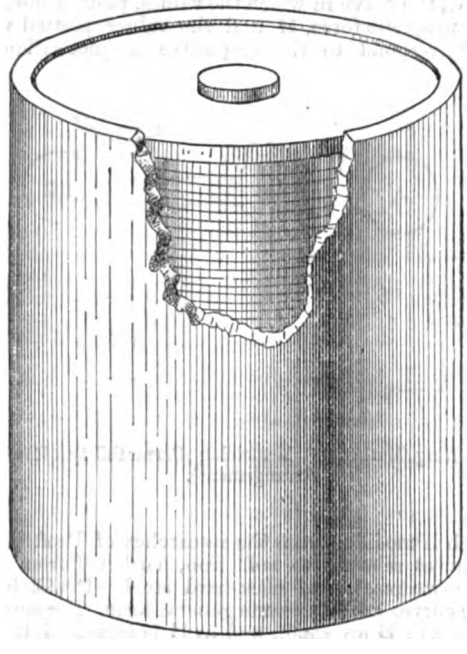

FIG. 12.—Iron-clad Electro-Magnet.

4. *Coil-and-Plunger.*—A detached iron core is attracted into a hollow coil, or solenoid, of copper wire, when a current of electricity flows round the latter. This is a special form, and will receive extended consideration.

5. *Special Forms.*—Besides the leading forms enumerated above, there are a number of special types, multipolar, spiral, and others designed for particular purposes. There is also a group of forms intermediate between the ordinary electro-magnet and the coil-and-plunger form.

Polarity.

It is a familiar fact that the polarity of an electro-magnet depends upon the sense in which the current is flowing around it. Various rules for remembering the relation of the electric flow and the magnetic force have been given. One of them that is useful is that when one is looking at the north pole of an electro-magnet, the

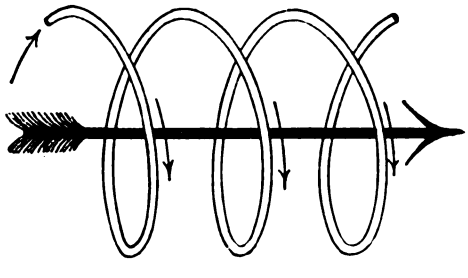

FIG. 13.—Diagram illustrating relation of Magnetising Circuit and resulting Magnetic Force.

current will be flowing around that pole in the sense opposite to that in which the hands of a clock are seen to revolve. Another useful rule, suggested by Maxwell, is illustrated by Fig. 13, namely, that the sense of the circulation of the current (whether right or left-handed), and the positive direction of the resulting magnetic force are related together in the same way as the rotation and the travel of a right-handed screw are associated together. Right-handed rotation of the screw is associated with forward travel. Right-handed circulation of a current is associated with a magnetic force tending to produce north polarity at the forward end of the core.

Uses in General.

Regarded as a piece of mechanism, an electro-magnet may be regarded as an apparatus for producing a mechanical action at a place distant from the operator who controls it; the means of communication from the operator to the distant point where the electro-magnet is being the electric wire. The uses of electro-magnets may, however, be divided into two main divisions. For certain purposes an electro-magnet is required merely for obtaining temporary adhesion or lifting power. It attaches itself to an armature, and cannot be detached so long as the exciting current is maintained, except by the application of a superior opposing pull. The force which an electro-magnet thus exerts upon an armature of iron, with which it is in direct contact, is always considerably greater than the force with which it can act on an armature at some distance away, and the two cases must be carefully distinguished. *Traction* of an armature in contact, and *attraction* of an armature at a distance, are two different functions. So different, indeed, that it is no exaggeration to say that an electro-magnet designed for the one purpose is unfitted for the other. The question of designing electro-magnets for either of these purposes will occupy a large part of these lectures. The action which an electro-magnet exercises on an armature in its neighbourhood may be of several kinds. If the armature is of soft iron, placed nearly parallel to the polar surfaces, the action is one simply of attraction, irrespective of the polarity of the magnet. If the armature lies oblique to the line of the poles there will be a tendency to turn it round, as well as to attract it; but, again, if the armature is of soft iron the action will be independent of the polarity of the magnet, that is to say, independent of the direction of the exciting current. If, however, the armature be itself a magnet of steel permanently magnetised, then the direction in which it tends to turn, and the amount, or even the sign of the force with which it is attracted, will depend on the polarity of the electro-magnet, that is to say, will depend on the direction in which the exciting current circulates. Hence there arises a difference between the operation of a *non-polarised* and that of a *polarised* apparatus, the latter term being applied to those form in which there is employed a portion—say an armature—to which an initial fixed magnetisation has been imparted. Non-polarised apparatus is in all cases independent of the direction of the current. Another class of uses served by electro-magnets is the production of rapid vibrations. These are employed in the mechanism of electric trembling bells, in the automatic breaks of induction coils, in electrically-driven tuning-forks such as are employed for chronographic purposes, and in the instruments used in harmonic telegraphy. Special constructions of electro-magnet are appropriate to special purposes such as these. The adaptation of electro-magnets for the special end of responding to rapidly alternating currents is a closely kindred matter. Lastly, there are certain applications of the electro-magnet, notably in the construction of some forms of arc lamp, for which it is specially sought to obtain an equal, or approximately equal, pull over a definite range of motion. This use necessitates special designs.

The Properties of Iron.

A knowledge of the magnetic properties of iron of different kinds is absolutely fundamental to the theory and design of electro-magnets. No excuse is therefore necessary for treating this matter with some fulness. In all modern treatises of magnetism the usual terms are defined and explained. Magnetism, which was formerly treated of as though it were something distributed over the end-surfaces of magnets, is now known to be a phenomenon of internal structure; and the appropriate mode of considering it is to treat the magnetic materials, iron and the like, as being capable of acting as good conductors of the magnetic lines; in other words, as possessing great magnetic permeability. The precise notion now attached to this word is that of a numerical coefficient. Suppose a magnetic force—due, let us say, to the circulation of an electric current in a surrounding coil—were to act on a space occupied by air; there would result a certain number of magnetic lines in that space. In fact, the intensity of the magnetic force, symbolised by the letter H, is often expressed by saying that it would produce H magnetic lines per square centimetre in air. Now, owing to the superior magnetic power of iron, if the space subjected to this magnetic force were filled with iron instead of air, there would be produced a larger number of magnetic lines per square centimetre. This larger number in the iron expresses the degree of magnetisation in the iron; it is symbolised[45] by the letter B. The ratio of B to H expresses the permeability of the material. The usual symbol for permeability is the Greek letter μ. So we may say that B is equal to μ times H. For example, a certain specimen of iron, when subjected to a magnetic force capable of creating, in air, 50 magnetic lines to the square centimetre, was found to be permeated

[45] The following are the various ways of expressing the three definitions:—B, the internal magnetisation; the magnetic induction; the induction; the permeation; the number of lines per square centimetre in the material. H, the magnetising force at a point; the magnetic force at a point; the intensity of the magnetic force; the number of lines per square centimetre that there would be in air. μ, the magnetic permeability; the permeability; the specific conductivity for magnetic lines; the magnetic multiplying power of the material.

Digitized by Google

by no fewer than 16,062 magnetic lines per square centimetre. Dividing the latter figure by the former, gives as the value of the permeability at this stage of the magnetisation 321, or the permeability of the iron is 321 times that of air. The permeability of such non-magnetic materials as silk, cotton, and other insulators, also of brass, copper, and all the non-magnetic metals is taken as 1; being practically the same as that of the air.

This mode of expressing the facts is, however, complicated by the fact of the tendency in all kinds of iron to magnetic saturation. In all kinds of iron the magnetisability of the material

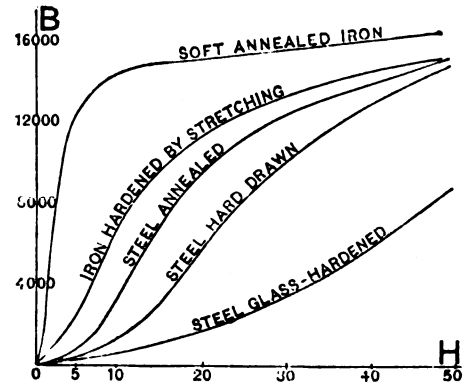

FIG. 14.—Curves of Magnetisation of Different Magnetic Materials.

becomes diminished as the actual magnetisation is pushed further. In other words, when a piece of iron has been magnetised up to a certain degree it becomes, from that degree onward, less permeable to further magnetisation, and though actual saturation is never reached, there is a practical limit beyond which the magnetisation cannot well be pushed. Joule was one of the first to establish this tendency towards magnetic saturation. Modern researches have shown numerically how the permeability diminishes as the magnetisation is pushed to higher stages. The practical limit of the magnetisation, B, in good wrought iron is about 20,000 magnetic lines to the square centimetre, or about 125,000 lines to the square inch; and in cast iron the practical saturation limit is nearly 12,000 lines per square centimetre, or about 70,000 lines per square inch. In designing the electro-magnets, before calculations can be made as to the size of a piece of iron required for the core of a magnet for any particular purpose, it is necessary to know the magnetic properties of that piece of iron; for it is obvious that if the iron be of inferior magnetic permeability, a larger piece of it will be required in order to produce the same magnetic effect as might be produced with a smaller piece of higher permeability. Or, again, the piece having inferior permeability will require to have more copper wire wound on it: for in order to bring up its magnetisation to the required point, it must be subjeted to higher magnetising forces than would be necessary if a piece of higher permeability had been selected.

A convenient mode of studying the magnetic facts respecting any particular brand of iron is to plot on a diagram the curve of magnetisation—*i.e.*, the curve in which the values, plotted horizontally, represent the magnetic force, H, and the values plotted vertically those that correspond to the respective magnetisation, B. In

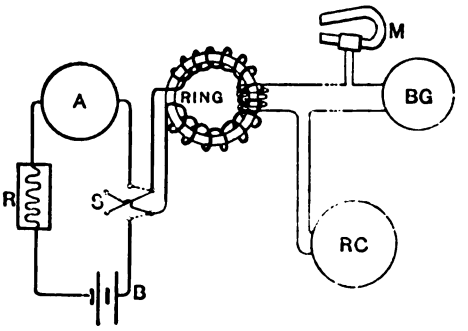

FIG. 15.—Ring Method of Measuring Permeability (Rowland's Arrangement).

Fig. 14, which is modified from the researches of Prof. Ewing, are given five curves relating to soft iron, hardened iron, annealed steel, hard-drawn steel, and glass-hard steel. It will be noticed that all these curves have the same general form. For small values of H the values of B are small, and as H is increased B increases also. Further, the curve rises very suddenly, at least with all the softer sorts of iron, and then bends over and becomes nearly horizontal. When the magnetisation is in the stage below the bend of the curve, the iron is said to be far from the state of saturation.

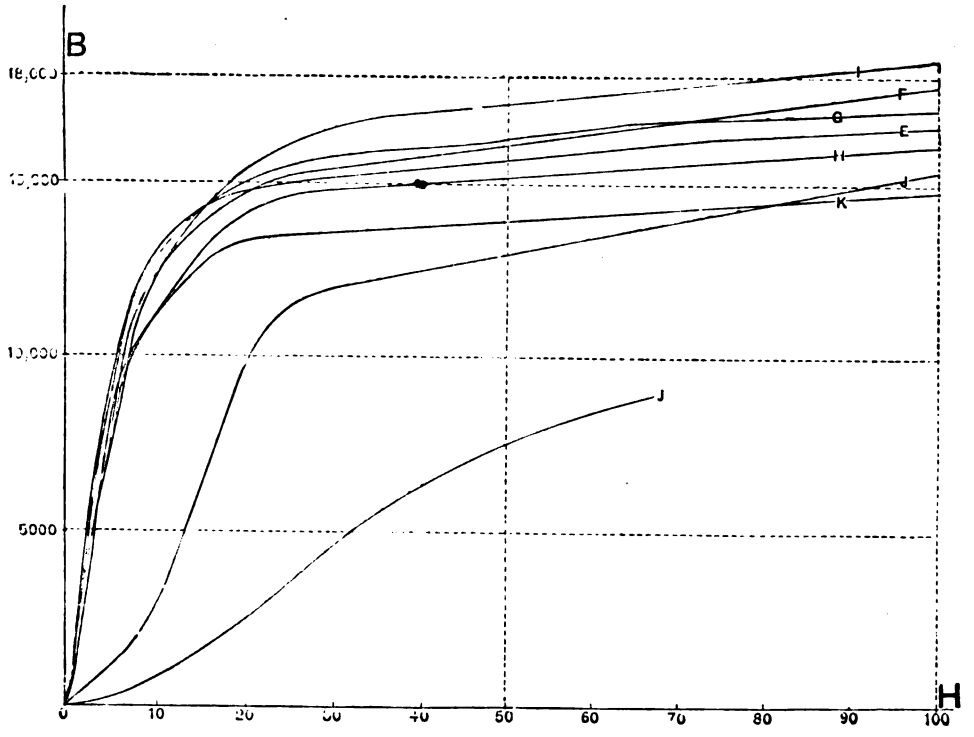

FIG. 16.—Bosanquet's Data of Magnetic Properties of Iron and Steel Rings

But when the magnetisation has been pushed beyond the bend of the curve, the iron is said to be in the stage approaching saturation; because at this stage of magnetisation it requires a large increase in the magnetising force to produce even a very small increase in the magnetisation. It will be noted that for soft wrought-iron the stage of approaching saturation sets in when B has attained the value of about 16,000 lines per square centimetre, or when H has been raised to the value of about 50. As we shall see, it is not economical to push B beyond this limit; or, in other words, it does not pay to use stronger magnetic forces than those of about H = 50.

Methods of Measuring Permeability.

There are four sorts of experimental methods of measuring permeability.

1. *Magnetometric Methods.*—These are due to Müller, and consist in surrounding a bar of the iron in question by a magnetising coil, and observing the deflection its magnetisation produces in a magnetometer.

2. *Balance Methods.*—These methods are a variety of the preceding, a compensating magnet being employed to balance the effect produced by the magnetised iron on the magnetometric needle. Von Feillitzsch used this method, and it has received a more definite application in the magnetic balance of Prof. Hughes. The actual balance is exhibited to-night upon the table, and I have beside me a large number of observations made by students of the Technical College by its means, upon sundry samples of iron and steel. None of these methods are, however, to be compared with those that follow.

3. *Inductive Methods.*—There are several varieties of these, but all depend on the generation of a transient induction-current in an exploring coil which surrounds the specimen of iron, the integral current being proportional to the number of magnetic lines introduced into, or withdrawn from, the circuit of the exploring coil. Three varieties may be mentioned.

(A) Ring Method.—In this method, due to Kirchhoff, the iron under examination is made up into a ring, which is wound with a primary, or exciting coil, and with a secondary, or exploring coil. Determinations on this plan have been made by Stowletow, Rowland, Bosanquet, and Ewing; also by Hopkinson. Rowland's arrangement of the experiment is shown in Fig. 15, in which B is the exciting battery; S, the switch for turning on or reversing the current; R, an adjustable resistance; A, an ampere meter; and BG the ballistic galvanometer, the first swing of which measures the integral induced current. RC is an earth-inductor, or reversing coil, wherewith to calibrate the readings of the galvanometer, and above is an arrangement of a coil and a magnet to assist in bringing the swinging needle to rest between the observations. The exciting coil and the exploring coil are both wound upon the ring; the former is distinguished by being drawn with a thicker line. The usual mode of procedure is to begin with a feeble exciting current, which is suddenly reversed, and then reversed back. The current is then increased, reversed, and re-reversed; and so on until the strongest available points are reached. The values of the magnetising force H are calculated from the observed value of the current by the following rule. If the strength of the current, as measured by the ampere meter be i, the number of spires of the exciting coil S, and the length, in centimetres, of the coil (*i.e.*, the mean circumference of the ring) be l, then H is given by the formula:—

$$H = \frac{4\pi}{10} \times \frac{S\,i}{l} = 1{\cdot}2566 \times \frac{S\,i}{l}.$$

Bosanquet, applying this method to a number of iron rings, obtained some important results. In Fig. 16 are plotted out the values of H and B for seven rings. One of these, marked J, was of cast steel, and was examined both when soft and afterwards when hardened. Another, marked I, was of the best Lowmoor iron. Five were of Crown iron, of different sizes. They were marked for distinction with the letters G, E, F, H, K. In the accompanying table are set down the values of B at different stages of the magnetisation.

Table *of Values of* B *in Five Crown Iron Rings.*

Name.	G.	E.	F.	H.	K.
Mean diameter.	21·5cm.	10·035cm	22·1cm.	10·735cm	22·725cm
Bar thickness.	2·535	1·298	1·292	0·7137	0·7544
Magnetising Force.					
0·2	126	73	62	82	85
0·5	377	270	224	208	214
1	1·449	1,293	840	675	885
2	4·564	3·952	3,533	2,777	2,417

(To be continued.)

Titmaning.—The village of Titmaning, in Bavaria, of 2,000 inhabitants, is about to adopt the electric light. The necessary power will be derived from a fall on the Schlossbach.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September* 12, 1890.

The First Westinghouse Electric Railroad.—The first Westinghouse electric railroad was started a short time since in Lansing, Michigan, and has been in most successful operation. The Westinghouse Company has been so quiet about the matter that the appearance of the first working road was awaited with a great deal of interest, and some description of it may not be without interest. The Westinghouse motor car resembles as nearly as possible, to outward appearance, the Sprague and Thomson-Houston car now in use. Like them it uses an overhead system with under-running wheel trolley, precisely similar in its general characteristics to those already in use. The motors are centred on the axles and rest at the free ends on compression springs supported by the truck. There are two motors used on each car, each of 15 horse-power, and operating on a standard railway voltage of 500 volts. The mechanical construction of the motors is admirable. Especially appreciated by practical electricians is a device that admits of very ready removal of the armature by withdrawing bolts. The field-magnets are so hinged that they then open out to permit ready access to field coils and armature. The general appearance of the motor is very similar to that of the Thomson-Houston motor now in extensive use. The motors are inclosed in sheet-iron cases, and the driving gear connecting with the car axle runs in oil tight boxes partially filled with oil, so that there is most thorough lubrication, and much of the objectionable noise and wear is obviated. The motors are controlled by a switch handle moving over a dial, and the method of regulation is a combination of that used in the Sprague and Thomson-Houston systems. Three resistance coils, exterior to the motor, are used, and besides that, the fields have two sets of coils, either of which can be employed. In starting the car the three resistances are cut out, one after another, and then the fields thrown into action successively. This arrangement avoids the complication of the Sprague switchbox and some of the inherent difficulties of a complicated rheostat like that in use on the Thomson-Houston system. The details of winding and construction of the motors are, however, as yet, kept secret, and great care is taken to keep outsiders from getting much information as to the system. The overhead wire arrangement includes a bare trolley wire, suspended by the usual methods, and much the same method of feeding as is employed on the Sprague system. The operation of the Lansing Road has been very successful, in spite of a rather poor roadbed; and a single motor car, drawing one or two trailers, has repeatedly taken 250 people up a long 5 per cent. grade.

An Edison Electric Traction Motor.—Mr. Edison has recently taken the field with a new form of motor for traction work, or, more strictly speaking, a new method of regulation. He employs two motors driving the axle or axles of the car through their differential action upon an epicyclic gear. The motors are shunt wound, and extreme nicety of speed regulation is obtained, while under some conditions one of the motors will be acting as a dynamo, and hence minimising the losses of the system. The plan is not yet in practical use, but the patents have been recently issued.

The National Telephone Convention at Detroit.—The National Telephone Convention at Detroit has just closed after a successful meeting. A number of Papers dealing with the details of exchange construction and management were read. The most striking feature of the Convention, however, was the growing feeling in favour of complete metallic circuits. At the last meeting there was most bitter opposition to an open discussion of the metallic circuit question; but a year's experience seems to have done its work, and now it is freely admitted that the more modern system must come into very extensive use, and that the changes involved in working an exchange through metallic circuits are not nearly as formidable as were feared at an earlier stage of the art.

Electrical Nomenclature.—The American Institute of Electrical Engineers holds the first of its autumn meetings on next

Digitized by Google

Tuesday, and the prominent question that will come up for discussion is the proposed nomenclature of certain electrical units. The Henry will hold a prominent place in the discussion, and some formal action will probably be taken by the Institute on its adoption. There is a rather general feeling, however, that in choosing a practical unit of self-induction, it should be made not to equal the earth-quadrant, but some convenient sub-multiple of it. American electricians do not take very kindly to Dr. Fleming's suggestion of abbreviating the aforesaid unit to "Hen;" it is considered somewhat too suggestive.

CORRESPONDENCE.

THE MAGNETISATION OF STEEL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your abstract of the discussion on Mr. Preece's Paper on "The Magnetisation of Steel," read at the Leeds meeting of the British Association, Sir William Thomson is reported to have stated that the results obtained by Mr. Preece are enormously better than had previously been deemed attainable. I do not remember whether Sir William Thomson actually made that observation, and fancy that some remarks he made as to attainable magnetisations must have been misunderstood. In any case, much higher inductions have been obtained in previous experiments than any of those given in Mr. Preece's tables, although these are very valuable as giving data for a large number of different kinds of steel.

A considerable number of experiments on this subject were made by my brother Prof. T. Gray, and their results are given in two papers by him in the *Philosophical Magazine* for November, 1878, and December, 1885. An abstract of the latter paper is contained in my little book on "Electrical Measurements." In the first paper are results of experiments made with steel at different tempers, produced by quenching in water and oil, in the second magnetic moments of magnets having different lengths, but all nearly the same diameter.

The magnets used by my brother were made for use as deflectors for determinations of **H**, and were naturally much smaller than those experimented on by Mr. Preece. Four cylindrical magnets, each 8cms. long and ·25cms. in diameter, had an average magnetic moment of 52 (C.-G.-S.) per gramme, or an induction of about 5,700, while one, 3cms. long and of the same diameter, had an induction of about 3,300. I do not think that bringing the length of the last down to 2cms., which would have given about the same ratio of length to thickness as in Mr. Preece's magnets, would have reduced the induction so low as his highest number, 2,218.

Besides calling attention to these experiments by my brother, perhaps I may be pardoned for giving here just a few particulars regarding the experiments referred to by Sir William Thomson, which were carried out by myself some years ago under his direction. Several different kinds of steel were experimented on, and the results for steels by different makers, but of very closely the same composition, were widely different. The best result obtained was a magnetisation of about 100 per gramme, that is a magnetisation intensity of about 780 obtained in steel bars 60cms. long, and of square section about 1cm. in side. This, so far from being 10 per cent. or more below the inductions which Mr. Preece's experiments have shown to be obtainable, as the report of the discussion would naturally imply, is an induction of about 10,000 in a plain straight bar of glass-hard steel, a magnetisation approximating to that obtained by Prof. Perry in his horse-shoe magnet, with its magnetic circuit completed by a special armature.

The inductions for other steels ranged from about 3,000 upwards, with the exception of one particular tool steel, said to be of high quality, which was hardly magnetisable at all, or, at any rate, had scarcely any retentiveness. It was quite easy with the most magnetisable steel to obtain inductions of about 8,000, which were retained practically undiminished for long periods of time.

I should like also to call attention to an interesting Paper in the *Phil. Mag* for May, 1887, on "The Effect of Percussion and Annealing on the Magnetic Moments of Steel Magnets," by Mr. William Brown (formerly Thomson Experimental Scholar in the University of Glasgow, now Demonstrator of Physics in the Royal College of Science, Dublin). Mr. Brown used cylindrical magnets having lengths from 33 times to 37 times their diameters, and obtained inductions at glass-hard temper varying from 6,000 to 7,000. He showed that heating in an oil bath at a high temperature and cooling in air, enormously increases the loss of magnetic moment by percussion. This loss is very small when the magnet is glass-hard.

I should like to say, finally, that the most convenient expression of results, such as those above referred to, seems to me to be the intensity of magnetisation as ordinarily defined, that is, the magnetic moment per cubic centimetre, and not 4π times this quantity, or the "induction," which is favoured by so many experimenters, and which I have used above for the sake of comparison.—Yours truly,

A. GRAY.

University College of North Wales,
Bangor, September, 1890.

COMPARING CAPACITIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to H. Casenhem's letter in last week's *Electrician*, the true capacity of the Porthcurnow-Gibraltar cable was taken, I believe, by Mr. Lilley to be that obtained by summing up the factory tests of the cable when in short lengths.

In my note on Saunders' Capacity Key, Figs. 3 and 6 are reversed. Fig. 6 shows the connections when both levers are *up*, not Fig. 3. On depressing the "discharge" lever, the connections become first, as shown in Fig. 3; then the condenser is put to earth, and immediately afterwards the galvanometer is inserted between the junction of the cable and condenser and earth giving the throw, α, from which the correction, v_2, has to be deduced. To obtain v_2 from α, proceed with both levers of the key *up*, and observe the throw on charging the cable and condenser together from a point on the slides a few studs from the zero end, as explained in the note.

It is assumed in the formula for this test that the whole of the conductor of the cable is at the same potential, viz., that of the junction of the cable and the condenser at the moment when the balance was obtained. Sufficient time to charge up the cable fully must, therefore, be allowed to elapse after the application of the battery before commencing to balance. Before the formula can be applied to the case of a cable of very low insulation, the average potential of the conductor will have to be calculated from knowledge of the conductor resistance and the insulation resistance at the time the balance was observed.

A comparison near enough for most purposes may be arrived at without wasting time in getting an exact balance by simply closing the galvanometer circuit (see Fig. 5) until no current is indicated (*i.e.*, until the potential of the junction of the cable and the condenser becomes equal to that of the point of application on the slides), and then afterwards depressing the "discharge" lever as before to obtain the correction, α. A high resistance, a megohm or so, in the galvanometer circuit facilitates the balancing immensely.

With an electrometer, the test is a perfect *null* method.—Yours, &c.,

ALEX. MUIRHEAD.

Laboratory: Cowley-street, Westminster, S.W.,

THE "STOCKPORT" GAS ENGINE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Our attention has been drawn to the very interesting and practical paper, which appeared in your issues of the 1st and 22nd August last, on the "Lighting of London Theatres by Electricity," by Mr. Ed. C. De Segundo, and in which reference was made to two of our 16-horse nominal "Stockport" gas engines as supplying the power for the installation at the Lyric Theatre.

Digitized by Google

With your permission, there are one or two points in that reference which we would wish to correct. As regards the consumption of gas by these engines, the "32 cubic feet per indicated horse-power," as mentioned, should be "*32 cubic feet per 'electrical' horse-power.*" This should be equivalent to 21 cubic feet of gas consumed per indicated horse-power.

The items representing "maintenance and wages" also, in the absence of explanation, appear excessive. This explanation may be found within the paper, where it says that "these engines run from 18 to 20 hours a day regularly." All practical men will quite understand that such forced work as here represented is the most expensive of all work. Besides, the circumstances under which these engines were erected were exceptional. They were constructed, erected, and running within four weeks from the date of the order, and, owing to this extraordinary pressure of time, they were not adjusted at the works in the usual way, but were made to work straight off from starting, *24 hours a day*, and continue to work at this pressure for many months with scarce a sufficient intermission for cleaning, to say nothing of adjustment.

Hoping you will insert these few lines for explanation, which we think are due to us—Yours, &c.,

TINSLEY WATERHOUSE, Secretary,
J. E. H. Andrew and Company (Limited).

TRADE NOTES AND NOTICES.

SALE BY AUCTION.—Messrs. Furber, Price, and Furber announce in our advertisement columns that they will sell by auction, at 42, Eagle-street, Red Lion-street, W.C., on Tuesday next, September 30th, a valuable electrical generating plant (Perreur-Lloyd's patent system), including reservoirs, primary and secondary batteries, vats, incandescent lamps, shades, carbons, porous cells, electrometers, wires, portable forge, vertical boiler, and other effects. Further particulars and catalogues may be obtained of the auctioneers, at their offices, Warwick-court, Gray's Inn, London, W.C.

MESSRS. GILL AND CO.—This firm have taken commodious offices in Parliament-street, Westminster, close to the Houses of Parliament.

BELL'S ASBESTOS COMPANY (LIMITED).—We are in receipt of an illustrated catalogue issued by this firm, which contains 66 large octavo pages of particulars and prices of the well-known manufactures of this firm, and includes a number of testimonials from firms using them. The catalogue is well got up, and is very comprehensive.

MESSRS. W. H. WILLCOX AND CO.—This firm have recently issued a new catalogue, descriptive of machine belting, fire engine and suction hoses, laces, belting fasteners, copper rivets, &c. The catalogue is well illustrated, and contains a mass of useful information for the electrical and engineering trades.

JAMAICA INDUSTRIAL AND MANUFACTURING EXHIBITION.—The contract for lighting this Exhibition has been secured by Messrs. Nicholson and Jennings, of 7, Westminster Chambers, Victoria-street, S.W., who have tendered in accordance with the specification prepared by Mr. Kenneth Mackenzie, of 15, Great George-street, Westminster, who is acting as consulting engineer to the Commissioners. The Exhibition will be opened in January next, and will remain so for at least three months, and being the first Exhibition held in that part of the world, it is naturally creating considerable attention. The contract includes motive power and plant for an equivalent of 70 arc lamps, and 650 glow lamps, or equal to an electrical output of 74,000 watts; and since the buildings which are being erected will be spacious and of an elegant design, the effect both in the interior of the Exhibition as well as the ornamental grounds will be very striking. The contract also includes two electric motors of 20 horse-power each for running some of the counter shafting supplying power to exhibitors. The West Indies are at present certainly, as far as regards the enterprise of electrical contractors, altogether untouched; since the greater part of whatever has been done there up to now has been supplied from the United States, and it is thought that a considerable impetus will be given to trade by the fact of this Exhibition being organised by the Government of the largest English colony there. We understand that Mr. Mackenzie will be glad to give information and particulars to any electrical firms who might feel inclined to utilise the advantages which this Exhibition will offer for opening up a trade in the West Indian Islands and Central America.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

COMPANIES' MEETINGS & REPORTS.

The General Electric Power and Traction Company (Limited).

The statutory general meeting of this Company was held at Winchester House, Old Broad-street, on the 23rd inst., under the presidency of Viscount Bury.

The CHAIRMAN said: The task before me is purely a formal one, and I need not detain you at any length. You are aware that a statutory meeting such as this is only held for the purpose under the Act of giving any shareholder an opportunity of satisfying himself, by personal communication with the Directors at a short period after the operations of the Company have begun, that all the requirements of the various Acts have been complied with, that everything is regular and in due order, and that the Company is starting on its way with every legal requirement satisfied and complied with. I am happy to tell you that we are in complete order in that respect. There are no accounts before us. Naturally at this very early period of the conduct of

the company, it would be entirely premature either to talk about what had been done or about the immediate future. The time will shortly arrive when we shall have more to say on that subject. All I can tell you is that the Company, which began as a going concern, is now proceeding in a satisfactory manner, that we have been energetically and constantly occupied with looking into the various details of our factory, our mining plant, our launches, and our electric cars, which are all in their several departments in a satisfaetory position. Our electrical works have been placed under the management of Mr. A. T. Snell, who is well known as a most efficient and successful engineer, and who occupied a high position under Mr. Immisch, when he was manager at the Immisch works. We are very satisfactorily developing our mining plant, and we have orders—and very considerable orders—in that direction. We have also most satisfactory inquiries from various departments of electric traction, especially those devoted to tramways. In fact, we have a future before us, which, as I am not addicted to strong language, I will not call brilliant, but which is satisfactory to the Directors and to myself. I do not think I need add anything more. Of course, the object for which we are met is that the Directors and the shareholders should be placed in communication at an early period, as I said, of the history of the Company; and if any question occurs to any shareholder, I beg that he will now put it. I have only to repeat that the legal formalities consequent on the inauguration of the Company have all been complied with, and I have merely to announce that the statutory meeting is now being held, and to ask whether any shareholder has anything to say.

A SHAREHOLDER said he did not know whether the point was quite before them, but he thought that some statement as to how far the shares had been taken up might be furnished to them. They did not know—at least, he did not know—what the position of matters was in that respect.

The CHAIRMAN: That is not pertinent to a statutory meeting, nor do I think it is a regular question.

The SHAREHOLDER observed that he did not wish to press it.

The CHAIRMAN: I am particularly anxious not to go beyond the usual routine, as it is not advisable to do so; but I do not think that there can be any objection to my stating that, with the exception of £8,000, the whole of the shares have been allotted.

A SHAREHOLDER: Including the ordinary?

The CHAIRMAN: The ordinary and Preference. It may be satisfactory if I tell you that the whole of the proceeds of the Preference shares will be devoted to the working of the Company. I need not detain you any longer, I think, and the meeting is now prorogued.

The proceedings then terminated.

Direct Spanish Telegraph Company (Limited).

The following is the report and accounts of the Directors for the half-year ended June 30, 1890, to be presented at the general meeting of shareholders, to be held at Winchester House, E.C., on Tuesday, the 30th inst., at 2 o'clock.

The accounts show, after providing for debenture interest, a balance to the credit of profit and loss of £7,199. 17s. 2d. The traffic receipts have again been satisfactory, and show an increase of £2,057. 1s. 8d., as compared with the corresponding half-year of 1889. The working expenses are £391. 0s. 8d. in excess of those for the corresponding period of last year.

The Company's cables and the land lines in connection with them have continued in good working order throughout the half-year.

The Company was represented at the International Telegraph Conference held at Paris in May last, and had, as well as other Telegraph Companies and Administrations, to submit to reductions of tariff which will affect the Company's revenue to some extent. These reductions do not come into force until July 1, 1891.

An extraordinary general meeting will take place immediately after the ordinary general meeting, in accordance with the following resolution, which was unanimously adopted by the shareholders at the last ordinary general meeting:—"That in the opinion of this meeting the Directors' remuneration should be now increased beyond the sum of £400 per annum, and that in view of their declared intention not to avail themselves of their rights under the 71st of the Company's Articles of Association as it now stands, the Directors be, and are hereby requested to give notice of a special resolution being brought forward at the next half-yearly meeting for altering Article 71 so as to increase their remuneration to £600, or otherwise as may from time to time be voted in general meeting."

Of the balance of profit and loss, £2,500 have been put to the reserve fund, which now amounts to £20,258. 6s. 6d., leaving a balance of £4,699 17s. 2d. Out of this amount the Directors recommend the payment of the dividend at the rate of 10 per cent. per annum on the Preference Shares, and a dividend at the rate of 6 per cent. per annum (free of income-tax) on the ordinary shares. This will admit of a sum of £1,685. 12s. 9d. being carried to the "Contingencies Account," which the Directors consider it indispensable to maintain, in view of fluctuations of traffic, &c., the reserve fund applying solely to the renewal of the cables.

The dividend warrants will be issued on October 1st, 1890.

NEW COMPANIES REGISTERED.

ELECTRICAL INVENTIONS COMPANY (LIMITED).—Registered by A. W. Riscon, 10, Austinfriars, E.C., with a capital of £35,000, in £1 shares. Objects: To acquire by original application, assignment, licence or otherwise, and to develop, promote the use of, work, buy, sell, grant licences in respect of, assign, and deal with patents for electrical inventions and improvements, and electrical instruments and apparatus of every description, whether patented, secret or not, including any interest or partial right in or to the same, either in the British Empire or elsewhere.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 19th amounted to £1,640.

EASTERN TELEGRAPH COMPANY (LIMITED).—This Company announce the payment on October 14th next, of interest of 3s. per share, less income-tax, being at the rate of 6 per cent. per annum, on the Preference Shares of the Company, for the quarter ending September 30th, and the usual interim dividend of 2s. 6d. per share on the ordinary shares, free of income-tax, in respect of profits for the quarter ended June 30th. The register of transfers will be closed from October 7th to 14th, both days inclusive.

EASTERN EXTENSION TELEGRAPH COMPANY.—An interim dividend for the quarter ended June 30th of 2s. 6d. per share has been declared by the directors of the above Company, payable on the 15th proximo.

GLOBE TELEGRAPH AND TRUST COMPANY.—The Directors of this Company have declared an interim dividend of 1s. 9d. per share, payable on the 18th proximo.

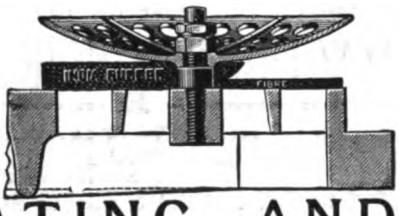
STOCK EXCHANGE.—The Committee have appointed this day (Friday) the 26th September, a special settling day in the shares of Elmore's Wire Manufacturing Company (Limited); and have ordered this security and the vendors' shares in Elmore's Patent Copper Depositing Company (Limited) to be quoted in the Official List. Application has been made to the Committee to appoint a settling day in, and to grant a quotation to, the International Okonite Company (Limited)—Preference shares Nos. 5,667 to 17,000, Ordinary shares Nos. 22,667 to 34,000, and £517,000 Six per Cent. Debentures; and Woodhouse and Rawson United (Limited)—Ordinary shares Nos. 1 to 31,416, and Preference shares, Nos. 40,001 to 54,285.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ending September 19, 1890, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,627.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated receipts of this Company for the half-month ended September 15th, amounted to £2,384, compared with £2,035 in the corresponding period last year, an increase of £349.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept. 1885.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 646.—Vol. XXV. FRIDAY, OCTOBER 3, 1890. Price Fourpence.

NOTES.

The Convention of the National Telephone Exchange Association of the United States, attended by more than a hundred members, is an indication of the great differences which exist not only between the telephonic industries of that country and of our own, but of the dissimilar relations which prevail between the companies and officials of the American telephone systems and of those of England. At present such a Convention is hardly possible with us; nor if such a meeting could be held, would the Papers and discussions be of so frank and practical a character. There are some who would attribute this to the effects of our patent laws, and others would explain it rather by the selfish traits which are developed in those who have to deal with monopolies. Another factor is the relative areas of the two countries, which largely modify the bitterness of competing interests. The veil which hangs round the management of our telephone exchanges is seldom withdrawn by the reading of a Paper on the practical working or on the comparative merits of different methods of construction or of arrangement. It is true that a Paper of that kind would not be of such general interest as most Papers which are presented to our scientific institutions; and it must be admitted that the deliberations of the Congress at Detroit were not of a deeply scientific character. There is reason in the roasting of eggs, but there is singularly little science in the construction, and still less in the practical management of a telephone system, though there is a great field for ingenious switches and such devices.

The paradise of the telephone manager, according to the opinions expressed in the Papers and in the discussions, will be a dustless room fitted with a rustless switch-board. Those who decry our London smoke and fogs, and imagine that the clear, dry air which we hear so much about is always present in American cities, will be surprised to hear of the difficulties of keeping out dirt and damp from the contacts; and those who are not familiar with telephone switch-boards will learn with interest that carpets, curtains, open windows, and even fluffy dresses are inimical to the satisfactory working of a switch-board. As a contrast to our recent note on the wages of our telephone operators, it is pleasant to read that "on the same floor as the operating room a cloak room and lunch room should be provided. The lunch room should be equipped with tea and coffee urns, lunch table, &c. By providing such conveniences for the operators a better class of women become available, and exchange service correspondingly improved."

Notwithstanding the great care with which the action of the telephone has been studied, little is known as to the character of the movements of the membrane. The most successful attempt in this direction appears to have been made by Prof. Frölich, with the aid of manometric flames; and we gather from a Paper read before the Montefiore Technical Institute that his method of analysis is susceptible of several useful applications. The beautiful experiments in sound, in which vibrations are investigated by Kœnig's manometric flames, are well known, and have the characteristic that the motions of the membrane are indicated without the need of attaching any substance whose inertia would alter the vibrations under test. Many of the investigations made, during the last two or three years, on the exact mode of variation of alternating currents, have had the fault that the inertia of the moving parts of the testing apparatus has rendered doubtful the meaning of the results obtained. By making the telephone membrane one side of the manometric capsule this difficulty is overcome, as the resistance of the air or gas may be neglected. The form of the pulsating flame is photographed, the clearest results being obtained when the gas burnt consists of a mixture of bisulphide of carbon and protoxide of nitrogen.

Among the applications suggested are, the determination of the intensity of a current during its variable period of the charge and discharge of a condenser, the mode of variation of alternate currents, and the measurement of short intervals of time. It has even been attempted to measure the velocity of a bullet in the interior of firearms, without placing any obstacle in the path of the shot, as occurs in the chronographs of Siemens, Sebert, and others. The bullet contains a soft iron core; the barrel of the gun is surrounded along its entire length by a primary magnetising solenoid, and also at intervals with secondary coils connected with the telephone. The movement of the lines of force, as the bullet proceeds, excites currents in the secondary coils which affect both the telephone and the pulsating flame, and from the form of the latter the velocity of the bullet can be calculated. Good results have not yet been obtained because it is impracticable to obtain the images sharply defined; but the method is remarkably ingenious.

The question has more than once been asked: Why should the ohm be described by the dimensions of a column of mercury when such a resistance would be so difficult to construct, so troublesome to set up, and so inconvenient to use compared

Digitized by Google

with a length of wire? An answer will be found in the consideration of the report of Mr. GLAZEBROOK "On Variations in the B. A. Standards," and in Mr. FITZPATRICK'S Paper on "The Specific Resistance of Copper." It was fully recognised, when the first B. A. standards were made, that changes might occur in them; and, as our readers are aware, they are from time to time compared with great care. It has been suggested that the most serious alteration which has taken place is due to the severe change of temperature to which the coils are subjected when they are brought down to freezing point. The wire being embedded in paraffin wax, the contraction due to the low temperature may give rise to a mechanical strain, and on this account it would appear advisable to make use of the very sensitive and accurate thermometric methods which we now have at our disposal, and to carry out the tests with a smaller range of temperature, thus avoiding the conveniently constant, but rather severe temperature of freezing. The modified form of coil suggested by Dr. FLEMING does not appear to meet with the approval of the B. A. Committee, since those who send in resistances for certification are invited to adhere to the old B. A. dimensions. Dr. FLEMING'S pattern offers several important advantages both as regards the state of the wire and its insulation. But even if the coil be constructed in the most approved shape, and be immersed in liquid paraffin instead of paraffin wax, there is still a considerable difficulty in the choice of a material of which the wire should be composed.

PLATINUM-SILVER, and similar alloys are convenient in having a small temperature correction, and an alloy has indeed been suggested which had a negative or even no temperature error whatever. One disadvantage of such alloys is that not only is it impossible to reproduce the exact mixture, but no two pieces cut from the same coil have the same properties. The production of a wire of any ductile pure metal, even if the temperature coefficient were considerable, would be an easy matter if only there were some method of relying on the similarity of different specimens. Given a standard metre, it would not be a very difficult or expensive matter for an experimenter in a distant colony to construct an accurate litre measure from which a kilogramme of water could be used as a practical standard of mass with an accuracy sufficient for all ordinary engineering purposes; but no such method is available whereby he can reproduce an ohm in the form of a wire. The "pure copper" of MATTHESON, which was for so many years the standard, became a merely arbitrary name when electrolytic copper was produced of "102 per cent. conductivity"; and the term now conveys less meaning than ever, when it is found that deposited copper is neither homogeneous or pure, and recourse must be had to chemical methods of the production of a metal which will perhaps be unsuitable for drawing into a wire, since the act of annealing it is liable to produce a chemical change.

IN accordance with the instructions of the Executive Committee of the Manchester Steam Users' Association, a series of experiments have been carried out by Mr. LAVINGTON E. FLETCHER, their chief engineer, to ascertain the result of injecting feed-water into a boiler when short of water, and with fires burning. These experiments, as may be readily understood, involved no little danger; but the results are very valuable, although they may not all be applicable in their present form to high-pressure boilers. Their principal object was to prove that the common idea that if feed-water be injected when the water in the boiler has fallen so low that the crown of the furnace is red-hot, a sudden and uncontrollable steam pressure will be generated which will blow the shell to pieces. The previous experience of the Association has been that explosions from shortness of water are rare, and that with internally fired boilers they are not very destructive. The furnace crown is rent, but the shell is uninjured, so that unless the attendant is standing directly in front of the furnace in a line with the rush of steam and water, but little injury need occur. Fatal accidents have taken place when attendants have discovered that the water was low, and were engaged in drawing the fire.

A FULL-SIZED mill boiler of the Lancashire type was laid down by the Committee on an open piece of ground, suitable barricades being erected, behind which were supplementary water gauges, pressure gauge, and indicators, showing movements of the furnace crowns. After numerous experiments, the red-hot state of the furnace crowns was indicated to the observers by the fusion of a zinc disc screwed to the plate, and connected with a wire strained by a counterpoise. This took place in some cases about 20 minutes after the water had been brought down to the level of the furnace crowns. The feed was turned on either through an ordinary dispersion pipe, or through one which was specially arranged to make the test more severe, by throwing the water directly on the hot plates. Not only was there no sudden rise of pressure, but on the contrary, the pressure at once began to fall in those experiments in which the safety valves were blowing, and even when these were fixed, and all the steam bottled up, the rise was by no means sudden or serious. The report, which contains several other results of great interest to engineers, does much credit to the Association, whose careful inspection of boilers insured by them, and whose readiness to give advice and information to all steam users, are so highly appreciated by those who have had dealings with them.

THE statements of our American correspondent this week with regard to some of the recent electric light accidents in the States bear out, what is indeed the general belief amongst those most competent to judge, namely, that these lamentable accidents are for the most part either grossly exaggerated, or due to the carelessness of the unfortunate victims.

Milan.—It is proposed to place a powerful projector at the top of the highest tower of Milan Cathedral.

Personal.—Mr. A. Grundy has retired from the firm of Baily and Grundy, and has joined the staff of the Gülcher Company.

The Martin Bi-Metallic Wire.—The Telegraph Administrations of Greece and Sweden have adopted the Martin bi-metallic wire for telegraph and telephone purposes.

Digitized by Google

The International Okonite Company (Limited).—Notice is given that the statutory general meeting of the members of this Company will be held on Thursday, the 9th inst., at the Cannon-street Hotel, E.C., at 12 o'clock noon, for the transaction of the general business of the Company.

Worcester.—Mr. Pritchett, of Oxford-street, has been appointed to report as to the probable initial cost of providing and the subsequent expense of maintaining electric lighting works in Worcester.

The Florence-Fiesole Electric Tramway.—Telegrams from Florence state that, such is the state of public feeling, owing to the recent accident, that it is thought the electric cars will have to temporarily stop running.

Zurich.—At the last meeting of the Town Council, permission was given for the proposed enlargement of the Town Waterworks in connection with the supplying of the power necessary to light the public streets by electricity.

Lectures on Electricity.—Mr. W. Perren Maycock is now delivering courses of lectures on the theory and practice of electricity at the Pitlake Institute, Croydon, the Whitgift Grammar School, and the Merton College for Ladies.

Woolwich.—At the last meeting of the Vestry, Mr. Green moved, pursuant to notice, that the lighting of the Woolwich area by the electric light should be in the hands of the Local Authority. The motion was rejected by seven votes to four.

Society of Engineers.—The next ordinary meeting of this Society will be held at the Town Hall, Westminster, on Monday, October 6th, at 7:30 p.m., when a Paper will be read on "Sewer Ventilation," by Mr. W. Santo Crimp, Assoc.M.Inst.C.E., F.G.S.

Electric Traction.—Experiments with an accumulator car undertaken by Messrs. Hostmann and Co., of Hanover, in conjunction with the Oerlikon Company, on the line of railway, 20 miles long, connecting Hildburghausen, Heldberg, and Friedrichshall, have been satisfactory.

The Production of Oxygen (A Correction).—On p. 571 of our last issue we stated that M. Schemer-Kestner estimated that about 36 francs' worth of coal was used in producing one kilogramme of oxygen by the electrolysis of water. This figure obviously should have been *·36 francs' worth.*

Lewes.—A public meeting of the Lewes ratepayers was held in the Corn Exchange on Wednesday evening to consider the question of improving the lighting of the public streets. No decision was come to, and the meeting adjourned for a fortnight in order to give the ratepayers time to think the matter over.

Telephonic Extensions.—On Tuesday last a further extension of the system of the National Telephone Company was marked by the opening of telephonic communication between Birmingham and Stafford. At Stafford, after the line had been formally declared open, vocal and instrumental music was transmitted from London.

Godalming.—The Electric Lighting Committee of the Godalming Town Council have reported that in their opinion the time has arrived when the electric light might be safely adopted, if thought desirable, on financial grounds. A canvass of the town will be made to see how many are inclined to use electricity for private lighting.

Magnetic Charts.—M. Th. Moureaux, of the Saint-Maur Observatory, who is engaged in much the same work with regard to France as is being carried on in this country by Profs. Rücker and Thorpe, recently called attention in the *Journal de Chimie et de Physique* to the anomalous behaviour of the isogonic line passing through Hazebrouck and Clermont. This line, it seems, deviates from its proper path to run through Paris, and only regains its normal direction near Chartres.

Technical Education in Austria.—The governing body of the Technologisches Gewerbe Museum of Vienna has decided to institute an electro-technical school, where a four years' theoretical and practical course will be given. The course is intended for youths not less than 14 years of age who are desirous of qualifying for the higher ranks of working electricians. It is anticipated that the school will be opened during the present autumn.

Chester.—At the annual conversazione of the Chester Society of Natural Science and Literature, which took place at the Town Hall last week, the Council Chamber, which was devoted to a microscopical exhibition, was lit by the electric light. More interesting still, however, the microscopes themselves were illuminated by incandescent lamps. The temporary plant was lent by the Manchester Edison-Swan Company. The work of fitting up the installation was done by Messrs. Fawcus and Cowan.

The Glasgow Tramway System.—As we stated in our issue of July 4th there is a probability that the Glasgow tramway system, which is owned by the Corporation, will at the expiration of the present lease (July 1, 1894) be actually worked by the municipality itself, and electric traction seems in that case likely to be adopted. How extensive the Glasgow system is may be seen by the fact that the cars run something like 4,000,000 miles per annum, and carry over 40,000,000 passengers.

Insulation Formula for Cables carrying High-Pressure Currents.—In a recent issue of *La Lumière Electrique*, M. Jacquin gives the following formula for the insulation resistance of cables carrying high-pressure currents :—$M = \rho \frac{1}{E}$, in which ρ is the total insulation resistance, l the total length in kilometres, and E the pressure in volts. The coefficient M is 400,000 ohms per volt per kilometre of cable used; and M. Jacquin considers a cable to have become unsafe if M has decreased to 10,000 ohms per volt per kilometre.

Brussels.—The electrical plant at the Tudor accumulator station in the Passage du Nord comprises one 40 kilowatt and two 16·8 kilowatt 140 volt dynamos, which supply current to a battery of 264 Tudor accumulators, arranged in four groups of 66 cells each. The cells have a capacity of 756 ampere-hours, with a maximum discharge current of 126 amperes. The station can supply 2,000 16 candle-power lamps. The wires, which are of phosphor-bronze, are run overhead. The station is provided with an electric alarm, which warns the electrician in charge whenever the difference of potential on the mains varies by 1 volt.

A Meritorious Telegraph Operator.—M. Emile Laurent, 1st class telegraph operator in the French Soudan service, has just been promoted for distinguished service. In April, 1886, during an Arab incursion, Laurent sheltered the women and children of the village of Bakel in the telegraph station, and, aided by six native soldiers, beat off all the attacks of the Arabs. In May of this year, accompanied only by one assistant, Laurent followed in the steps of a flying column sent in pursuit of 4,000 Arabs, and repaired in four days 100 kilometres of wire destroyed by the enemy. Owing to the commander of the column being so rapidly placed in telegraphic communication with his base, he was able to take measures which ended in the complete defeat of the Arabs.

Electrical Glass Breaker.—The Pittsburgh *Dispatch* states that several glass factories are now using electricity for a novel purpose. Heretofore, when they wanted to cut one of the large cylinders of window glass, a simple but primitive method was used. This consisted of the pulling out from the furnace of a thin strip of glass heated white. This was quickly wrapped around the bottle-shaped end of the cylinder, and it melted through or fractured the glass. By the new method the glass cylinder is encircled with a fine wire, the extremities of which are put in connection with a small electric battery. When a current of electricity is passed through the wire, the latter becomes red hot and heats the glass beneath it. Then a single drop of water deposited on the heated place will cause a straight break of the glass clear around the path of the wire.

Projected Canal at Rheinfelden.—The plans for the construction of a canal between Beuggen and Rheinfelden have been approved of by the Bavarian and Swiss Governments. According to this project a company of Swiss manufacturers will apply two-thirds of the waters of the Rhine (measured at low water) to driving an electric power station. The amount of water passing down the river at this point has been found to be 300 cubic metres per second (1 cubic metre = 35·3 cubic feet) at the minimum. The company will draw off 210

Digitized by Google

cubic metres per second for its turbines, and the Bavarian Government has stipulated that 30 cubic metres are to be supplied free for agricultural and manufacturing purposes; so that when the water is at low level, 60 cubic metres per second only will be left in the original bed of the river. The canal will be three kilometres long, and will drive double turbines of 1,000 horse-power.

Long Distance Telephony.—On Monday evening last the Manchester Field Naturalists' Society—presided over by Mr. Alderman W. H. Bailey—and many members of the Corporation, met at the Manchester office of the National Telephone Company; and a lively discussion took place on the effect of town fog on animal and vegetable organisms, between Dr. Baily, of Owens College, and Mr. Oglesby (Manchester), and Colonel Mackenzie, superintendent of Epping Forest, Dr. Charles Roberts, Prof. R. Meldola, F.R.S., and Mr. Philip Hartog, at the London offices of the Company in Oxford-court. The Berliner transmitter and the Bell receiver were used; and the voices of the Manchester members were heard quite distinctly in London, and easily recognisable. After the formal proceedings were over, the London office was connected with the Princess's Theatre, Manchester, and the Manchester office with the Savoy Theatre.

Proposed Hydro-electric Power Station at Lyons.—In Lyons the number of domestic manufactures is very great, so that it offers a promising field for the distribution of power by electricity. A project to make use of the water power of the Rhône is now being inquired into by the Government. The promoters of the scheme have constituted themselves into a syndicate (Syndicat Lyonnais des forces motrices du Rhône), and they propose to spend nearly three-quarters of a million sterling in digging a navigable canal 18·6 kilometres long, and establishing a hydro-electric generating station, having an output of 12,800 horse-power. It is estimated that a charge of about 125fr, per horse-power year will yield a fair return on the capital outlay. Hitherto considerations connected with the navigation of the river have prevented any utilisation on a large scale of the Rhône waters; but the present scheme overcomes that objection by the construction of the navigable canal.

Paris.—There was a curious scene in Paris the other day just outside the Opera House, says a correspondent of the *Daily News*. Traffic was in full swing, when a lady who was crossing the street and had got on to one of the refuges sunk to the ground with a scream. She had put her foot on a large metal plaque, and immediately felt an electric shock. The usual crowd collected, and the usual police arrived. But the cause was clear to all. Quite close to the scene of the accident was an electric light standard. With great presence of mind the police sent for several electricians, keeping a cordon in the meantime round the plaque. The experts went to work quickly and cautiously. The metal plate itself was raised. It communicated with one of the subterranean passages that lead to the drainage system of the city. Then at last the cause of the accident was discovered. A workman employed in the drains wanted to emerge, and happened to push up the plate at the moment the lady's foot was on it. Hence the shock.

Electricity as Applied to the Extinction of Fires.—In a Paper recently read before the Firemen's Convention at Detroit, Mr. H. L. Lufkin sketched several methods by which electricity might be made use of in extinguishing fires. In each large block of buildings he would have an electric motor geared to a powerful pump connected to the water mains, the motor being actuated from various points in the block by means of switches which close the circuit of the coils of a powerful electromagnet attached to the starting gear of the motor. It would not then be necessary to drag heavy fire engines through the streets, light hose carts only being necessary. The block would, of course, be fitted with a network of water pipes, valves, &c., and the motor would obtain its current from the mains of an electric supply company. Mr. Lufkin also proposed that instead of automatic sprinklers, whose action is frequently "too previous," sprinklers should be fitted in theatres and similar buildings in connection with a system of waterpipes, as described above. Switches could be placed at various points in the building, by the turning of which the electric pumping apparatus could be started, and the valve of the appropriate sprinkler opened.

Municipal Rapid Transit Statistics.—The following figures are taken from a Paper recently issued by the United States Census Bureau. In the 50 odd towns of the United States having a population of over 50,000, the total mileage of the street railways was 1,689 in 1880, and 3,151 in 1889, or an increase of over 86 per cent. The total mileage of 1889 was made up as follows:—

	Miles.	Per cent.
Animal power	2,351	74·62
Electricity	260	8·26
Cable	256	8·12
Steam (elevated roads)	62	1·96
Steam (surface roads)	222	7·04
Total	3,151	100·00

These figures, says the *Electrical Engineer* of New York, show that in 56 leading cities electric railways only form 8·26 per cent. of the total—a respectable figure, it is true, but still small. On the other hand, the figures for the whole country have been shown to be very different. They run thus:—

Miles of horse railway	5,902½
Miles of electric railway	1,753
Miles of dummy railway	556
Cable	441
Total mileage	8,652½

Taking the whole country, therefore, electric railways already form more than 25 per cent. of the total mileage.

The Interactions of Circular and Longitudinal Magnetisations.—In a short Paper communicated to the September number of the *Phil. Mag.*, by Prof. C. G. Knott, of the Imperial University, Tokyo, are given the results of some investigations undertaken by him on the effect of a current passing along a wire upon its apparent longitudinal permeability. The results of previous investigators, says Prof. Knott, would lead one to expect that a diminution of longitudinal intensity would be an evident accompaniment of a steadily sustained circular magnetisation; and this has been fully established in Prof. Knott's experiments. The wire to be experimented with was carefully annealed and then inserted as the core of a solenoid of copper wire of 138 coils per centimetre length. The wire and solenoid lay magnetically east and west. The current, which was about two amperes, entered the iron wire at the end furthest removed from the magnetometer and returned along two copper wires stretched parallel to the iron wire and very close to it. The results plotted out as curves show clearly that the linear current modifies the properties of iron in relation to the magnetic after-effect in three well-marked ways. First, there is a diminution in susceptibility. Secondly, when the linear current is flowing, the average magnetic intensity over a whole cycle no longer corresponds to the condition of zero polarity, as in the normal case when no linear current is flowing. For the one current, the magnetic intensity oscillates, so to speak, about a large positive polarity; and for the current in the reverse direction it oscillates about a nearly equal negative polarity. Thirdly, the curves, with the linear current in opposite directions, are no longer symmetrical on the side of the zero-line of magnetic force. A current passing along an iron wire, which is being magnetised, diminishes, as stated above, the apparent susceptibility of the wire; but this effect is more pronounced when the wire is acquiring a longitudinal polarity in the opposite direction to that in which the linear current is flowing. Hence, during any cyclic operation, the wire tends to acquire an average polarity in the same direction as that in which the current flows. These effects are more pronounced the stronger the linear current is as compared with the magnetising field. In a moderate cyclic field the effect of the linear current may be so strong as to prevent the wire ever acquiring other than one kind of polarity. In the course of these experiments it was noticed that if, before the wire has been magnetised at all, a current is passed along it, no appreciable longitudinal polarity is produced. Suppose, however, that the wire has been pretty strongly magnetised and then demagnetised by reversals, then, by simply passing a pretty strong current along the wire, a very pronounced polarity will be evidenced.

ELECTRICAL DISTRIBUTION BY TRANSFORMERS FROM CENTRAL AND ECCENTRIC STATIONS.*

BY DR. J. A. FLEMING, M.A.

(Continued from page 409.)

§ 12. **Westinghouse Transformer System.** — In the last four years, beginning in 1886, the Westinghouse Electric Lighting Company has developed in the United States an immense industry in the manufacture and erection of alternating-current plant for distribution of electric energy by transformer systems. At the present date (1890) there have been established by this Corporation in America about 300 central stations, comprising a total of over 500,000 16-candle-power incandescent lamps operated by alternate-current transformers. The several portions of this system have been designed with great care, and the mechanical and electrical construction of all parts has been brought to a high level of perfection. The standard type of alternator is represented in Fig. 30. In this alternator the revolving portion constitutes the armature, and the stationary magnets the field. The field-magnet is composed of a series of radial magnetic poles projecting inwards from the interior of a ring-shaped frame. These magnets are arranged to have alternate polarity at the inner ends. The magnet cores are formed of solid or laminated wrought iron, bolted to the inner circumference of a cast-iron cylindrical frame. On these cores are slipped exciting coils wound on shells, which are held in position by bolts at the extremities. These field-magnet poles are excited by the current from a small continuous-current dynamo. The armature revolves in the cylinder space in the centre of these radial magnetic poles. The armature core consists of a drum-shaped mass of laminated soft iron, built up of sheet-iron discs, compressed and secured to the steel shaft. On the surface of this drum-core are laid flat coils of insulated wire wound on formers, and laid on side by side, so as to clothe the drum with a layer of insulated wire coils. The ends of these flat coils of wire are bent over the flat ends of the drum, the whole set being secured by wire-binding (*see* Fig. 31). The number of coils on the drum is equal to the number of radial magnetic field poles. The coils on each half of the drum surface are joined in series and the two series connected in parallel, the diametra terminal wires coming to collecting rings on the shaft. The armature can be easily removed for repairs by lifting the upper half of the ring shaped iron frame of the field, and then taking the armature and shaft out of the bearings. These bearings

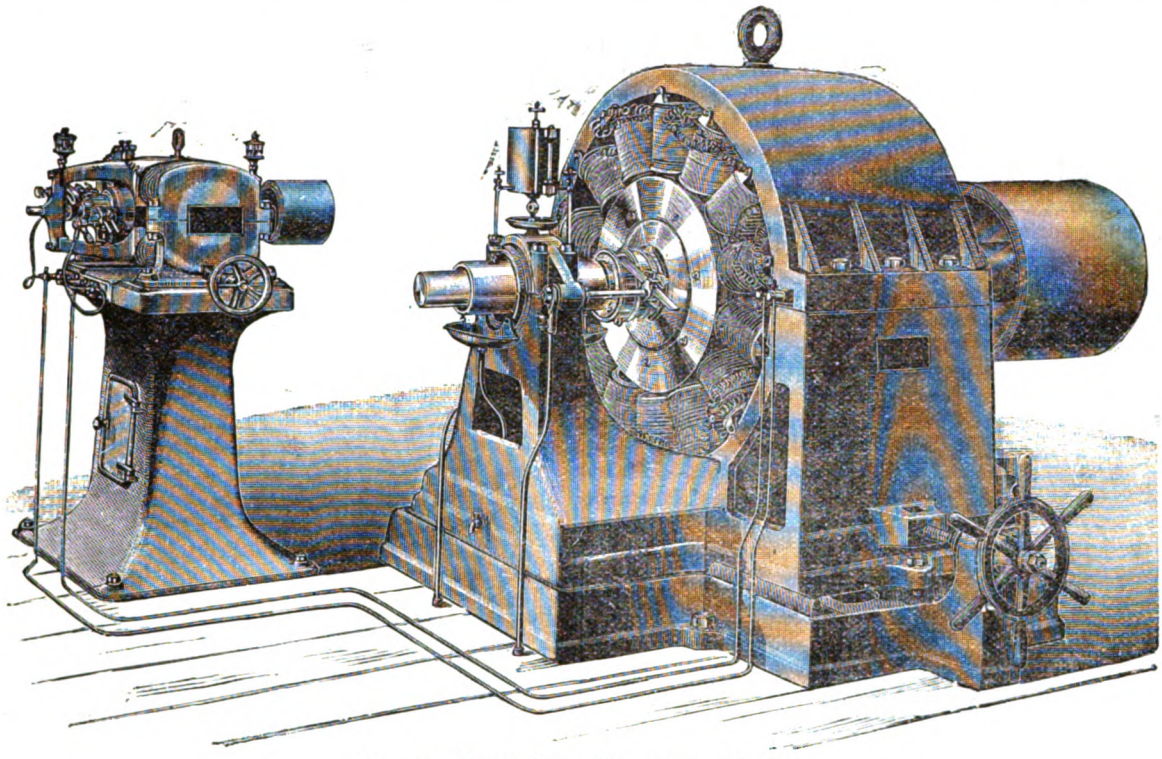

FIG. 30.—Westinghouse Alternator and Exciter.

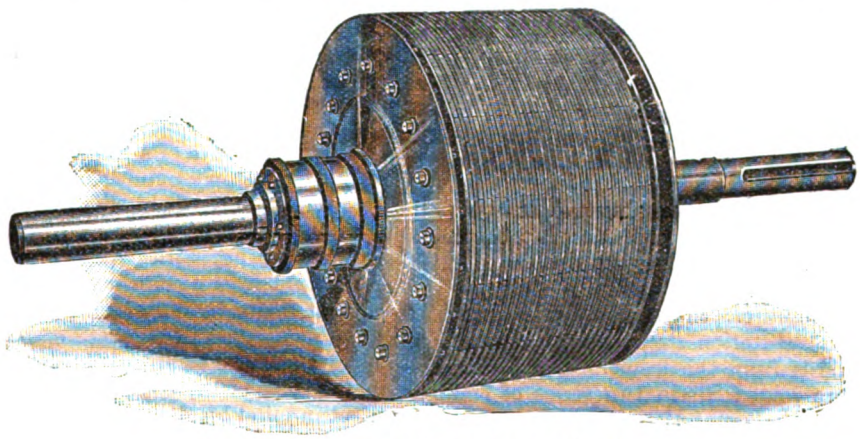

FIG. 31.—Armature of Westinghouse Alternator.

are ball-bearings, a section of which is shown in Fig. 32, and oil is fed from sight-feed oil cups to them, and working out into a drip pan, flows thence into a tank cast in the hollow base of the dynamo, from which it can be drawn off and re-used. The dynamo rests on a cast-iron base, and has the necessary belt-tightening arrangements.

This dynamo is manufactured in five sizes—

No. 0,	500-lights,	floor-space 4ft. 2in. × 5ft.
No. 1,	750-lights,	floor-space 5ft. 2in. × 5ft. 6in.
No. 2,	1,500-lights,	floor-space 7ft. 4in. × 7ft.
No. 3,	3,000-lights,	floor-space 8ft. × 7ft. 6in.
No. 4,	6,000-lights,	floor-space 11ft. × 8ft. 4in.

The capacity being reckoned in 16 candle-power lamps.

In large stations, in place of having an exciter for each machine, it is usual to excite an entire battery of dynamos from one or two large exciters driven by separate engines.

The armatures of these dynamos are all wound to deliver current at 1,000 volts. On the 750-light size the total weight of copper on the armature is 16lb., and as it is disposed in a single layer on the surface of the drum it is readily kept cool and well insulated.

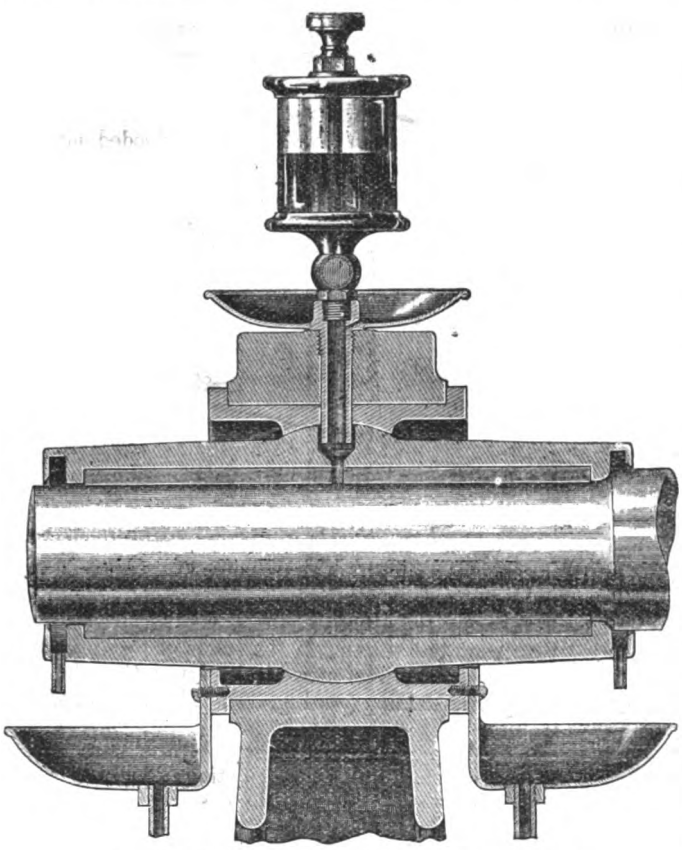

Fig. 32.—Ball Bearings of Westinghouse Alternator.

The leading-out wires from the collectors are carried on lugs on the main-bearing caps. The number of complete periods per second, or the frequency of the alternation of the current, is 130, or 8,000 per minute. Hence there are 16,000 alternations or reversals of current per minute. The usual speed of revolution is 1,000 per minute. In the No. 3 size, which is a commonly adopted central-station size, there are 16 magnet poles projecting inwards from the frame. The exciting coils of these magnets are joined up in two series of eight coils, on the upper and lower halves of the ring frame respectively, and the two series of magnet coils are joined up in parallel. These magnets are excited by a continuous current of about 25 to 30 amperes, supplied at 100 volts. The armature coils are joined up in a like manner.

The diagram in Fig. 33A* will indicate the manner in which these armature coils are connected, and Fig. 33B will show how the ends of the flat armature coils are turned over the flat end of the drum core to get them out of the way. The centre of the flat coil is occupied by a wooden lathe or core, and a narrow wood slip is inserted between adjacent coils. The whole armature when clothed with coils is wound round with steel piano wire. The clearance space between the surface of the wire and the end surface of the magnet poles is very small. Hence the wire moves in a very strong field. In operating a

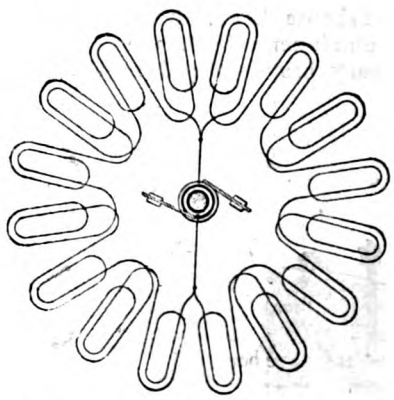

Fig. 33A.—Diagram of Winding of Westinghouse Armature.

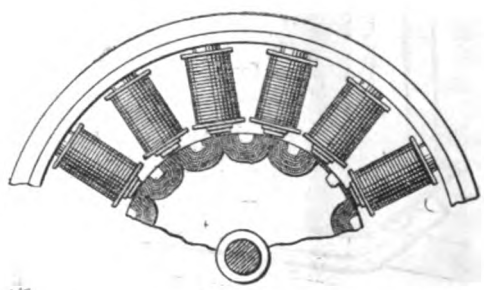

Fig. 33B.

battery of central-station dynamos, the whole of the field circuits of the alternators are joined in parallel with the armature circuits of one or more exciting dynamos operated by independent engines, the field-circuit of each alternator being controlled by a double-pole switch on the switch-board.

(To be continued.)

THE ELECTRIC LIGHTING OF A MODERN MAN-OF-WAR.

Electric lighting afloat, especially on board men-of-war, differs in certain details from lighting ashore; and, although ship installations are confined to a small area, they have a good many enemies to contend with, not least of which is the inquisitive ignorance of a large population.

In wiring a ship a number of most important considerations arise, peculiar only to ship-life—circuits have to be arranged, and dynamos placed so as to combine convenience in peace time with the necessities of war; the chances of flooding a compartment from a collision or other accident; the danger of damaging mains by fire from the combustible matter carried in store-rooms, the "sweating" of bulkheads and the sides of the ship; and the enormous adjacent earth in the iron of the ship, are some of the points which have to (or rather should) be kept in mind by the electrician who wires a modern fighting ship. It would not be proper to publicly discuss the efficiency or otherwise of the existing arrangements, but a few remarks on fitting up, installation, and the management of circuits on board ship will not be without interest, and perhaps benefit, in these times, when auxiliaries to the navy in time of war will undoubtedly be drawn from our fine mercantile marine.

Dynamos.—Dynamos for sea service are naturally of low constant potential, usually about 80 volts, and of varying current capacity, from 200 to 400 amperes, according to the size of the ship. Their position depends on their number, that

Digitized by Google

is to say, a reserve of power sufficient to work all the important lights must be placed below the water, or protected by armour, any additional power can be placed in more airy and convenient places above the water line; this, of course, is the supply usually employed in peace time, the lower or war dynamo room being chiefly, from its necessarily high temperature, used but little except in cases of necessity.

Switch-board.—The main switch-board, of course, is placed in the lower dynamo-room, well protected. It does not of itself call for much remark. Its requirements are as follows:—To enable one to put all or any of the circuits on to any machine, and to enable one to effect such a change of circuits or machines with rapidity. To provide each lead with a cut-out, to carry up to 200 amperes in each circuit without heating, to have a quick cut off to prevent fusing at the contacts. The return board should never be, as often is the case, a common return bar, with plugs to each circuit; each circuit should be as separate on the return as in the main. There are two important reasons for this. As regards the incandescent circuit, there is a danger of reversing the polarity of one machine, and, with earth in the circuit, 80-volt lamps have been known to have been worked by the two machines in series at 160 volts. Fig. 1 shows such a case, where half the lights are working at 80 volts, the others at 160 volts. The second inconvenience is caused when working arc lights, such as search lights, off the same board as incandescents. Often the search lights have to be kept ready for immediate use night after night; to avoid unnecessary wear and tear it is customary to run the dynamos for them slow, to keep them just excited; and with the return plugged up, it is an even chance that the polarity is reversed, therefore, of course, the crater forms in the wrong carbon, and the leads have to be shifted. It is for reasons such as these that the common return board is such a curse in practical use.

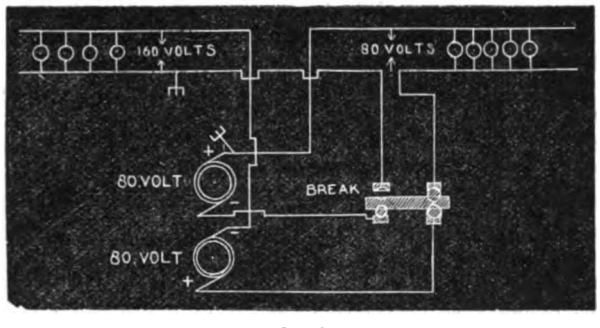

FIG. 1.

Wiring.—The next thing to consider is the wiring of the ship. In order to know how to wire a ship conveniently, *i.e.*, conveniently for future use, not conveniently for putting up, practical knowledge concerning the general disposition of the watertight compartments, the position of longitudinal and transverse bulkheads below the water relative to the decks above, and the distribution of the protective armour is required, as well as an insight into the ordinary routine of daily life on board ship. For instance, it is useful to know the various store-room lights and deck circuits which are switched on and off together at stated times, as well as the compartments whose watertight doors are closed every evening. The bearing of these points on the grouping of lights, and position of switches and cut-outs, is obvious, especially to the person who happens to have the main cut-outs of the bow and steaming, or other important lights, boxed up in a watertight compartment below. It is quite impossible to enter into details as regards these points, each ship varies so much in essential details of sub-division and construction that the most we can do is to broadly discuss the subdivision of lights in modern ships.

Sub-Division of the Lights.—There are two leading principles in the division of lights (one of necessity, the other of convenience). Firstly, the vital parts of the ship, such as the engine and boiler rooms, the magazines, and all protected fighting positions should be on mains of their own, with no submain or branch wires leading in unprotected places. This is necessary, as a short circuit in a branch may cause the main cut-outs to go, and so reduce an important part of the ship to darkness and confusion. Secondly, all lights which are exposed to the weather, such as the upper deck lights, which are particularly liable to leakage from wet and exposure, should be on a separate circuit to the lights between decks. A convenient way of subdividing lights in a large ship will probably be found to be as follows:—

(1) Engine and boiler rooms.
(2) Magazines, shell rooms, and other war store rooms.
(3) After accommodation and store rooms.
(4) Fore accommodation and store rooms.
(5) The central portion of the ship, with mains for upper deck.

Now, having decided the subdivision of lights, a few words about the leads of the mains. Naturally, as far as possible, they should be led below the water line, avoiding all store-rooms where inflammable material is kept; for it would greatly add to the danger of a fire to be at that time deprived of the usual method of lighting. It will also often be found necessary, on account of the space occupied by the mains (for the search light as well as the incandescent mains have to be led along, and the latter should be separated so as to have only one lot disabled in case of accident), to lead half the mains on opposite sides of the ship. As the mains arrive at their respective lighting areas a most important point arises which affects all ships, whether war or merchant vessels, namely, as to how the submains should be forked in.

Cut-outs.—We must constantly keep before us the contingency of any compartment in the ship being flooded either through collision or a submarine explosion in war time, when the whole circuit in that compartment would be short-circuited, and it is impossible to over-estimate the fuel that would be

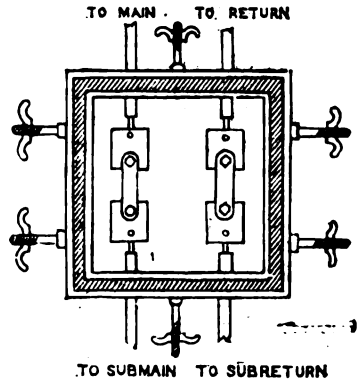

FIG. 2.—Watertight Cut-Out Box, with top removed.

added to the tendency to panic and confusion resulting from the "hurling" explosion of a torpedo or the crash of a collision, if they were followed by an extinction of light. Men can probably be trained to stand at their stations after the shock of some unknown accident; but to the listing ship and rush of water add darkness, the result can well be imagined. It is useless to talk of having the fighting candles always lit. These undoubtedly would be useful some ten minutes or so after the electric light had gone out; but shining through their small bulls-eyes after the glare of the electric light they would relatively produce but sufficient light to make the darkness visible. It is for reasons such as these that a proper method of connecting sub-mains in watertight compartments should be strongly insisted on, so that as far as possible the extinction of light may be confined to that one compartment. To do the first, the mains should be run the whole length of the compartments to be lighted, a submain being forked into each; secondly, a watertight cut-out box should be fitted near the fork in the submain, and all leads to that compartment taken away from the further side of this box. Such an arrangement would act as a disconnecter, and insulate the mains from the flooded area around. A rough sketch of such a box is given in Fig. 2. Of course, it is quite possible only one cut-out would go, in which case the other wire would put the dynamo to earth, which, for many reasons, is objectionable; but should it be thought necessary to arrange for the fusing of both, methods will occur to any mechanic or electrician

Digitized by Google

of causing both cut-outs to go on the fusion of one. One more practical point in connection with this subject. Any person accustomed to cut-outs knows that often it is impossible to predict which of several cut-outs in series will go first; sometimes a short-circuit in a branch may cause the main cut-out to go, another time a sub-main, and perhaps a third time both—it is entirely a question of additional heating and of contact in the cut-outs. To save main cut-outs as much as possible, the mains should be large for the current they carry, their cut-outs as large as possible consistent with their fusing before the mains heat dangerously, and their contacts kept scrupulously clean; more than this cannot be done.

In placing cut-outs much of their efficiency depends on the positions chosen for them. Of course, in all circuits so liable to earths as those on board ship cut-out wires should be in the lead, and return wires of mains, sub-mains, branches, and in leads for single lamps as near the place of branching as possible. A single cut-out cannot guard against an earth leak in the opposite wire; it is therefore very necessary to have one in each. Cut-out blocks should not, if it is possible to avoid it, be placed under steam or water service pipes, or if they have to be placed there, they should be made thoroughly watertight, since the condensation of moisture due to varying temperature is often considerable. The wooden backs of switches or cut-outs, as well as brackets, should be filled in, where the wires lead through them, with an insulating cement, otherwise, with a sweating bulkhead, the horizontal holes become receptacles for the dripping water, and corrosion of the contacts, and earth leaks ensue. It is also a great help to sweat the lighting wires into the cut-out block, thereby reducing the number of surface contacts and the heating. If the man who wires a ship knows his work, he will place the switches and cut-outs in places where they are reasonably getatable, not, as is only too often done, some 10ft. overhead on the underneath side of the deck above, or high up out of reach on a vertical bulkhead. As may well be imagined, it is an exasperating thing replacing such cut-outs with the ship rolling. On such occasions a screwdriver, kept in the mouth, will prevent the active use of emphatic epithets. Whenever a cut-out is placed in the lead, and another in the return (as always should be the case), one should be a switch cut-out; if this is done it often means a great saving of time to the person replacing the cut-out, as he can at once switch off the circuit and replace the wires, otherwise he would be obliged either to switch off the whole circuit, or every individual light beyond.

Laying the Wires.—On board ship a favourite method of laying wires used to be to bed them in putty in wood casings, this, if carefully done, was often a very successful way; but if, as often was the case, the wire was put in first, and then putty pressed in on top, it was worse than useless, for the putty never fairly surrounded the wire, and there was invariably a space behind, not only for the wet to creep along, but to lodge and collect, and this, of course, put the first faulty place to earth, or in the case of a leak in each wire connected the two. In vertical casings the ends should be made watertight. Leaks are often traced either to water in a vertical casing, or to water which has come down such a downtake, and lodged in a horizontal casing. This especially applies to places where pipes form the continuation of a wooden casing. Junctions or forks in insulated wires cannot be made with too much care. It is perfectly useless using wire of high insulation if the forks in it are carelessly made, especially as the forks in the main and return are often close together inside the same casing, and therefore particularly disadvantageous for "non-contact" if carelessly made. With lead-covered wires of course casings can be totally dispensed with, except occasionally as "Scotchmen" in exposed places, clips and brackets of brass being used in lieu, consequently there is but little danger of water lying about the junctions in the wire. The junctions, however, in the class of wire should be most carefully made (and they require a little skill in making neatly), for the insulation or rather packing between the wire and the lead case is not watertight, and, therefore, any water inside the lead puts the conductor at once to earth. For really trying places, where the wires are exposed both to heat and wet, if carefully put up, this class of wire is invaluable. Whenever wires pass through watertight bulkheads, or any deck, watertight glands should be used to preserve the integrity of the bulkhead, otherwise, in time, if this is not scrupulously adhered to, the bulkheads become honeycombed and rendered perfectly useless.

Light Fittings.—It is a difficult matter to light a ship well, on account of the small height between decks. The officers' and men's quarters present but few difficulties, but the gangways or passages fore and aft the decks are different. These are the very places where overhead light is wanted, and yet cannot be placed for fear of damage to the fittings. All side lighting with bulkhead lights must necessarily be about the height of the eyes; consequently, if at the end of a passage these tend rather to blind one than to show the way. The only thing to do is to make the best of the circumstances, and light from the side if overhead lighting is unpracticable. Great care is required in selecting the places for lamps to be quite certain they are not "in the way." "Overhead" in a modern ship is a mass of hooks and brackets for the stowage of spare or handy gear; every hook and bolt has its meaning and use, which may interfere with a light in its close proximity. Careful selection for the position of fixings means great saving in repairs and broken glass afterwards. Another important point to consider about lamp fittings is suitable methods to prevent the injury to glass from the shock and concussion of guns. I say shock and concussion, because the damage is twofold, and may be communicated either by shock through the ship or directly by the concussion of the air. There is much still to be done in this direction, and at present the safest way is to unship the shades and often the lamps. The position of greatest danger of damage is that where the fitting is exposed directly to the concussion of the air, and is, therefore, above rather than on the gun deck.

Wandering Leads.—These are a nuisance wherever fitted, unless treated with care. Their chief place is in store rooms, as well as the engine and boiler rooms. Here they last but a short time. Oil, heat, and rough usage from people who have not their refitting, soon shortens their life. The plugs for their connection are a source of weakness. Flat spring contacts should be avoided in them if possible, for heating soon takes the temper out of the metal, and worse heating and fusing ensue.

Lanterns.—The prevalent idea is that any lantern will do to shade an incandescent light, or that any lens will suit it. The consequence is that the lanterns for incandescent lights are merely copies of those used for oil lamps. What really is wanted is merely a protective covering of metal and glass, as light as possible, with as large an aperture as may be required for the class of work it is to be used for, the protective covering to be only such a size as to prevent the glass being heated by radiation sufficiently to endanger it when brought in contact with cold or wet. As regards the use of a lens, it is doubtful if any would be of much good for the long filament of an incandescent lamp, and whether the extra expense and weight entailed would be repaid by an increase in range of visibility. The more ventilated such a lantern, consistent with actually keeping out water, the better. If bottom loops are used in the lamp they should be soldered to the hooks and the base filled in with putty. No trouble from damp or bad contact need then be feared.

Accumulators.—A few words about accumulators. If properly managed they are most useful auxiliaries to incandescent lighting. They are subject to no special ailments from living on board ship. The rolling of a ship affects the level of the liquid but little; and provided the containing vessel is built up some inches higher than the plates, no portion of them need ever be uncovered. They have been used in a ship rolling 36deg. each way without any trouble whatever. The most awkward part was the ventilation of the battery room, which was often not so good as might be wished; but after the first couple of months the discomfort of entering the room, when the cells were fully charged and charging, was not great, although the cells occupied about one quarter of the total cubic capacity of the room, which was below the water. The effect on the surrounding iron of the acid carried off with the gas was inappreciable. The containing vessels for service afloat are usually made of a form

Digitized by Google

of hardened lead, thus are less liable to damage through concussion than if made of glass. The drawback, of course, is that the plates cannot be seen without lifting them out of the liquid, but one soon gets fairly expert at finding out any ailment, and its cause, without ever consulting the appearance of the plate. A thin strip of ebonite passed every week between the plates detects and removes any pellet that may have lodged between them. Should a cell fall in specific gravity and E.M.F., it is probably due to sulphating, and by reversing it in discharge and letting the discharging current charge it up (thus in charge or discharge it is always charging) their hearts, *i.e.*, the sulphate, will be broken, and they will come up. One must be careful at the same time to see that the temperature of the cell does not rise much. By carefully watching variations in specific gravity or E.M.F., or both together, and keeping the plates apart, it will rarely be found necessary to unbuild the cells to look at the plates.

Arc Lighting.—Arc lighting is dying out on board ship for lighting purposes. It never was much liked, being too brilliant for small areas. For search lights it is, of course, largely used, it being perfectly simple to keep an absolutely steady light for an hour or more together, worked as they are, by hand, with close attention, and, above all, much practice.

Testing Circuits.—It should be the aim of every one in charge of a circuit to prevent as far as possible any breakdown, however small. This can only be done by keeping the circuits free of faults, and the cut-outs, &c., clean. If once a circuit gets into bad repair it is a great labour to detect and correct *all* the leaks. It is only, therefore, by detecting and correcting

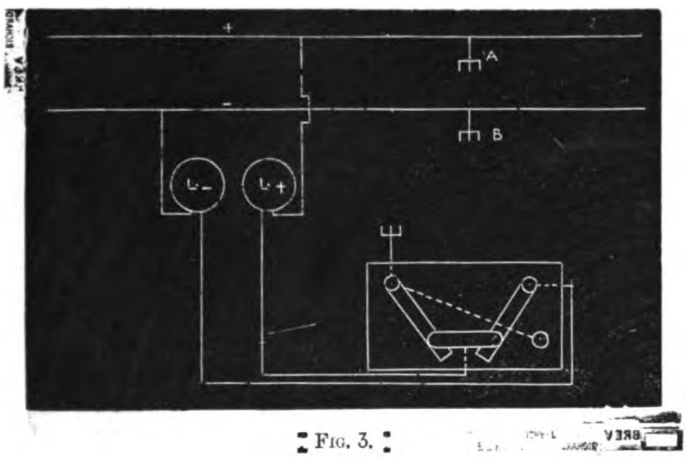

Fig. 3.

each leak as it forms that a circuit, with such an enormous adjacent earth as one on board ship has, can be kept in an efficient condition. Taking the ordinary insulated wire run in casings, the leaks that arise are twofold, leaks to earth and away to another leak and back to the machine, and two leaks adjacent in the casing never reaching the iron of the ship. Earth leaks can always be detected forming, or after they are formed, by the use of "earth lamps." Although the principle involved is simple, and the device old, the writer has met so few people who appreciated the use of these lamps, that he is tempted, at the risk of simply repeating what is well known, to dwell on the use and fitting of these lamps.

Two lamps, L+, L−, Fig. 3, of the voltage used in the circuit, are placed close together. A wire runs from L+ to the positive wire of the circuit, and one from L− to the negative; the other wires from these two lamps are taken to a switch, as shown, which is capable of doing the following things:—(1) putting both lamps in series; (2) putting the junction of the two lamps to earth; (3) putting each of the lamps separately to earth.

Now, suppose the right-hand bar moved to the left, both lamps will be burning in series, and will burn with roughly equal intensities, but, of course, at a greatly reduced candle-power. Now, by a motion of the left hand bar to the right, the junction of these two lamps will be put to earth. If there is no leak in the circuit, the relative brilliancy of the lamps will not be altered; but suppose a leak in the positive wire at A, it is evident that L+ and A will be in parallel, consequently more current will pass through L− than L+, and the lamps will burn with different brilliancies dependent on the size of the leak at A. Consequently these lamps show not only which wire the leak is in, but approximately the size of the leak, whether it is increasing or not; and often a good idea of the position of the leak may be formed, by its variation in wet weather—its intermittance, if in a portable connection—or its disappearance or alteration on switching on or off circuits. It is necessary on discovering a leak to put each of the lamps to earth to see that there is not a leak in both wires, otherwise the estimation of the size of the leak may be erroneous.

A peculiar case arises in Fig. 4, where A and B are the earth lamps, S a switch, and E an earth. While S is switched on, B will burn brighter than A, but with S to off the reverse will be the case, so that often a leak may be traced on a circuit being switched on or off in this manner.

It is not, however, in detecting the position of the leak that the chief value of these lamps lies, but rather in at once telling of the formation of a leak. To find the leak the simplest way is at some convenient time, probably during the night, to walk round with a lamp with two short leads of wire, start at the main switch-board, burn the lamp to earth, break each circuit for a second, and see in which circuit the leak lies; then follow it up by breaking the main circuit at each cut-out of the various sub-mains or branches till at last the branch with the leak is discovered; by this means leak after leak may be detected without the current ever being off a lamp except for a few seconds at a time. It is wonderful how cunning, after a time, men get in the use of these earth lamps, and are able to very shortly put their hands on a leak. Such lamps show a leak in the circuit of about 2,000 ohms.

As to the other class of leaks, which we might call "non contact," or double leaks to damp in the same casing, yet not to the earth of the ship, the writer knows of no method of discovering these except by keeping a careful look-out for signs of damp near a casing. The same old tale occurs time after time. A break in the circuit, or a casing heats; on taking the cover off the casing and removing the putty, that well-known green powder comes into view, the wire is removed, and found at the break as fine as a needle point, the insulation charred

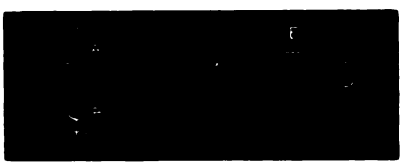

Fig. 4.

by the heating of the fine wire. The writer has a piece of wire before him with three breaks in the main and three in the return within a length of 4ft. The end of a vertical casing was not filled in, and the putty badly put in. One thing about these leaks. If in a case of this sort a break is found in a wire through this action, and there is no leak to earth, examine the other wire, and find the fault in the insulation that must exist, otherwise half the work is only done, and the whole casing will soon have to come down again.

The writer may have appeared to harp on leaks and cut-outs to an unwarrantable extent. He can only say that on board ship, with an installation of about 500 lights or so, and some 1,200 switches and cut-outs, iron and wet everywhere, to say nothing of carelessness and ignorance, the detection and repairing of leaks becomes part of one's daily duty; and there is no more pleasing sight with which to assure yourself that your staff are doing their work than your earth lamps burning with equal brilliancy.

The Telegraph in China.—China at present possesses no less than 16,488 English miles of telegraph wires, and the system is being constantly extended. The Government is now laying a line for more than a thousand miles, west to Kansuh, in order that it may be kept fully informed of Russian movements in the north-west.

ON THE SPECIFIC RESISTANCE OF COPPER.*

BY T. C. FITZPATRICK.

All the values given in tables for the specific resistance of the metals are directly or indirectly obtained from the values given by Matthiessen in his series of Papers published in the *Transactions* of the Royal Society for the years 1860-64, and in the reports of the British Association for the same years.

In the *Transactions* † for the year 1860 is a Paper by Matthiessen, on the conductivity of pure copper and on the effects of impurities. No alloy of copper has so high a conductivity as the pure metal. His results are expressed in terms of the conductivity of a hard-drawn silver wire (100 at 0deg.). He gives the following values for samples of copper carefully prepared by himself:—

(1)	93·00 at 18·6°	Giving a mean value of 93·08 at 18·9° as the conductivity of pure copper.
(2)	93·46 „ 20·2°	
(3)	93·02 „ 18·4°	
(4)	92·76 „ 19·3°	
(5)	92·99 „ 17·5°	

Numbers are given showing the effect of small quantities of oxide on the conductivity, and he states that he found it necessary to pass hydrogen through the molten metal for some time for entire reduction. In the *Transactions* for 1862, Dr. Matthiessen had a Paper on the influence of temperature on the conductivity of metals. He again expresses his results in terms of a hard-drawn silver wire. On page 8 will be found the results of his experiments on copper; the lowest temperature at which measurements were made was 12deg. or 16deg.; he there shows how the results for pure copper measured at 18deg. may be reduced to 0°C.; but no measurement was actully made at 0deg. for any of the metals experimented with. He expresses the influence of temperature on a hard-drawn copper wire; the mean result of a number of determinations by the equation

$$\lambda = 100 - \cdot38701\, t + \cdot0009009\, t^2$$

where 100 is the conductivity of copper at 0°C., so that a hard-drawn silver and copper wire have the same conductivity at 0°C.

The values obtained by comparison with a hard-drawn silver wire are then largely the source of the tables of specific resistances; but at the end of his appendix to the Report of the Electrical Standards Committee for 1864 Matthiessen gives values for hard-drawn silver and copper wires in terms of the new B.A. unit, expressed as the resistance of a wire one metre long, weighing one gramme.

These values are:—

Copper	·1469
Silver	·1682

The same table of values is given in the *Philosophical Magazine* for 1865, where also is given a table of specific resistances for wires one metre long and one millimetre diameter expressed in terms of the B.A. units, calculated from the value of the known conducting power of the gold-silver alloy in terms of hard-drawn silver, and also in terms of the B.A. unit.

The values thus obtained do not agree at all well with the results calculated for the resistances of the gramme metre by the specific gravities of the elements furnished by tables.

Thus:—

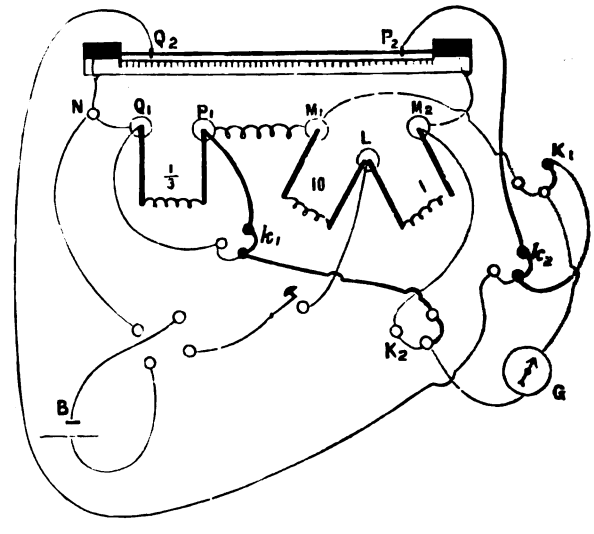
Silver	·02048		·02603
Copper	·02090		·02104

He states that he omitted to determine the specific gravity of the copper used in his experiments; he probably would not have obtained any very adequate results, and the weight of copper he used varied from 1·5 to 4 grammes.

The accuracy of Matthiessen's results seems to depend, therefore, on the accuracy of his determination of the resistance in terms of the B.A. unit of a hard-drawn silver wire; in considering, therefore, the question of the preparation of samples of copper of higher conductivities than Matthiessen obtained, it may be suggested that the cause of the difference is not the fact that Matthiessen did not prepare pure copper, but by the error in the value of the standard with which the comparison was made. I have, therefore, made a series of experiments on the resistance of pure silver wires, and, as a general result, have obtained a value identical with that of Matthiessen; the difference is not due, therefore, to an error in the standard employed, as far as my experiments go.

Matthiessen does not give anywhere the details of his measurements of the specific resistances of the metals in terms of the B.A. unit; in the B.A. report he simply mentions that an approximate table is subjoined, not even stating the fact that the values are for a temperature of 0°C. I conclude, therefore, that these values are calculated out from the former, of which an account is given in the same B.A. report, and which were performed at a temperature of 20°C. I have, therefore, in this account, as well as for other reasons stated later, made my measurements at the temperature of the air, and believe that as his values were reduced by a temperature coefficient to values at 0°C.; I shall, by using the same temperature coefficient, and raising his value to near that for 20°C., obtain results directly comparable with Matthiessen's direct measurements.

For the measurement of the resistance of the specimens of wire a Wheatstone's bridge arrangement was employed, two of the arms of the bridge were formed by a 10 and 1 standard B.A. unit, namely (66 and G); these were so nearly 10 to 1 that they were taken to be in that ratio. The third arm was one-third of a B.A. unit, and in the fourth arm was the wire to



be measured, this was stretched on a flat board, and soldered at the ends to copper plates, to which connecting wires were also soldered; the length of wire used was generally a little less than two metres, and the wires were, approximately, No. 18 B.W.G. The board had scales screwed to it at the two ends; the board and wire were placed in a long bath made of zinc, and filled with paraffin; wires which were left in the bath for some days, and, in more than one case, several weeks, were not found to have been at all acted on by the oil. One end of the wire, P_2, Q_2, was connected by a binding screw through an adjustable resistance, r, ($\frac{1}{2}$ metre of copper wire) to the mercury cup, Q_1, in which was one of the legs of the one-third coil, and also to a reversing key in the battery circuit. The one-third and the 10 were connected up together through an adjustable resistance, P_1, M_1, one leg of each of the coils 10 and 1 were in the same mercury cup, L; and the other end of the 1 B.A. unit was connected with the other end of the wire, P_2, Q_2.

A single Leclanché cell was connected up with the reversing key and the fourth point of this key was connected with the mercury cup, L, into which the legs of 10 and 1 dipped. In this circuit there was also a touch key. The galvanometer circuit was always made, and thus there was no thermo-electric effect on making the galvanometer circuit. To each of the mercury cups, Q_1, P_1, M_1, M_2, were connected with separate binding screws two thick wires, one of which was welded to the copper plate at the bottom of the mercury cup. Each of these latter wires were connected with two way-keys; those in P_1 and

* Paper read before the British Association in Section A, Leeds, September, 1890, being an Appendix to the Report of the Committee on Electrical Standards.

† *Phil. Trans.*, 1860, p. 85.

Q_1, to the key, k_1; those in M_1 to the key, K_1; those in M_2 to the key, K_2.

The base points of the keys, K_1 and K_2, were connected with a delicate reflecting galvanometer, that employed for the comparison of the standards on the Fleming bridge. The base of the key, k_1, was connected with the third point on the key K_2, and the third point, on the key, K_1, was connected to the base point of a fourth key, k_2, the two other points on this key being connected with riders, with which contact can be made with two points on the wire, P_2, Q_2; the riders had straight edges, and thus their positions on the scale could be easily determined. In performing an experiment, the keys, K_1 K_2, were so connected that the mercury cups, and the ends of the coils, 10 and 1, were in circuit with the galvanometer. The resistance, R—P_1, M_1—was then varied till, on making the battery circuit, no deflection resulted. The ends of the 10 and 1 were then at the same potential, and as the other ends of these coils were connected with the same pole of the battery, there was the same fall of potential on the two lines. The keys, K_1 and K_2, were then reversed, and by the keys, k_1 and k_2, one end of one-third coil and one point on the wire, P_2 Q_2, were connected through the galvanometer, and afterwards the two other ends. The riders were adjusted till there was no deflection of the galvanometer. The length of wire between the two riders had a resistance of one-tenth that of the one-third B.A. unit coil.

By means of the series of keys it was easy to repeat the observations and to connect the ends of one-third coil with the wire. The resistance R did not often change during the experiments, as the room was at a constant temperature, any change in R only caused a shifting of the position of the riders. In each experiment, after all the adjustments, the bath was well stirred, and everything left for half-an-hour. It was generally found that the riders did not require any adjustment. The battery was reversed and all the coils moved. The latter never caused any effect; sometimes the reversal of the battery caus d a shifting of the two riders a millimetre or two in the same direction.

Another reading was taken three or four hours after. The coils one-third, 10, and 1, were in water baths, and their temperature remained the same for hours together. The temperature of the paraffin bath, of course, was not so constant, it was kept well stirred and a thermometer reading to ·2°C. never showed any difference in the temperature at the different ends of the bath when the readings were taken. The thermometer employed was Kew corrected; and the corrections given were verified by recent comparisonwith a platinum thermometer by Mr. Griffiths.

Since the two standard coils employed were accurately in the ratio of 10 to 1, the accuracy of the resistance measurement depended entirely on the value of the one-third B.A. unit. This was first made as nearly as possible one-third, but it was found that for the size of the wires measured (18 B.W.G.) this was too high a resistance; it had, therefore, to be reduced. For the determination of its value, there was cut out in a block of paraffin wax a large central mercury cup, and outside this a circular channel; thick copper plates were cut to fit them, and both were well amalgamated. By means of this cup arrange ment, the three B.A. units (H, G, and Flat) were connected up in multiple arc, and by means of stout copper rods the multiple arc arrangement was connected with the mercury cups with the Fleming's bridge, and so compared with the one-third B.A. unit, the temperature of the one-third being given. The following observations were taken:—

July 12, 1889:—1/3, (18·4°) + 986·6 (b.w.d.) = M.A. + 24·6 (b.w.d.)
July 22, 1889:—1/3, (17·4°) + 986 (b.w.d.) = M.A. + 24·1 (b.w.d.)
Aug. 26, 1890:—1/3, (16·8°) + 986·1 (b.w.d.) = M.A. + 23·9 (b.w.d.)

where M.A. denotes the resistance of the multiple arc arrangement.

The value of a bridge wire division (b.w.d.) is ·0000498 B.A. units at 15deg., and the wire has a temperature co-efficient of ·00143.

It is evident from these series of values that the one-third has not changed in resistance during the period of the experiments.

This comparison, however, introduced a possible error as the temperature of the bridge wire at the time of experiment was not accurately known, and this is important when nearly the whole of the bridge wire is employed. To eliminate this possible error, the one-third was compared with four B.A. units in multiple arc. In this case a large number of bridge wire divisions had to be subtracted from the value of the one-third, and the whole number of bridge wire divisions entering into the calculation for the values of the one-third was largely reduced. The four coils in multiple arc were (F, G, H, and Flat):—

Aug. 25, 1890:—1/3, 16·8° + 157 (b.w.d.) = M.A. + 852·05 (b.w.d.)
Aug. 26, 1890:—1/3, 16·8° + 157·5 (b.w.d.) = M.A. + 851·9 (b.w.d.)

All the four coils were at the same temperature (16·8). These values are taken from the B.A. Report, 1888.

Flat	1·000448
F.	1·000028
G.	·99955
H.	·99969

These give for the two multiple arc arrangements the values ·33330 and ·24998. The connecting rods had a resistance of ·00042, and hence the value of the one-third at 16·8° is found to be ·28537. The temperature coeffieient for the coil is ·0001 per 1°C.

To measure the lengths of the wires, two microscopes with scales and verniers reading to ·1 of a millimetre were set up and firmly clamped in position; the distance between them was determined by means of the beam compass with the aid of a third microscope; the distance between this and the other two being directly read off on the beam compass for set positions of the verniers. The wires were cut with a fine fret saw at the points corresponding to the position of the riders in the resistance measurements. Before weighing the wires were carefully cleaned with methylated spirits, the balance employed was the one used by Mr. Glazebrook for our determination of the specific resistance of mercury, the weights were balanced against one another, and in all cases double weighings were taken.

The specific gravity of most of the wires was measured, for this purpose distilled water was boiled and cooled rapidly, the coil of wire immersed and the beaker and its contents placed under the receiver of an air pump, which was connected up with a water pump, this was left running for two or three hours till all air bubbles had disappeared, the weight of the wire in water was determined, and a second reading taken some hours later; as the weight of wire used was from 16 to 20 grammes, fairly accurate values for the specific gravity of the several wires ought to have been obtained, and thus the value for each wire in terms of the B.A. unit for the resistance to conduction between the opposite faces of a cube of the material was found.

The first object of these experiments was to test directly in comparison with the B.A. standards samples of copper wire of high conductivities, with the view of comparing them with Matthiessen's standard. Application was therefore made to several firms for high conductivity copper wires; my thanks are due to those who sent samples.

A table of results is subjoined, the results for all the specimens tested are given, and they show the variation in resistance of high conductivity wires.

IV. and IV¹. are the same copper, but IV. is hard drawn, IV¹. is annealed; they were measured just as they were sent from the manufacturers; the same is true of V. and V¹., VI. and VI¹.

It will be noticed that VI. and VI¹., which are of considerably less resistance than the other wires, are of higher specific gravity; the firm that sent them thus wrote of them, "it is only occasionally we come across copper as high as this or high enough to be called the highest (in conductivity) we can produce. This copper has been produced electrolytically by our ordinary process." How this copper was treated after electrodeposition I do not know, I am inclined to think from my own experience that this difference in density is due rather to the condition of the copper, than to its relative purity. Matthiessen found that very small quantities of impurities reduced the conductivity 20 or 30 per cent. and a sufficient amount of impurities to cause a decrease in density from 8·94 to 8·90 would therefore make a larger increase in the resistance of the copper than is shown in the case of VI. and VI¹.

Digitized by Google

The temperature coefficient is stated to be different for various specimens of metal, according to their purity; Matthiessen himself seems to have been of this opinion, but the mere difference in density of the metal might be expected to affect the alteration of conductivity for a given change in temperature.

I have not been able to find any experiments bearing on this question. It is quite easy to obtain samples of wire of different density by varying the process of drawing, and the temperature coefficients of such wires might be found to be different.

Comparing V. and V^1. with VI. and VI^1. it is seen that with this increase of density there is a distinct diminution in the effect of annealing.

IV. - IV^1. = ·00677
V. - V^1. = ·00577
VI. - VI^1. = ·00400

I thought it might be possible that VI^1. was not completely annealed, so for a direct comparison, two specimens of VI., which had been measured hard drawn on July 10 and 14, 1890, were annealed; for this purpose a flat copper vessel was made of about 2cm. height and 18cm. diameter, with a closely-fitting lid; the wire was packed in this between sheet asbestos, which had been previously heated up; the vessel was filled up with lampblack and heated over a big Bunsen burner; it was then gradually cooled; the process generally took about 24 hours; the wire was found not to be oxidised at all after the process was over.

Wire.	Hard-drawn.	Annealed.	Difference.
I.	1549	1510	·0039
II.	1548	1509	·0039

The difference Matthiessen obtained was ·0038.

The above method of annealing was found very effective. Silver wires, which on annealing decrease 10 per cent. in resistance, gave the same value in a second annealing as they did on the first occasion.

Wire VII. was a wire sent me by Mr. H. A. Taylor, and had to be drawn down before it could be measured; another piece of the same wire drawn down on a different occasion, gave the same value; this wire has the lowest resistance of any I have obtained; it has, too, the highest specific gravity. Mr. Taylor says of it, "That it has a higher temperature coefficient than that given by Matthiessen."

VIII. was a sample of wire obtained from Germany, and said to be electrolytically prepared; its high resistance is, I think, due to the presence of oxide, and I fused some of it up in hydrogen, and when measured partially annealed it gave the value 1566 at 18°C. for the wire 1 metre weighing 1 gramme, thus showing a very marked reduction.

IX., X. and XI. are wires of my own preparation. Pure copper was prepared electrolytically by Messrs. Sutton, of Norwich, and supplied me in thin sheet, and this was fused down in porcelain tubes of 18 centimetres in length and one centimetre in diameter; the tube was fitted up in a small furnace made of sheet iron and lined with ganister; this was heated readily by a blast flame led in at the bottom. Some difficulty was experienced in obtaining the copper in a solid cylinder; in the early experiments hydrogen was passed into the tube whilst the copper was being fused and was made to bubble through the molten copper; on breaking the tube, the copper was found to be full of small holes; the copper had absorbed the hydrogen at the high temperature and given it off again on cooling; on another occasion the copper was fused down in hydrogen and the tube was connected with a water pump and exhausted, and the copper allowed to cool in a vacuum; this gave a more continuous cylinder. It was found best to fuse the copper under borax, it having been previously reduced; a good cylinder of the metal was thus obtained.

I was unfortunately not able to draw down the copper for myself; this was very kindly done for me by Messrs. Smith, of Halifax, and Messrs. Johnson and Matthey. The porcelain tubes had been prepared of such a size that the cylinder of copper could be drawn without further heating; the copper, therefore, was not fused after it left my hands. Two sheets of the electrolytically prepared copper were fused down on different days, and one was sent to Messrs. Smith to be drawn, and the other to Messrs. Johnson and Matthey. Wires IX. were drawn by Messrs. Smith, wires X. by Messrs. Johnson and Matthey.

Wire XI. was drawn by Messrs. Johnson and Matthey from a sample of copper which I prepared by electrolysis, from a pure solution of copper sulphate; the copper was deposited on a plate of copper, which had had its surface rubbed over with graphite; by this means the deposited copper was easily stripped off the plate, the other plate was of platinum, after a time the solution was changed; the deposition was very slow, as it was thought that there would be less likelihood of copper sulphate getting in between the layers of copper. The deposit was boiled with dilute sulphuric acid and then in water, and was afterwards fused down as above described. Wires IX. were measured as received, this accounts for the close agreement between the two determinations. Wires X. and XI. I had to draw down further to measure them on my bridge. Wires X. (2.) and XI. were drawn down with great care and not so much as X. (1).

Resistance of Various Specimens of Wire.

Wire.	Date.	Resistance of a wire such that 1 metre weighs 1 gramme at 18°C.		Specific gravity.	Specific resistance per cc. at 18°C.

Matthiessen's value reduced to 18°, using his own coefficient.		1571	...	not given	1766·6	As calculated by Fleming, Jenkin & Fitzpatrick.

Below is a table of the measurements made for the determination of their specific resistances:—

Wire.	Value of 1/3.	Temp.	Weight of wire.	Length of wire for determination of resistance.	Length cut and weighed	Resistance of gramme per metre.		Density.	Specific resistance.
IX. (1.)	·28547	17·9°	20·388	192·1	192·5	1574	18·3°	8·90	1766
„ (2.)	·28541	17·4°	20·153	192·4	190·45	1569	17·5°	8·90	1766
X. (1.)	·28550	18·2°	19·708	189·3	188·8	1577	18·6°	8·91	1767
„ (2.)	·28536	16·8°	20·252	192·39	192·34	1561	17·1	8·92	1751
XI.	·28535	16·7°	20·262	192·11	192·51	1563	17·2°	8·93	1760

These values reduced to a common temperature of 18deg. are:—

IX. (1)	·1572	
IX. (2)	·1572	Mean value
X. (1)	·1573	·1571
X. (2)	·1569	B.A. units.
XI.	·1569	

Thus ·1571 B.A. units is the resistance of a metre of hard-drawn copper wire at 18deg. weighing 1 gramme.

Digitized by Google

Matthiessen in the B.A. Report* gives as the resistance of a gramme metre at 0deg. ·1469 B.A. units. I have calculated from this the value at 18deg., using the temperature coefficient that he gives in his Paper on the influence of temperature on the conducting power of metals. I have taken no account of the terms in t^2, as they practically cancel one another.

$$R.\ (\text{at } 18°) = R_0\ (1 + ·0038701\ t)$$
$$R.\ (18°) = ·1571.$$

This is the same value that I have obtained as the mean of my own observations.

All my observations were taken at the temperature of the room, and in the table above the values for the different wires are given at the observed temperature, and then all reduced to a common temperature of 18°C. Most observations of this character are taken at the temperature of 0°C., but on the whole it seemed more satisfactory to work at the temperature of the room. In the comparison of the B.A. units I have found that with a difference of temperature between coils which are connected by thick pieces of copper there is always conduction of heat, and it is impossible to tell accurately what is the real temperature of the coils.

My observations were made in the B.A. room at the Cavendish Laboratory, which has a north aspect, and often the temperature does not alter more than a few tenths of a degree, whilst the temperature of the coil baths often remains perfectly steady for several consecutive days. I cannot find any observations of Matthiessen's at 0°C; certainly his observations on copper were made at 18deg., and, consequently, if the value given by him at 0°C. has been obtained by the use of a temperature coefficient, my value might be expected to agree with his at 18deg., the temperature of his observation, supposing the samples of copper of the same character.

Matthiessen's results are given in terms of a gramme per metre, also for wires of metre length and 1 mm. in diameter. In his Paper in the *Philosophical Magazine* above referred to Matthiessen gives us the value for hard-drawn copper in these terms as,

·02104 B.A.

From his value for the gramme metre, using the specific gravity 8·95 given by tables, the same quantity was calculated but gave the result ·0209; in a note added, he states that had he used the specific gravity 8·91, his results would have been more nearly alike; a specific gravity 8·90, I find, would give an almost identical value.

This would show, then, that Matthiessen's own table calculated for values obtained by comparison with hard-drawn silver is accurate; I have tested silver wires, but have not had time to draw up the results in tabular form; and I obtained an almost identical value for hard-drawn silver wire, as supplied me from Messrs. Johnson and Matthey, as is given by Matthiessen for the resistance of a gramme per metre.

It will be observed that wires IX. have the specific gravity 8·90, and give a value in terms of B.A. units for a cubic centimetre of the material identical with Matthiessen's value; this value is not given directly by Matthiessen, but is calculated from his results by Fleming Jenkin, and given in his table in his book "Electricity and Magnetism," it is 1652. I have calculated it from Matthiessen's value given in the *Philosophical Magazine*, and get the number 1653. Using the same temperature coefficient as before, the resistance of a cubic centimetre of hard-drawn copper is 1766·6. On comparing the values for wires IX., X., and XI. in these terms, the results do not agree so well together as when expressed in terms of the gramme metre; there is a corresponding difference in the values of the specific gravities, these latter have been very carefully determined, repeated with the results given. Wires, therefore, of the same resistance expressed for grammes per metre may give a very different result, when expressed as per cubic centimetre; attention has been drawn to this fact in the discussion on the Elmore copper in *The Electrician*.† M. Roux, of Paris, in a letter gives the following table for high conductivity wire, from a paper of M. Hospitalier in *l'Electricien*, 1887; this paper I have, unfortunately, not been able to see.

Density	8·897	9 32	9·6
Conductivity equal volume	102·4	106·7	110·8
Conductivity equal weight	101·7	101·2	101·6

What is 100 in the conductivity units is not expressed. M. Roux thinks that the former is the more rational method of expressing the result, *i.e.*, for one of equal volume.

Matthiessen expressed all his results in terms of equal weight, justifying it by the greater accuracy obtainable when working with small weights of wires. Small errors in the value of the specific gravity are easily made, and cause a similar error in the result for equal volumes of different wires; unless working with long lengths of thick wire the weight of the wire is small, and the weight of the water displaced cannot be determined within ·5 to 1 milligramme, and that only with care; this error in ·5 of a gramme means only an accuracy of 1 in 500. The values given in my table are probably correct to 1 in 1,500 or 1 in 2,000, as the weight of water displaced was in all cases over 2 grammes. Results, therefore, for resistances of wires of equal weight are the most trustworthy, and, I think, also the most satisfactory if used to express the resistance of a material and not of any given wire.

Wires X. (1) and X. (2) are of the same copper, but drawn down separately; X. (1) was beginning to fray, and another specimen of the same copper drawn down still further had on this account to be rejected; this has effected the resistance value expressed in both ways. Thus

X. (1)	1573	.....	1767
X. (2)	1569	.....	1751

but much more so when expressed for equal volumes. In both the copper is of the same quality.

It will be noticed that with increase of specific gravity there is a decrease of resistance, even when the results are expressed for wires of equal weight; the resistance diminishes, therefore, more rapidly than the density increases. Wires, therefore, of the same quality may, in consequence of a difference in drawing, have a different density, and so the results expressed in terms of equal volume will differ considerably; while those for equal weight are the same, or approximately so.

The values obtained for IX., X. and XI. are so nearly identical that it is not unfair to conclude that they are samples of pure copper; their value is identical with that obtained by Matthiessen at, I believe, the same temperature. The greater difference obtained at 0°C. between Matthiessen's value and samples of copper tested now at that temperature, is probably due to the fact that Matthiessen's value was not determined at 0°, but reduced in value for that temperature from observations, as stated above, at about 20°C.

The higher conductivity or less resistance for the two samples given in the table is due not to increased purity in the preparation of the copper, but in the difference in the process of preparation, whereby a sample of greater density is obtained than results from the working up of small quantities of copper in the laboratory.

A sample of copper has been prepared by chemical means with the help of my friend, Mr. Skinner, but has not yet been measured.

Sparks from Belts.—An interesting note comes from a correspondent of the *Electrical World* in Woonsocket, R.I. Some time ago there was trouble with one of the arc machines in use, and after a careful investigation by the electrician, it was found that the static discharge from a belt to the frame, and thence to the armature, perforated the insulation so that the machine current had followed it and burned out the armature coil. The trouble once found, a very simple and effective remedy was employed. Grounded rods were bent from the pulleys so as to take the static discharge from the belt. It is well known that a powerful spark can be obtained from belts under certain circumstances, but this is a remarkable instance of its effect,

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xv.) are accepted up to 5 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1890 Edition consists of about 850 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

Orders for the 1890 issue should be forwarded AT ONCE *to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.*

ELECTRICAL BOOKS AND PUBLICATIONS.

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

DISTURBANCES ON TELEPHONE AND TELEGRAPH LINES.

The interference of inductive and stray currents on telephone and telegraph lines is a difficulty which has sufficiently asserted itself, but which is at present "nobody's business" to remedy. Vested interests are so often synonymous with selfish obstruction, and have in most cases to be fought by the interested minority in so unpleasant a fashion, that efforts to uphold them meet with little sympathy from the general public. We do not see at present how the difficulties which have already cropped up are to be most economically and equitably met; and it is somewhat doubtful if the metallic return which was pronounced to be an effectual cure by General WEBBER in the discussion, at Leeds, on the Lineff tramways, and which it was hinted would speedily be adopted by the telephone companies, will prove to be so complete as could be desired.

The paper by Dr. LOUIS BELL, of which an abstract will be found in another column, sufficiently indicates that a metallic return in a tramway system will not necessarily remove the evil, though it may be presumed that both the railway and the electrical authorities of the Board of Trade will take care that, as far as actual leakage is concerned, we shall have less cause for complaint than our American friends. But as far as the Board of Trade rules have gone at present the first consideration is the security of the public from shocks, and it was from this point of view, we believe, that the Northfleet line was passed by Major CARDEW. The Postmaster-General has a voice in the matter, and all regulations of the Board of Trade are submitted to his scientific adviser, who is fully alive to the difficulties which have already arisen in connection with Deptford and other experiments, and who has protected the postal telegraphic service, not only by means of these regulations, but by very general and comprehensive clauses in the Provisional Orders. The magnitude of a disturbance which would not appreciably effect an ordinary

Digitized by Google

even a refined and delicate form of duplex telegraph line might have most serious effects on a telephone circuit, and every London subscriber is already aware that cross-talk and innumerable varieties of buzzing and humming even now seriously detract from the value of the telephone service in the metropolis.

The Post Office, having as yet done little else in telephony than to provide a pattern service in a single town, it cannot be expected that the regulations and clauses which have been drawn up for the protection of its lines will be used for the benefit either of the telephone companies or of their subscribers. If the telegraph lines of the Post Office are affected by induction from neighbouring circuits used for industrial purposes, or are disturbed by stray leakage currents, the effects, if objectionable, will also be measurable; and if measurable, there will be but little difficulty in determining the nature of the disturbance, and in detecting the exact cause. But buzzing on a telephone line may be sufficient to render conversation impossible, and yet the currents which produce it may be of an order of magnitude that would tax even the measuring powers of Mr. Vernon Boys. A simple case was discussed in our columns some time ago (see *The Electrician*, November 9, 1888), in which a distinct note of a more or less musical, but none the less undesirable character, was heard on a private city telephone line. Neither the line nor the instrument which caused the noise could be discovered for some time, since the only knowledge that could be obtained about it was the period of the vibration and the time of day at which it occurred. A buzz or hum in a telephone is generally the result of a minute current or succession of currents, which are otherwise utterly inappreciable, and there is no evidence to produce about such a nuisance than that, at a certain time of day, conversation between certain individuals by means of certain telephonic apparatus is rendered difficult or impossible. Such a nuisance would be considerably more difficult to prove than the obstruction of ancient lights or production of noxious vapours. Even the crowing of a cock has been held to be a nuisance, but the actual cock had an existence, and could be fully described in the indictment. A humming in a telephone is *vox et præterea nihil*. There is no doubt but that a noise which is highly objectionable to one person causes but a slight inconvenience to another, and without some measurement it will be difficult to say when a disturbance on a telephone circuit begins to become a nuisance.

The idea of the right to use the earth for a return circuit on account of prior use, thus constituting a vested interest, was not only set up but was seriously contested only a few months ago. The comprehensiveness of such a claim is rather difficult to conceive, and it is quite impossible to tell how such a notion will strike the legal mind in this country. The matter has come to the front so recently that we are at present without evidence as to the nature or degree to which these disturbances are likely to exist. The case described by Mr. Cuttriss, in which the cable of the Commercial Cable Company was affected by an electric railway running parallel to it, is probably an extreme one, although only one line was disturbed. The other cases mentioned by Dr. Louis Bell are not so formidable, and when further accounts of similar instances have been collected with numerical details, we shall be in a better position to judge whether our telephone systems are likely to be seriously affected by the growth of electric lighting and transmission of power, or whether such interference will be rare. A simple formula could be easily given on the basis of the factors given in Dr. Bell's Paper, omitting, however, the periodicity of the disturbing current, since this will affect the quality and pitch of the noise only if the alternations be sufficiently rapid to produce a musical note. But before we can use such a formula, it will be necessary for us to know more exactly than at present the magnitude of the currents which are audible in a telephone.

It might be advisable if only for the purpose in question, though the general importance is obvious, that we should have some further knowledge of the actual strength of telephonic currents. The experiments of Mr. Preece are almost our only source of information, and the method by which they were arrived at is open to several objections. We should have some easily reproducible micro-milli-ampere, or whatever else the word-coiners may call it; we might then perhaps balance these disturbances by a small measurable current of a similar period, and thus determine their value. From continuous current supply, whether with batteries or without, there is not much probability of disturbance. Electric lighting circuits can do no harm, motor circuits may have a slight effect if frequently switched on and off, and tramway lines, owing to imperfect contacts and the changes of position of the points of contact, have already given rise to very perceptible effects. For alternating current supply we fear a new difficulty is thus presented; but we are sure that the combination of science and good engineering will find a remedy for ordinary work, and it is to be hoped that accidental leaks will be as rare in the future as in the past, so as to make unnecessary any special precautions on this score. For the telegraphs we have nothing to say; they are fully protected by the Board of Trade and Provisional Order regulations. The only parties with whom we really sympathise are subscribers to telephone exchanges.

ON THE VALUES OF CERTAIN STANDARD RESISTANCE COILS.*

BY R. T. GLAZEBROOK, F.R.S.

The B.A. Unit Standards.

The Standard B.A. units of the Association have during the year been several times compared together both by the Secretary and by Mr. Fitzpatrick. Table I. gives the results of two sets of comparisons made in August, 1890. The differences between the various coils and the platinum silver standard Flat are given in the third column in bridge-wire divisions. One bridge-wire division is very nearly ·00005 B.A. unit.

Table I.—*Resistance of the B.A. Standards, August, 1890.*

Coil.	Temperature.	Difference between each coil and flat in bridge-wire divisions.		Observed calculated.	Change of resistance per 1°. C in b.w.d.
		Observed Aug. 15, 1890.	From chart 1888.

* Paper read before the British Association in Section A, Leeds, September, 1890, being an Appendix to the Report of the Committee on Electrical Standards.

Digitized by Google

In the fourth column are given the corresponding differences obtained from the chart made in 1888. In the next column will be found the differences between the observed values and those given by the chart, while the sixth column gives the change in resistance for 1° C. for the various coils. It will be seen that for the first five coils the differences between observation and the chart are such as would be readily accounted for by a small error in the temperature, and we may say that there is no evidence of a change in the resistance of these coils relative to Flat. This conclusion is borne out by the results of a series of observations made in January and February by Mr. Fitzpatrick. But when we come to the three platinum silver standards, F, G, H, the results are at once seen to be quite different. Thus F would appear to have risen relatively to Flat by about 12·5 bridge-wire divisions, while G and H have fallen by 4 and 2·5 divisions respectively.

Since these are the most important standards, their temperature coefficients being all very small, it was necessary to examine their history with some care. A change in F had been noted in a postscript to the Report for 1888. The general conclusions of that Report were that up to the summer of 1888 there had been no change in the value of the coils. It was shown that all the original platinum silver coils examined then—those of Messrs. Elliott, H. A. Taylor, and others, as well as those belonging to the Committee—had apparently fallen in value relatively to the mean B.A. unit by about ·0007 B.A.U. since 1867, but evidence was adduced to show that the fall was only apparent and was due to an error in the temperature coefficient used at that date. A single observation of Chrystal in 1876 pointed to the possibility of a change in F, but that change was not confirmed by other evidence; while so far as the platinum silver coils were concerned, the observations of Dr. Fleming in 1881, and myself in 1888, agreed closely.

Since 1888, however, changes have shown themselves.

These are evidenced by the three following tables II., III., and IV., which give the differences Flat-F, Flat-G, and Flat-H respectively.

Table II.—*Value of* Flat-F.

Aug. 29, „	16·4	18·2

The three first lines in each table give the differences at the temperature shown taken from the chart drawn in 1888; the remaining lines give the differences actually observed, with the dates and temperatures. Thus, taking the various coils, it is clear that while up to May, 1888, the difference between Flat and F remained the same as shown by the chart and observations up to that date. A change took place during the low temperature observations in July, 1888, while by the time the coils were again examined in January, 1890, a further change had manifested itself. This continues up to the present date, so that now at temperature of about 15deg. the coil F has increased in resistance relatively to Flat by about 12·7 bridge-wire divisions. This, assuming the whole change to be in F, will correspond to a rise of resistance of ·00063 B.A. units, or in other words the temperature at which the coil is right has fallen by about 2°3. In January, 1890, the coils were again exposed to a low temperature, and it seems probable that the changes took place when the coils were in ice.

Turning now to Table III., which gives the values of Flat-G we see there is no evidence of change till May, 1890. The observations in July, 1888, and January and February, 1890, are quite in accordance with the chart, but in May, 1890, it is clear that G has fallen relative to Flat.

The value of the difference at a temperature of 16deg. is 22·1 b.w.d. as against 18·1 given by the chart. Thus G has fallen relatively to Flat by 4 b.w.d., or ·0002 B.A. units. This change was first observed after the coils had been exposed to a low temperature.

With regard to H the change first showed itself during the low temperature observations in January and February, 1890, and Table IV. indicates that the difference between Flat and H is now 17·5 divisions as against 15·5 in 1888, or in other words, that G has fallen by ·0001 B.A. unit. Also since Flat-F changed in 1888, while Flat-G and Flat-H did not, we infer that the change at that date was in F, not in Flat, while since Flat-H changed in January, 1890, without a change in Flat-G, it appears that the change was in H, not in Flat; and finally, from the observations in May, 1890, which show a change in Flat-G, but none in Flat-H and Flat-F, we infer a change in G.

As to the cause of these changes, we can say but little. We hope to investigate them more completely by the aid of the coils lent by Mr. H. A. Taylor and others, and referred to in the 1888 Report; but it seems possible that they are due to strains set up in the wire by the great contractions and expansions produced by cooling and heating in the paraffin in which the coils are embedded. The coil Flat is of a different shape to the others and little or no paraffin has been used in its construction. The other coils, F, G, H, are embedded in paraffin in the usual way. On cooling down to 0°, this shrinks greatly, and it is quite conceivable that this shrinkage may have strained the coils and so caused the change. We hope to test this by having coils made free from paraffin and investigating with them the effects of repeated heating and cooling. The fall of H and G would be accounted for by a loss of insulation causing a slight leak either from the wire to the case or across the surface of the paraffin. The insulation resistance for F, G, H, was therefore tested and found in each case to be several thousand megohms, while the surface of the paraffin, which had

Digitized by Google

become dirty with time, was scraped, but without producing any change in the resistance. A leak, of course, would not produce the rise found in F.

Observations of the coils at 0° have always been unsatisfactory and attended with considerable difficulty. This is mainly due, I believe, to the fact that the temperature of the room in which the observations have been made has usually been above zero, and that heat is conducted into the coils by the thick copper connecting rods. It would seem possible, however, that part of the difficulty (*See* Report of the Committee for 1888, Table VII.) may have been due to real changes in the resistance arising from strains set up by the cooling.

The Legal Ohm Standards.

The results of observations on the legal ohm standards of the Association are given in the Report for 1886. Experiments made in these between July, 1884, and January, 1886, showed that while one coil, C.L.C. 100, had retained its value unchanged, the other, C.L.C. 101, had varied. These observations have been continued, and the results are given in the following tables, which give the value of each coil as found by direct comparison with the standard B.A. units, and its value as given by the chart in 1886.

Table V.—*Results for C.L.C. 100.*

Date.	Standard used in comparison.	Temperature.	Value.	Value on Chart.	Difference.
Feb., '87	F	16·3	1·00009	1·00008	·00001
Nov., '89	G	15·8	·99997	·99996	·00001
"	"	14·8	·99971	·99968	·00003
"	"	16·0	·99998	1·00000	·00002
Dec., '89	Flat	14·4	·99962	·99959	·00003
"	"	14·8	·99969	·99968	·00001
"	"	13·2	·99925	·99924	·00001
...	...	6·2	·99744	·99735	·00009
...	...	5·7	·99729	·99720	·00009

Table VI.—*Results for C.L.C. 101.*

Date.	Standard used in comparison.	Temperature.	Value found.	Value on chart in '85, '86	Difference.
Feb., '87	F	16·3	·99970	·99930	·00040
Nov., '89	G	15·9	·99955	·99920	·00035
"	"	15·1	·99932	·99899	·00033
"	"	16·0	·99955	·99922	·00033
Dec., '89	Flat	14·4	·99909	·99880	·00029
"	"	15·0	·99925	·99897	·00028
"	"	13·3	·99879	·99850	·00029
...	...	7·6	·99725	·99695	·00030
...	...	6·5	·99701	·99668	·00033

These tables show three facts conclusively: (1) That up to December, 1889, no appreciable change had taken place in the relative values of C.L.C. 100—the Legal Ohm Standard—and Flat or G; (2) that between January, 1886, and February, 1887, C.L.C. 101, which had varied previously, changed by about ·0004 ohms; and (3) that the greater part of that change has remained permanent up to December, 1889. At present the difference between C.L.C. 100 and C.L.C. 101 is about ·0004; in 1886, it was about ·0008. The agreement between the observations in November and December, 1889—in one set of which Flat was the standard of comparison, while in the other G was used—show that the relative change in G and Flat took place after this date.

A COMPARISON OF A PLATINUM THERMOMETER WITH SOME MERCURY THERMOMETERS AT LOW TEMPERATURES.*

BY E. H. GRIFFITHS, M.A.

The Paper describes the mode of constructing an air-tight platinum thermometer for use at low temperatures. The thermometer was graduated by means of the freezing and boiling points of water, and as regards intermediate points Regnault's determinations of the temperature and pressure of aqueous vapour were adopted. The curves, showing the result of comparison with a number of thermometers standardised at Kew, are in remarkably close agreement.

In a communication* to the Royal Society read on June 19, 1890, a method was described of constructing and graduating platinum thermometers and a table of boiling and freezing points for various substances lying between 100deg. and 500deg., determined by means of these instruments. I was unable to discover any suitable non-conductor capable of resisting high temperatures; but in anthracene (melting point 213deg.) I found a substance suitable in every respect for use at low temperatures. I subjected a sample to severe tests, and, up to a temperature of about 130deg., found it to be a better insulator than paraffin. The leads to the coil were constructed of silver, the inner one a rod and the outer a tube. The resistance of these leads was about ·001 ohm, and, therefore, any change in the external resistance, caused by change of temperature, might be disregarded. The wire forming the coil was about 56in. in length, and had a diameter of ·005in. The spiral was about 1½in. long, having a resistance of about 13·5 ohms at 0°C., and the external diameter of the covering tube was about ·3in. The ends of the asbestos roll were made of greater diameter than the portion on which the spiral was wound, and thus there was no glass contact. The tube and contents were heated up to a temperature of several hundred degrees, and dried air passed through it for some hours. It was then exhausted and the open end placed under the surface of melted anthracene, which was allowed to rise until nearly in contact with the coil. When cool, the whole of the thermometer, from the spiral to the upper end (about 13in.) was a solid mass, while the spiral and asbestos roll were perfectly dry and in an almost vacuous space. When the lower part was undergoing rapid changes in temperature, thermo-electric effects showed themselves, but by reversing the battery and galvanometer connections during each reading these effects were eliminated. A low-resistance galvanometer was used, and the current, which passed through the thermometer when determining its resistance, did not exceed one hundredth of an ampere.

The expression for the platinum temperature by this thermometer was

$$\frac{(R - 13{\cdot}5219)}{4{\cdot}6811} \times 100, \text{ again } \frac{R_{100}}{R_0} = 1{\cdot}3462,$$

almost exactly agreeing with the coefficient of the wire in Mr. Callendar's air thermometer (*Phil. Trans.* A 1887).

Mr. G. M. Clark now joined me, and as we proposed to use this thermometer for the calibration and graduation of mercury thermometers between 0deg. and 100deg., we decided to obtain intermediate temperatures by means of Regnault's numbers connecting the temperature and pressure of aqueous vapour.

The extremities of the curve at 0deg. and 100deg. having been determined, it was only necessary to get points between 30deg. and 80deg.

Ninety observations were taken, and although occasional divergences presented themselves, the mean path gives a curve which we believe to be within less than ·02deg. of the true path at all points. It agrees closely with the curve obtained by Mr. Callendar from the parabola $1{\cdot}57\left[\left(\frac{t}{100}\right)^2 - \frac{t}{100}\right]$, by measuring one-tenth of the ordinate along the abscissa.*

The following equation, however, represents its path more accurately.

$y = {\cdot}018795t - {\cdot}0001991t^2 \times {\cdot}000{,}000{,}111{\cdot}5t^3$; the curve itself is shown in Chart A.

The results of comparison with thermometers standardised at Kew show:—

1. That thermometers whose range does not include 0deg. and 100deg. may have certain fixed points determined by this method.

2. That an actual calibration of a mercury thermometer can also be readily accomplished.

* Abstract of Paper read before the British Association in Section A, Leeds, September, 1890, being an appendix to the Report of the Committee on Electrical Standards.

* It must be remembered that Callendar's difference curve gives the connection between platinum and air-thermometer temperatures, whilst Regnault used a mercury thermometer (M.A.S. XXI.), and thus curve A gives the relation between platinum and mercury thermometer temperatures.

Digitized by Google

3. That the platinum thermometer, properly constructed, may serve as a standard by which to trace the changes which may take place in mercury thermometers.

4. That since the readings of the platinum thermometer are independent of the extent of the stem-immersion, it can be conveniently employed for the graduation of thermometers partially immersed, as in ordinary use.

We have calibrated about twenty thermometers by this method, and we believe the results to be satisfactory in all cases.

ON THE AIR CONDENSERS OF THE BRITISH ASSOCIATION.*

BY R. T. GLAZEBROOK (with a Note by Dr. A. MUIRHEAD).

The question of issuing certificates of capacity has from time to time been discussed by the committee. The following Paper gives an account of some experiments that have been in progress during the past two years with this object in view.

In the report for 1887 the committee express the opinion that it is desirable to proceed with the construction of an air condenser. In conformity with this opinion, a meeting was held in London, at which Dr. A. Muirhead exhibited an air condenser consisting of a series of concentric brass cylinders insulated by glass rods, which appeared to the committee to possess great merits; and it was decided that the secretary should test this and two similar condensers which Dr. Muirhead offered to lend, before proceeding further with the construction of condensers for the Association. The tests were carried out with satisfactory results.

The capacity of each condenser was determined repeatedly, using the method of a vibrating commutator, due to Maxwell, already employed by J. J. Thomson, *Phil. Trans.*, 1883, and Glazebrook, *Phil. Mag.*, August, 1884. The values found were :—

$$C_1 = \cdot0030514 \text{ microfarads.}$$
$$C_2 = \cdot0031258 \quad ,,$$
$$C_3 = \cdot0033288 \quad ,,$$

It was found that the capacities remain constant from day to day, and that the accuracy of a single determination was about 1 in 1,000, although the capacity to be measured was so small.

A mica condenser belonging to the Cavendish Laboratory was compared with these—details of the method will be given shortly—and it was found that when comparing a condenser of one microfarad with the three air condensers, having thus a combined capacity of ·009506 microfarads, so that the ratio of the two was about 100 to 1, an accuracy of about 1 in 1,000 was attained. It was also shown that the capacity of the mica condensers as thus found, differed by nearly 2 per cent. from its value as determined by the rapid commutator, thus proving that the commutator method was unsuitable for a condenser showing absorption.

Thus, for three mica condensers, the following values were found :—

With commutator.	By slow method of comparison.
·9690	·9868
·4934	·4994
·09543	·09644

These results make the necessity for an air standard all the more apparent. A report on the experiments, made up to that date, was laid before the committee at a meeting in London, in April, 1889. It was then decided to adopt Dr. Muirhead's form of condenser, and to have two made on the same pattern for the Association. These have been constructed by the Cambridge Scientific Instrument Company, following Dr. Muirhead's plan, but on an enlarged scale. Each has a capacity of about ·02 microfarads, or about six times that of one of the original condensers.

Fig. 1 shows the arrangement.

The condensers consist of 24 concentric tubes; the outer tube is about 2ft. 9in. high and 6in. in diameter. Each succeeding tube diminishes in diameter by half an inch; the tubes are about $\frac{1}{32}$nd of an inch in thickness, and the air space between the inside of one tube and the outside of the next is about $\frac{3}{32}$in., but it was found impossible to get all the tubes of exactly the same thickness, so that in some cases the distance between the tubes is less than the above. These tubes are carried by two conical brass castings; the outside surface of each casting forms a series of twelve steps, over which the successive tubes fit. Each

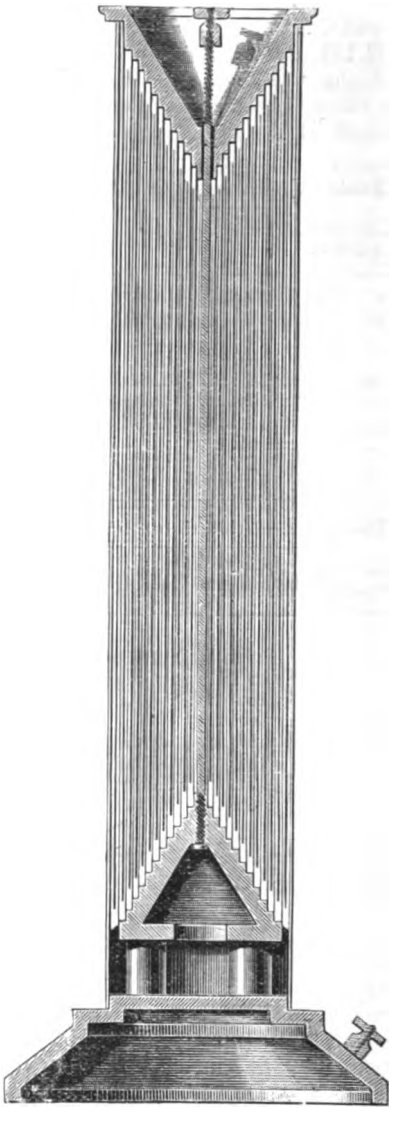

FIG. 1.—Section of a Muirhead Standard Air Condenser constructed by the Cambridge Scientific Instrument Company.

tube is held in position by screws. The upper cone is supported by the outside casing of the condenser, and twelve of the tubes hang vertically from it. The lower cone is carried by three ebonite pillars, about 3in. in height; the twelve tubes which are attached to it come respectively between those which are suspended from the upper cone. Thus the insulation depends on the ebonite pillars, assuming there is no leakage across the air from the edges of the tubes. There is an opening in the outer casing, closed by a door, by means of which the ebonite can be cleaned; the whole is dried by placing inside a small vessel of sulphuric acid. In the centre of the upper cone there is a hole through which a rod passes. The rod is connected with the lower cone and forms the electrode for the insulated cylinders. An ebonite plug, fitting tightly round the rod, can

* Paper read before the British Association in Section A, Leeds, September, 1890, being an Appendix to the Report of the Committee on Electrical Standards.

Digitized by Google

be pushed down so as to close the hole and prevent the ingress of dust when the condensers are not in use; when they are being used the plug is removed.

The condensers are placed in the testing-room at the Cavendish Laboratory, and covered by a wood and canvas case to protect them from dust. It is not intended that they should be moveable.

After this description of the condensers, we will proceed to an account of the tests to which they have been subject. The first test was for leakage.

One set of cylinders was put to the earth while the other was connected with a gold leaf electroscope. An attempt was then made to charge them with an electrophorus, or a small electrical machine, but this failed entirely. The electricity either sparked across at places where the tubes were very close together; or, before the potential rose sufficiently to affect the electroscope, small fibres or dust particles which adhered to the tubes formed leaks across; it was clear that the condenser could not be charged to the potential of the machine. Tests were then applied for leakage when the potential was lower. One set of tubes were connected to one pole of a battery—about 36 storage cells were generally employed, having an E.M.F. of 75 volts—the other set being in connection with an insulated key, the second pole of the battery was connected through a galvanometer to the key, and the condenser charged. After an interval, usually about five minutes, contact was again made at the key, the deflection of the galvanometer needle—assuming the E.M.F. of the battery not to have changed—was a measure of the quantity of electricity which had leaked from the condensers in the five minutes.

The amount of leakage was very different in the two condensers, and depended greatly on the dryness of the air and ebonite pillars. Thus, on March 11th, when strong acid had been enclosed for some time, for condenser I., the leak per one minute amounted to about ·1 per cent. of the whole charge, while with condenser II., it was about ten times as great.

The sulphuric acid was removed during the Easter vacation and replaced by calcium chloride, and after this the leak in I. rose to about 1 per cent. per minute or 10 times its former value, while that in II. was from 3 to 4 per cent. of the charge. With the calcium chloride inside the leak was never reduced to less than about ·8 per cent. per minute. In August the condensers having been closed since June with calcium chloride there was a leak in one of about 3 per cent. per minute, while in the same time II. lost about 8 per cent. of its charge.

On August 14th, immediately after this test, the calcium chloride was replaced by sulphuric acid, and the leak was quickly reduced to about 1 per cent. per minute for I. For II., no improvement showed itself at once. The next day the leak in I. was about ·4 per cent. per minute, that in II. had not been greatly reduced. On August 16th the ebonite was, therefore, well cleaned, and air was blown through the tubes of II., and the whole closed for about two hours; the leak had then fallen to about 2 per cent. per minute. By August 18th, the leaks were still more reduced, that in I. being ·2 per cent. per minute, while that in II. was ·6 per cent. per minute.

By the afternoon of this day, the upper parts of the condensers having been open to the air of the laboratory for some six hours during other tests, the leaks had appreciably increased, but they had fallen again the next day when the condensers were left closed during the night.

Thus, during the observations in August, with the exception of those on August 14th, the condenser I. was losing its charge at the rate of about $\frac{1}{500}$th part per 1 minute, while the leakage in II. was some five or six times as great, being about $\frac{1}{100}$th part of the charge per 1 minute.

As will be seen later, several mica condensers were compared with I. and II., the leaks in them were all small, and did not exceed more than $\frac{1}{500}$th per minute.

We come now to the experiments for determining the capacities of the two condensers. Of these, three independent series were made, viz., in December, 1889, May and June, 1890, and August, 1890.

The method, already referred to, was used. Fig. 2 gives a diagram of the method; in Fig. 3, the connections actually employed are shown. With the notation employed, *Phil. Mag.*, August, 1884.

We have, if C be the capacity of the condenser, n the number of times it is charged per 1 second.

$$n\,C = \frac{a\left\{1 - \frac{a^2}{(a+c+g)(a+b+d)}\right\}}{c\,d\left\{1+\frac{a\,b}{c\,(a+b+d)}\right\}\left\{1+\frac{a\,g}{d\,(a+c+g)}\right\}}$$

In most of the experiments about to be described, we had the following values in legal ohms:—

$a = 10$ $\quad d = 1{,}000$
$b = 18$ $\quad g = 17{,}600$

while c, which was the adjustable arm, varied from 6,000 to 15,000.

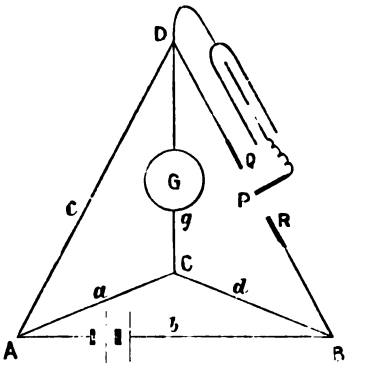

Fig. 2.—Diagram of arrangements for determining the capacities of the Air Condensers.

With these values, the only correction which need be included is the last factor in the denominator, and we may write

$$n\,C = \frac{a}{c\,d\left\{1+\frac{a\,g}{d\,(a+c+g)}\right\}}$$

The resistances were taken from a legal ohm box belonging to the laboratory; the various coils in this box were carefully compared with each other by Mr. Searle, and found to be consistent with each other, at any rate to within 1 in 10,000. The coils were also compared with the standards of the Association, and it was found that at 16° they were greater than

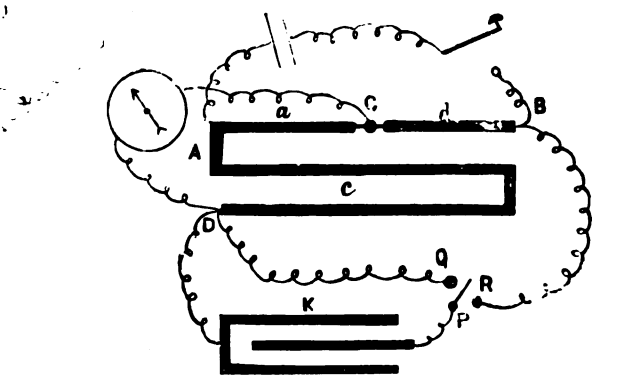

Fig. 3.—Actual connections employed in determining the capacities of the Air Condensers.

legal ohms in the ratio of 1·0011 to 1. The standard temperature adopted in the experiments was 17°, and since the coefficient of increase of resistance of the box is about ·0003 per 1°C., the resistances require to be multiplied by 1·0014, to reduce them to legal ohms. In some cases, in the value of c, coils from a B.A. unit box, containing coils of ten, twenty, thirty, and forty thousand B.A. units were employed.

The values found for these coils by myself in these terms of the legal ohm box showed that they were very consistent with each other, and that the nominal 10,000 B.A.U. was equal to 9,880 legal ohms, as measured by the legal ohm box.

Digitized by Google

In the comparisons of two condensers certain coils from a megohm box were used; the value of each of these was also determined. They were as follows:—

1 ..	98,731	Legal ohms of standard box.
2 ...	98,625	,, ,,
3 ...	98,698	,, ,,
4 ...	98,735	,, ,,
9 ...	98,725	,, ,,
10 ...	98,776	,, ,,

In the experiments on Dr. Muirhead's condensers, the vibrating commutator described in Prof. Thomson's Paper, *Phil Trans.*, 1883; or in my Paper, *Phil. Mag.*, 1884, was used, and that with complete success. In the experiments about to be described, this was replaced by a rotating commutator, which had been fitted up by Prof. Thomson and Mr. Searle for their experiments on the other value of "v," and which possesses certain advantages over the other form. Dr. Muirhead and Dr. Fleming have also used a somewhat similar arrangement of apparatus. Fig. 4 shows the arrangement. The split ring commutator is carried on the axle H K, which is driven by a water motor. Two wire springs, Q R, are in contact with the two halves of the commutator respectively, and as it rotates the brush P, made of very fine brass wire, is brought into communication alternately with Q and R. The disc, L, M, was of iron, and its mass helped to steady the motion. On one face of the disc a series of circles were drawn forming a number of

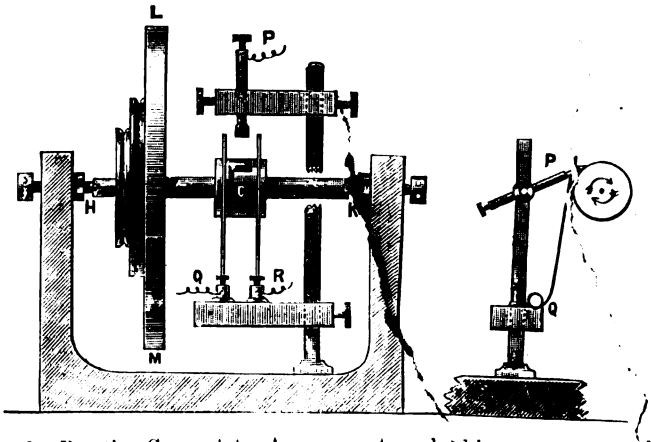

Fig. 4.—Rotating Commutator Arrangement employed in connection with the determination of the capacities of the Air Condensers.

annuli. The successive annuli were divided each into a different number of divisions by radial marks. Thus in the innermost annulus there were four, on the next five, and so on. The disc as it rotated, was watched in the usual stroboscopic manner through two slits on two pieces of thin metal carried by the prongs of a tuning fork, which made about 64 vibrations per second.

When the frequencies of the disc and of the fork were in certain simple ratios to each other, the corresponding pattern on the disc was seen in a steady position. The driving pulley of the motor carried a second band, which passed over an idle pulley near the observer at the tuning fork, and the speed of the motor and hence of the disc was partly adjusted by varying the flow of water, partly by friction on this band until the desired pattern was seen in the steady position; this position was easily maintained by varying the friction on the string. The tuning fork drove a second fork an octave above itself in frequency. This fork was mounted near the standard fork of the Laboratory, and the beats between the two were counted. The frequency of the standard fork was determined by Prof. Thomson and Mr. Searle for their experiments on "v" recently communicated to the Royal Society. They found that it had changed slightly since it was determined by Lord Rayleigh, and give as the result of their experiments, frequency at temperature $t°$

$$= 128{\cdot}105\,\{\,1 - (t - 16)\,{\cdot}00011\,\}$$

The driven fork was always adjusted to a slightly lower frequency than that of the standard, so that there were about 20 beats to the minute between the two. During any series of observations 10 beats were repeatedly counted, but they rarely varied during the series sufficiently to affect the result. The commutator was designed and partly constructed by Mr. Searle, who observed at the tuning fork throughout. A little attention was required to secure good contact between the springs, Q, R, and the rotating parts, and also to adjust the brush, P, but with moderate care in the adjustments the apparatus worked perfectly.

The galvanometer was one constructed in the laboratory; it had a resistance of 17,600 ohms, with a long silk fibre suspension— a quartz fibre would have been an improvement.

Its sensitiveness was such that 1 scale division corresponded to $\cdot 83 \times 10^{-10}$ C.G.S. units of current; the time of swing was 7·2 seconds, so that the sudden discharge through the galvanometer of 10^{-10} C.G.S. units of electricity produced a throw of one division, or, in other words, the quantity which, when discharged suddenly through, gave a throw of γ divisions, $\gamma \times 10^{-10}$. This was determined by discharging through the galvanometer a condenser of capacity ·1 microfarad when charged to 1 volt, the throw observed was 100 divisions, while the steady current due to an E.M.F. of ·001 volt produced a deflection of 72 divisions.

The observations were made by varying c. There was a commutator in the battery circuit; in each position of this commutator two values of c were taken and the corresponding resting points of the spot on the scale observed. From these the value of c, which corresponded to the zero position of the spot, was obtained by interpolation.

These observations were made twice for each position of the commutator and the mean taken.

We will give one series as an example:—

August 27, 1890.
Temperature of standard fork, 23·8°
Beats..... 20 in 65·4 sec.
20 in 65·2 sec.

Condenser No. I.

Frequency, 80 approximately.

Position of Commutator.	Zero Reading.	Resistance.	Resting Point.
/	48	5890	47
		5880	51
\	48	5880	46
		5890	49
/	48	5890	48
		5880	51
\	49	5880	46
		5890	50

Temperature of coils, 17·5deg.
Beats 20 in 64·8, at 19·3deg.

It will be seen that between the third and fourth series the galvanometer zero has shifted slightly.

From these we get as the four values of c the following:—

5887·5
5886·6
5888·3
5887·5

Mean 5887·5 at 17·5
Correction to 17° ·9

Value C = 5888·4 at 17°

while the beats are 20 in 65 seconds at 19deg. or ·307 per 1 second; at 19deg. the frequency of the standard is 128·066, thus the frequency of the driven fork is 128·066 – ·307, *i.e.*, 127·759. Thus for the driving fork we have the octave below this, or 63·879, while the frequency of the commutator is 5/4 of this.

Hence in this series

$$n = 79{\cdot}849 \qquad c = 5888{\cdot}4$$

The accuracy attained in this series is a fair specimen of the whole.

With these explanations we proceed to give the results in tabular form, showing the date, the values of n and c, and

Digitized by Google

the resulting value of C. The wire by which the condenser was connected to the commutator, together with the commutator itself, had a certain capacity which was determined in the same way, merely disconnecting the wire from the condenser. In the observations in December and June we found

$$a = 10 \quad d = 98{\cdot}730 \quad c = 28{\cdot}460 \quad n = 63{\cdot}9$$

whence the capacity of the wires is ·0000625 microfarads; while in August, after the apparatus had been set up afresh in a different position with new connecting wires, the value of c was 22,200 and the capacity ·0000799 microfarads; for the wires, the values of c could be determined to about 1 per cent.

In the table the value of C has been corrected for the capacity of the wires.

32	...	·09642	...	·09642
64	...	·09634	·09612	·09638

Taking the air condensers first the tables show that, at any rate for frequencies between 32 and 80 per second, the time of charging has no effect on the capacity, while the individual observations in each series are within 1 in 2,000 of each other.

For Condenser I. the observations at frequency 64 are in all the series the least, but this is not the case with Condenser II.

The capacity of condenser I. shows no change between December, 1889, and June, 1890. The observations in August, 1890, are all rather greater than the earlier series, but the increase about 1 in 2,000 is almost within the error of the experiments. With regard to Condenser II. there is an indication of a rise in its capacity all through. It will be remembered that we have already shown that the insulation resistance of II. is considerably less than that of I.; but it is easy to see that this leak was not sufficient to account for the change, for if R be the resistance of the leak, then our approximate formula becomes

$$n\,C + \frac{1}{R} = \frac{a}{c\,d} \text{ instead of } n\,C = \frac{a}{c\,d}.$$

Now, the current through the Condenser when leaking most was about ·0002 EC, where E is the E.M.F. to which it is charged and c the capacity of the condenser.

Thus the resistance of the leak is $\frac{1}{\cdot 0002 \times C}$ or $\cdot 25 \times 10^{21}$ C.-G.-S. units, since the value of C is $\cdot 02 \times 10^{-15}$. This resistance is 250,000 megohms.

Hence the correction to the capacity $= 1/n\ R = \cdot 0002 \times C/n$, and this is far too small to affect us.

There is no doubt, then, that the capacity of II. altered during the experiments by about 1 per cent., and it will be necessary to take it to pieces and set it up again.

It will be remembered that, in the early part of August, the leak in II. was very great, and it seems probable that the steps taken to discover the cause of the leak have produced a change in capacity. The experiments on II., then, serve merely to show that the capacity can be found by the rotating commutator method to a high degree of accuracy, while those on I. prove that an air condenser, of ·02 microfarad capacity, has been constructed which has retained its capacity unaltered for the eight months between January, 1889, and August, 1890.

The effect of the leak in Condenser II. was still further investigated on August 28th. The plates of II. were connected by a resistance of 30 megohms. Hence the correction to C, which is—

$$-\frac{1}{n\,R}, \text{ becomes } -\cdot 000520 \times 10^{-15}, \text{ when } n = 64.$$

The value of C found with the leak in was $\cdot 023813 \times 10^{-15}$.

Hence, making the correction, C = ·02249 microfarads, which is sufficiently close to the value found without the artificial leak.

Table III. shows that with mica condensers not very much greater in capacity than the air condensers. A change in the frequency of the charge from 21 to 80, produces an appreciable change in the capacity; this, of course, is in consequence of the absorption. With large condensers, as we have already seen, the effect is more marked.

(To be continued.)

THE MARES ENERGY METER.

We are indebted to *Le Génie Civil* for the following particulars with regard to the Marès watt-hour meter, which might be briefly described as a combination of a Snelgrove electric balance and a Thomson current weigher.

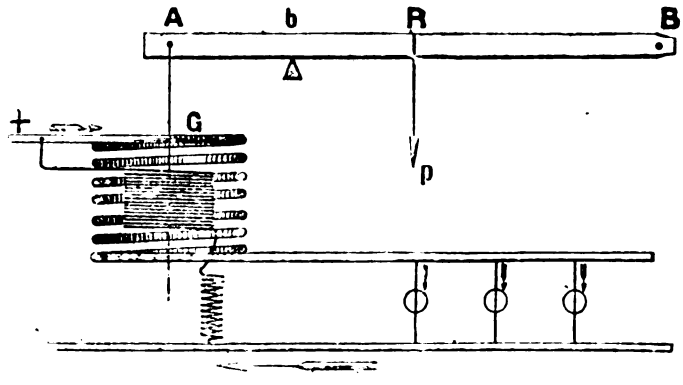

Fig. 1.—Diagram of the Marès Meter.

The watt-hour meter of M. E. Marès may be placed in the category of intermittent integrating meters since it adds up at regular intervals of time (4 minutes) the number of watts expended at that instant in the circuit. Fig. 1 explains the principle of the

Digitized by Google

apparatus. G is a thick wire coil in series with the lamps, and inside it is the movable fine wire shunt coil. The latter is suspended from the end A of the lever A B, oscillating about the knife-edge *b*. The electro dynamic action between the coils is equal to a force, *f* (E C), and this may be balanced by a weight, *p*, acting, say, at the point R. Hence we have.

$$f(\mathrm{E\,C}) \times \mathrm{A}\,b = p \times b\,\mathrm{R},$$

or,

$$f(\mathrm{E\,C}) = b\,\mathrm{R} \times \text{a constant}.$$

That is to say, E C at any instant is equal to *b* R multiplied by a constant. What we have to do, therefore, in order to measure E C is to move a weight, *p*, along A B, and to measure off the value of *b* R. This result is attained in the following manner.

The current is shut off from the shunt coil during half of each revolution of M N by means of an appropriate commutator. During the half revolution when the current is diverted from the shunt coil, it is made to wind up the clockwork. One complete revolution of M N causes the scape-wheel of the clockwork to run down by five teeth. One half of the commutator is, therefore, provided with five studs, and as these come into contact with the spring conveying the current five impulses are transmitted to an electro-magnet, which by giving five pulls to its armature winds up the scape-wheel by the amount it has run down.

The Marès meter, which is made by M. Dejardin of Paris, has been used with satisfactory results on the circuits of the Montpellier central lighting station. A perspective view of the meter is given in Fig. 3.

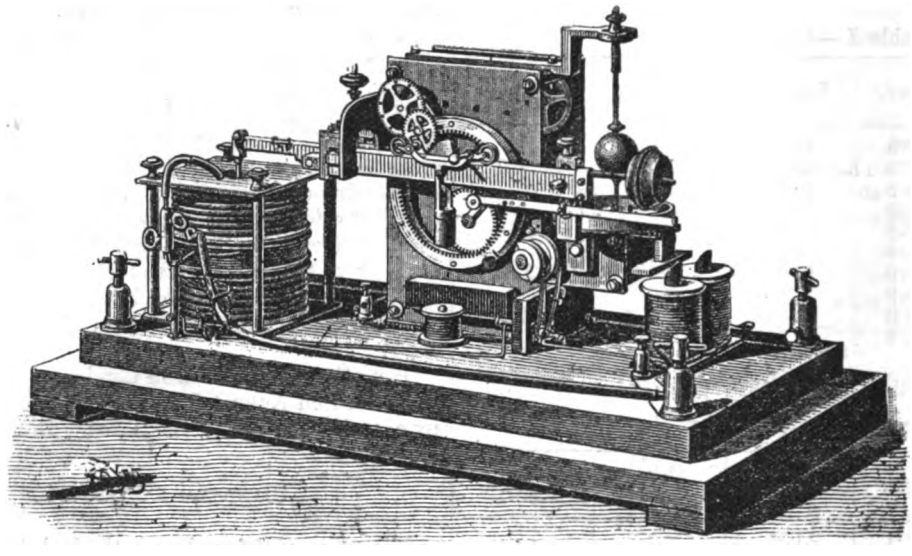

Fig. 3.—The Marès Meter (Back).

The moving weight *p* consists of a rack D (Fig. 2), which rolls along the arm A B, and which carries a small hollow metal cylinder *g*. The apparatus is adjusted by varying the load carried by *g*, and by moving the screw nut *e*. The rack D is actuated by the Lahire gearing M O N, and in virtue of the motion of the inner toothed wheel the rod T moves to and fro, carrying with it the rack D.

The integration is effected every four minutes as stated above. In that space of time, therefore, the rack D has to effect a complete to and-fro movement. The Lahire gearing is worked by clockwork, which is wound up electro-magnetically. The rectilinear motion of the rack D causes the toothed wheel F to rotate, and this in turn gives motion to a train of wheels actuating a registering apparatus. In order that the rotations of F may be proportional to E C, it is

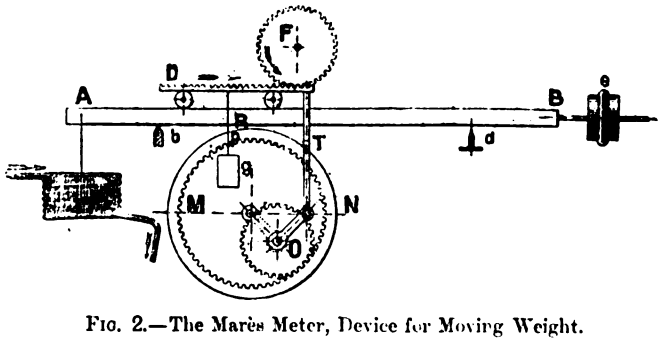

Fig. 2.—The Marès Meter, Device for Moving Weight.

necessary that the rack D should cease to come in contact with it the moment the beam is balanced, and the rack D should not again be engaged with the wheel F until it again commences a forward movement. This is effected in the following manner. When the weight *p* passes the point of equilibrium the beam tilts downwards on to the stop *d*, and the wheel F is disengaged. In order to prevent D from engaging with F on its return journey, the current, which continues to pass through the shunt coil during the whole of the forward movement of the rack, is cut off during the second half revolution of M N. The beam thus maintains such a position during the return journey of the rack as enables it to clear the wheel F. If the series coil of the meter is not traversed by any current the beam tilts over as soon as the rack begins to move forward and nothing is therefore measured.

INDUCTIVE AND EARTH INTERFERENCE WITH TELEPHONE SERVICE.*

BY DR. LOUIS BELL.

Until within the last three or four years the telephone service of this country had gone on its steady course of growth and extension without meeting serious difficulty from interference of extraneous circuits. Of course, the well-known phenomena of cross-talk had made it very clear to all telephone men that they were dealing with a remarkably sensitive instrument; but it required the advent of the alternating current and the electric railway to bring electricians to a realising sense of the conditions that must in the future be contended with. Although the practical features of the case are already known to many telephone engineers, it may be worth while to re-state the matter here. Given a telephone line running parallel to an electric light or power circuit, it finally results that the factors entering into the disturbance produced will be the distance between the lines, the length of parallelism, the self-inductions and resistances of the respective circuits, and the period and strength of the disturbing current. The total effect varies directly with the distance through which the circuits are parallel and inversely with the distance between them. Consequently it is quite possible for very severe induction to take place between lines which nowhere approach each other within several hundred feet, provided the length of parallelism is sufficient. On the other hand, a telephone wire running near a disturbing circuit, even for a very short distance, will be affected in a most marked way. In fact, the amount of induction depends on the ratio between the distance of parallelism and the distance between the lines rather than on the absolute value of either of these.

This fact is not entirely new, but is one to which comparatively little attention has been paid. A pair of cases from the writer's observation will illustrate the point admirably; both were specimens of pure inductive interference from an electric railway circuit. In the one case the telephone wire ran parallel to the disturbing circuit for about a third of a mile with the full width of a rather wide street between them—75ft. or so. The disturbance produced by the variations in the railway current were exceedingly marked, and almost destroyed the usefulness of the telephone. In the other case the trouble was nearly as great, but the entire inter-

* From the *Electrical World* of New York.

Digitized by Google

fering portions of the two wires were not more than 100ft. long, running, however, on the same pole about 18in. apart.

Another case that was brought to the writer's attention was a telephone wire between Chicago and Milwaukee, paralleled a large part of the distance by a telegraph line, on which an automatic transmitter was in use, the intervening distance being more than 100 yards. The result was the disabling of the telephone line. Still another example on a small scale was found in a long distance telephone line that ran nearly parallel to a railway circuit for a length of about 100ft. at a distance of about 3ft. The result was very marked interference, so that not only the running of the cars, but the whirr of the dynamos at the power station was distinctly heard. These examples are sufficient to show the importance of considering the distance ratio previously mentioned. In a very large number of places it seems to be forgotten by both the interested parties that to avoid trouble the wires must be kept away from each other. There is too much tendency to fancy that a power circuit will do no harm because it runs parallel to the telephone lines for only a very little distance. A great deal can be learned by locating the various disturbing causes through the pitch of the sounds produced. In some cases of induction complaints of disturbed telephone service were very loud shortly after the advent of an electric road, while on listening at the telephone the sounds proved to be produced by an old and familiar electric light circuit, as could be readily told by the pitch and uniformity of the tone produced.

So much for a view of the phenomena concerned. As regards remedy, in the discussions that have taken place on the subject several things have frequently been forgotten. One of these is that a return wire for the inducing current may or may not completely remedy the difficulty. If the two are closely parallel and the currents are in the same phase, there will be no effect on neighbouring wires; but if, as is always the case in street railway work, the phase of the disturbance is changed by the interposition of the motors, there is likely to be some residual interference with neighbouring wires. In other words, if anything disturbs the balance of the outgoing and returning current, either in quantity or in phase of disturbance, there will be trouble. This is sufficiently exemplified in the case of double trolley railroads where, so long as there is no leakage through the car or along the line, there is little or no trouble with the telephones; but if there is a ground on the car, even in a position where there would be no direct passage of the current to the grounded telephone wires, the trouble will be nearly as great as on a single trolley line. Only a complete return circuit on telephone wires can avoid every trace of interference.

Unfortunately, induction is not the only thing we have to deal with, and some interesting cases have recently come to light of extraordinary difficulty with stray currents in the ground. Perhaps one of the most striking came from London, where the alternating mains of the great Ferranti system produced ground disturbances that caused currents as high as the one-tenth of an ampere on the London telegraph lines, and especially on a circuit that ran from London to Rome, rendering it almost useless.

A similar formidable disturbance was recently observed on the lines of the Commercial Cable Company near New York. This ground interference is something that is comparatively little understood, and ought to receive very careful study both from electric power and telephone electricians. It constitutes by far the most formidable part of the difficulty usually met with. Very severe interference with telephone wires, such as shutters dropping at the exchange, and bells ringing when a car is passing, is almost invariably caused by ground leakage, and can usually be traced to grounds on water or gas pipes that run near to the disturbing conductor. A little care in keeping away from lines that are liable to disturbance would avoid most of the trouble from induction, but that from the ground is very singular in its persistence and erratic ways. We have very little information as to what really becomes of a current after it enters the ground. It certainly appears to stray in a very remarkable manner and without any great regularity of purpose. It would be a great service to practical electricity if all the striking cases of ground interference that come under the notice of telephone managers could be gathered together and used to form some general idea of the conditions in which trouble could be expected, and how far it is possible to avoid it by simple precautions. As it is now, the difficulties encountered by telephone managers are very great, and the remedies, aside from a very complete metallic return, have not been altogether satisfactory. It seems highly probable that if a more careful study of the conditions that follow grounding a variable current were generally made, it might be possible to avoid difficulty with telephone lines from grounds as easily as we now can avoid serious induction by keeping at a reasonable distance, and to secure excellent service without the expense of metallic circuits. The facts in the case have not been collated as yet with the care that the importance of the subject demands; and if this brief discussion of some of the facts involved can stir up sufficient interest in the matter to lead to proper investigation of the very extraordinary behaviour of earth currents, it will have served its purpose. It is more a plea for the study of the complicated and interesting phenomena met with in these disturbances of telephone service than anything of a more scientific and definite character.

A vast store of information on this subject has been accumulated by independent observers in the course of practical experience; and if it could be gathered and utilised the public would undoubtedly soon have the advantage of lessened trouble with so important a factor in business affairs as the modern telephone system. There ought to be full harmony between the telephone and other electrical interests in the matter of interference. The legal aspects of the question are not in a very satisfactory state, and much more good can be done by a thorough policy of arbitration than has been accomplished by more vigorous means. It is pretty clear that the public will not tolerate destruction of its telephonic facilities, nor will it sacrifice its electric light and power. It is a most unfortunate thing that the interests involved have come into collision so often, and it would be of general benefit if the whole subject could be looked into exhaustively and means taken to secure as amicable an adjustment of existing differences as is possible. If it were quite clearly understood just what interferences may be regarded as preventible by simple means and what are unavoidable or can only be escaped by great trouble and expense, the equitable adjustment of the differences now existing between the parties concerned would become very much simpler than it is at present. A thorough study of the phenomena would very much facilitate adjustment of the whole matter, and it is in the hope of stimulating such an investigation by calling attention to some of the conditions to be met, that this brief discussion of the matter has been written.

THE ELECTRO-MAGNET.*

BY PROF. SILVANUS P. THOMPSON, D.SC., B.A., M.I.E.E.

(Concluded from page 593.)

I have the means here of illustrating the induction method of measuring permeability. Here is an iron ring, having a cross section of almost exactly one square centimetre. It is wound with an exciting coil supplied with current by two accumulator cells; over it is also wound an exploring coil of 100 turns connected in circuit (as in Rowland's arrangement) with a ballistic galvanometer which reflects a spot of light upon yonder screen. In the circuit of the galvanometer is also included a reversing earth-coil. As a matter of fact this earth-coil is of such a size, and wound with so many convolutions of wire, that when it is turned over, the amount of cutting of magnetic lines is equal to 840,000, or is the same as if 840,000 magnetic lines had been cut once. By adjusting the resistance of the galvanometer circuit it is arranged that the first swing due to the induced current when I suddenly turn over the earth coil is 8·4 scale divisions. Then, seeing that our exploring coil has 100 turns, it follows that when in our subsequent experiment with the ring we get an induced current from it, each division of the scale over which the spot swings will mean 1,000 lines in the iron. I turn on my exciting current. See, it swings about 11 divisions. On breaking the circuit it swings nearly 11 divisions the other way. That means that the magnetising force carries the magnetisation of the iron up to 11,000 lines; or, as the cross-section is about 1 square centimetre, $B = 11{,}000$. Now, how much is H? The exciting coil has 180 windings, and the exciting current through the amperemeter is just 1 ampere. The total excitation is just 180 "ampere-turns." We must, according to our rule given above, multiply this by 1·2566 and divide by the mean circumferential length of the coil, which is about 32 centimetres. This makes $H = 7$. So if $B = 11{,}000$ and $H 7$, the permeability (which is the ratio of them) is about 1,570. It is a rough and hasty experiment, but it illustrates the method.

Bosanquet's experiments settle the debated question whether the outer layers of an iron core shield the inner layers from the influence of magnetising forces. Were this the case, the rings made from thin bar iron should exhibit higher values of B than do the thicker rings. This is not so; for the thickest ring, G, shows throughout the highest magnetisations.

(B) Bar Method.—This method consists in employing a long bar of iron instead of a ring. It is covered from end to end with the exciting coil, but the exploring coil consists of but a few turns of wire situated just over the middle part of the bar. Rowland, Bosanquet, and Ewing have all employed this variety of method; and Ewing specially used bars the length of which was more than 100 times their diameter, in order to get rid of errors arising from end-effects.

* A series of four Cantor Lectures delivered before the Society of Arts, January—February, 1890.

Digitized by Google

(C) Divided Bar Method.—This method, due to Dr. Hopkinson,[34] is illustrated by Fig. 17.

The apparatus consists of a block of annealed wrought iron about 18in. long, 6½ wide, 2 deep, out of the middle of which is cut out a rectangular space to receive the magnetising coils.

The test samples of iron consist of two rods, each 12·65 millimetres in diameter, turned carefully true, and slide in through holes bored in the ends of the iron blocks. These two rods meet in the middle, their ends being faced true so as to make a good contact. One of them is secured firmly, and the other has a handle fixed to it, by means of which it can be withdrawn. The two large magnetising coils do not meet, a space being left between them. Into this space is introduced the little exploring coil, wound upon an ivory bobbin, through the eye of which passes the end of the movable rod. The exploring coil is connected to the ballistic

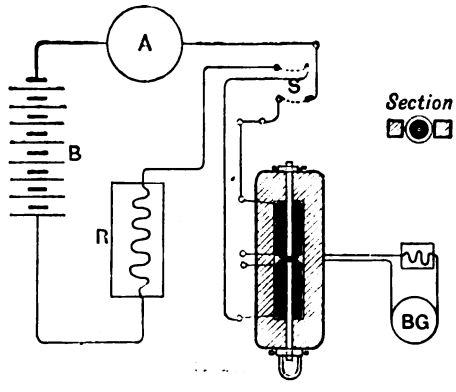

FIG. 17.—Hopkinson's Divided Bar Method of Measuring Magnetic Permeability.

galvano-meter, B G, and is attached to an india-rubber spring (not shown in the figure), which, when the rod is suddenly pulled back, causes it to leap entirely out of the magnetic field. The exploring coil had 350 turns of fine wire; the two magnetising coils had 2,008 effective turns. The magnetising current, generated by a battery, B, of eight Grove cells, was regulated by a variable liquid resistance, R, and by a shunt resistance. A reversing switch and an ampere-meter, A, were included in the magnetising circuit. By means of this apparatus the simple rods to be experimented upon could be submitted to any magnetising forces, small or large, and the actual magnetic condition could be examined at any time by breaking the circuit and simultaneously withdrawing the movable rod. This apparatus, therefore, permitted the observation separately of a series of increasing (or decreasing) magnetisations without any intermediate reversals of the entire current. Thirty-

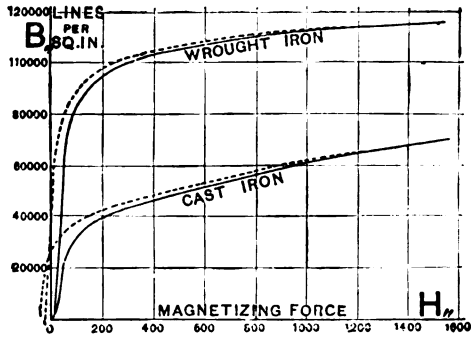

FIG. 18.—Curves of Magnetisation of Iron.

five samples of various irons of known chemical composition were examined by Hopkinson, the two most important for present purposes being an annealed wrought iron and a grey cast iron, such as are used by Messrs. Mather and Platt in the construction of dynamo machines. Hopkinson embodied his results in curves, from which it is possible to construct, for purposes of reference, numerical Tables of sufficient accuracy to serve for future calculations. The curves of these two samples of iron are reproduced in Fig. 18, but with one simple modification. British engineers who unfortunately are condemned by local circumstances to use inch measures instead of the international metric system, prefer to have the magnetic facts also stated in terms of square inch units instead of square centimetre units. This change has been made in Fig. 18, and the symbols $B_{\prime\prime}$ and $H_{\prime\prime}$ are chosen to indicate the numbers of magnetic lines to the square inch in iron and in air respectively.

[34] *Phil. Trans.* 1885, p. 456.

The permeability, or multiplying power of the iron is the same, of course, in either measure. In Table II. are given the corresponding data in square inch measure; and in Table III. the data in square centimetre measure for the same specimens of iron.

Table II.—(*Square Inch Units.*)

It will be noted that Hopkinson's curves are double, there being one curve for the ascending magnetisations, and a separate one, a little above the former, for descending magnetisations. This is a point of a little importance in designing electro-magnets. Iron, and particularly hard sorts of iron, and steel, after having been subjected to a high degree of magnetising force, are subsequently to a lesser magnetising force found to retain a higher degree of magnetisation than if the lower magnetising force had been simply applied. For example, reference to Fig. 18 shows that the wrought iron, where subjected to a magnetising force gradually rising from zero to $H_{\prime\prime}=200$, exhibits a magnetisation of $B_{\prime\prime}=95,000$; but after $H_{\prime\prime}$ has been carried up to over 1,000, and then reduced again to 200, $B_{\prime\prime}$ does not come down again to 95,000, but only to 98,000. Any sample of iron which showed great retentive qualities, or in which the descending curve differs widely from the ascending curve, would be unsuitable for constructing electro-magnets, for it is important that there should be as little residual magnetism as possible in the cores. It will be noted that the curves for cast-iron show more of this residual effect than do those for wrought-iron. The numerical data in Tables II. and III. are means between the ascending and descending values.

As an example of the use of the Tables, we may take the following:—How strong must the magnetising force be in order to produce in wrought-iron a magnetisation of 110,000 lines to the square inch? Reference to Table II., or to Fig. 18, shows that a magnetising field of 664 will be required, and that at this stage of the magnetisation the permeability of the iron is only 166. As there are 6·45 square centimetres to the square inch, 110,000 lines to the square inch corresponds very nearly to 17,000 lines to the square centimetre, and $H_{\prime\prime}=664$ corresponds very nearly to $H=100$.

Traction Methods.

Another group of methods of measuring permeability is based upon the law of magnetic traction. Of these there are several varieties.

(D) Divided Ring Method.—Mr. Shelford Bidwell has kindly lent me the apparatus with which he carried out this method. It consists of a ring of very soft charcoal iron rod 6·4 millimetres in thickness, the external diameter being eight centimetres, sawn into two half rings, and then each half carefully wound over with an exciting coil of insulated copper wire of 1,929 convolutions in total. The two halves fit neatly together; and in this position it constitutes practically a continuous ring. When an exciting current is

Digitized by Google

passed round the coils both halves become magnetised and attract one another. The force required to pull them asunder is then measured. According to the law of traction, which will occupy us in the second lecture, the tractive force (over a given area of contact) is proportional to the square of the number of magnetic lines that pass from one surface to the other through the contact joint. Hence the force of traction may be used to determine B ; and on calculating H as before, we can determine the permeability. The following Table IV. gives a summary of Mr. Bidwell's results :—

Table IV.—(*Square centimetre measure*). *Soft Charcoal Iron.*

B	μ	H
7,390	1899·1	3·9
11,550	1121·4	10·3
15,460	386·4	40
17,330	150·7	115
18,470	88·8	208
19,330	45·3	427
19,820	33·9	585

(*E*) *Divided Rod Method.*—In this method, also used by Mr. Bidwell, an iron rod hooked at both ends was divided across the middle, and placed within a vertical surrounding magnetising coil. One hook was hung up to an overhead support ; to the lower hook was hung a scale-pan. Currents of gradually-increasing strength were sent around the magnetising coil from a battery of cells, and note was taken of the greatest weight which could in each case be placed in the scale-pan without tearing asunder the ends of the rods.

(*F*) *Permeameter Method.*—This is a method which I have myself devised for the purpose of testing specimens of iron. It is essentially a workshop method, as distinguished from a laboratory method. It requires no ballistic galvanometer, and the iron does not need to be forged into a ring or wound with a coil. For carrying it out a simple instrument is needed, which I venture to denominate as a *permeameter*. Outwardly, it has a general resemblance to Dr. Hopkinson's apparatus, and consists, as you see (Fig. 19) of a rectangular piece of soft wrought-iron, slotted out to receive a magnetising coil, down the axis of which passes a brass tube. The block is 12in. long, 6½in. wide, and 3in. in thickness. At one end the block is bored to receive the sample of iron that is to be tested. This consists simply of a thin rod about a foot long, one end of which must be carefully surfaced up. When it is placed inside the magnetising coil, and the exciting current is turned on, the rod sticks tightly at its lower end to the surface of the iron block ; and the force required to detach it (or, rather, the square root of that force) is a measure of the permeation of the magnetic lines through its end-face. In the first permeameter which I constructed the magnetising coil is 13·64 centimetres in length, and has 371 turns of wire. One ampere of exciting current consequently produces a magnetising force of H=34. The wire is thick enough to carry 30 amperes, so that it is easy to reach a magnetising force of 1,000. The current I now turn on is 25 amperes. The two rods here are of "charcoal iron" and "best iron" respectively; they are of quarter,

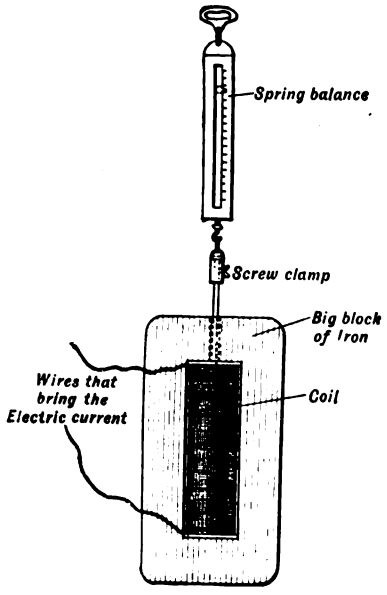

Fig. 19.—The Permeameter.

inch square stuff. Here is a spring balance graduated carefully and provided with an automatic catch so that its index stops at the highest reading. The tractive force of the charcoal iron is about 12⅓lb., while that of the "best" iron is only 7½lb. B is about 19,000 in the charcoal iron, and H being 850, μ is about 22·3. The law of traction which I use in calculating B will occupy us much in the next lecture, but meantime I content myself in stating it here for use with the permeameter. The formula for calculating B when the core is thus detached by a pull of P pounds, the area of contact being A square inches, is as follows :—

$$B = 1{,}317 \times \sqrt{P \div A} + H.$$

Curves of Magnetisation and Permeability.

In reviewing the results obtained, it will be noted that the curves of magnetisation all possess the same general features, all tending toward a practical maximum, which, however, is different for different materials. Joule expressed the opinion that "no force of current could give an attraction equal to 200lb. per square inch," the greatest he actually attained being only 175lb. per square inch. Rowland was of opinion that the limit was about 177lb. per square inch for an ordinary good quality of iron, even with infinitely great exciting power. This would correspond roughly to a limiting value of B of about 17,500 lines to the square centimetre. This value has, however, been often surpassed. Bidwell obtained 19,820, or possibly a trifle more, as, in Bidwell's calculation, the value of H has been needlessly discounted. Hopkinson gives 18,250 for wrought iron, and 19,840 for mild Whitworth steel. Kapp gives 16,740 for wrought iron, 20,460 for charcoal iron in sheet, and 23,250 for charcoal iron in wire. Bosanquet found the highest value in the middle bit of a long bar to run up in one specimen to 21,428, in another to 29,388, in a third to 27,688. Ewing, working with extraordinary magnetic power, forced up the value of B in Lowmoor iron to 31,560 (when μ came down to 3), and subsequently to 45,350. This last figure corresponds to a traction exceeding 1,000 pounds to the square inch.

Cast iron falls far below these figures. Hopkinson, using a magnetising force of 240, found the values of B to be 10,783 in grey cast iron, 12,408 in malleable cast iron, and 10,546 in mottled cast iron. Ewing, with a magnetising force nearly fifty times as great, forced up the value of B in cast iron to 31,760. Mitis metal, which is a sort of cast wrought iron, being a wrought iron rendered fluid by addition of a small percentage of aluminium, is, as I have found, more magnetisable than cast iron, and not far inferior to wrought iron. It should form an excellent material for the cores of electro-magnets for many purposes where a cheap manufacture is wanted.

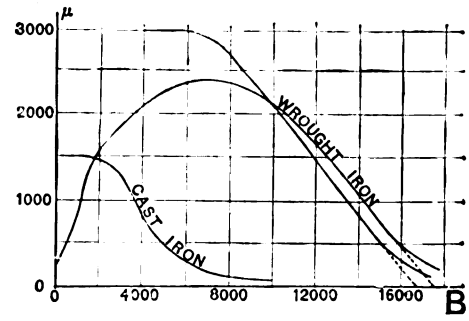

Fig. 20.—Curves of Permeability.

A very useful alternative mode of studying the results obtained by experiment is to construct curves, such as those of Fig. 20, in which the values of the permeability are plotted out vertically in correspondence with the values of B plotted horizontally. It will be noticed that in the case of Hopkinson's specimen of annealed wrought iron, between the points where B=7,000 and B=16,000, the mean values of μ lie almost on a straight line, and might be approximately calculated from the equation—

$$\mu = (17{,}000 - B) \div 3{\cdot}5.$$

Hysteresis.

I have already drawn attention to the difference between the ascending and descending curves of magnetisation, and may now point out that this is a part of a set of general phenomena of residual effects. The best known of these effects is, of course, the existence in some kinds of iron, and notably in steel, of a remanent or sub-permanent magnetisation after the magnetising force has been entirely removed. To this retardation of effects behind the causes that produce them the name of "hysteresis" has been given by Prof. Ewing. If a piece of iron is subjected to a magnetising force which increases to a maximum, then is decreased

Digitized by Google

down to zero, then reversed and carried to a negative maximum, then decreased again to zero, and so carried round an entire cycle of magnetic operations, it is observed that the curves of magnetisation form a closed area similar in general to those shown in Fig. 21. This closed area represents the work which has been wasted or dissipated in subjecting the iron to those alternate magnetising forces. In very soft iron, where the ascending and descending curves are close together, the enclosed area is small; and, as a matter of fact, very little energy is dissipated in a cycle of magnetic operations. On the other hand, with hard iron, and particularly with steel, there is a great width between the curves, and there is great waste of energy. Hysteresis may be regarded as a sort of internal or molecular magnetic friction, by reason of which alternate magnetisations cause the iron to grow hot. Hence the importance of understanding this curious effect, in view of the construction of electro-magnets that are to be used with rapidly alternating currents. The following figures of Table V. give the number of watts (1 watt = $\frac{1}{746}$ of a horse-power) wasted by hysteresis in well-

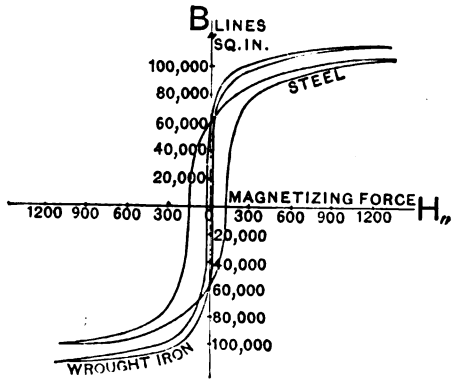

FIG. 21.—Curves of Hysteresis

laminated soft wrought iron when subjected to a succession of rapid cycles of magnetisation.

Table V.—*Waste of Power by Hysteresis.*

B	$B_{\prime\prime}$	Watts wasted per cubic foot at 10 cycles per second.	Watts wasted per cubic foot at 100 cycles per second.
4,000	25,800	40	400
5,000	32,250	57·5	575
6,000	38,700	75	750
7,000	45,150	92·5	925
8,000	51,600	111	1,110
10,000	64,500	156	1,500
12,000	77,400	206	2,060
14,000	90,300	262	2,620
16,000	103,200	324	3,240
17,000	109,650	394	3,910
18,000	116,100	487	4,870

It will be noted that the waste of energy increases as the magnetisation is pushed higher and higher in a disproportionate degree, the waste when B is 18,000 being six times that when B is 6,000. In the case of hard iron or of steel the heat waste would be far greater.

Another kind of after-effect was discovered by Ewing, and named by him "viscous hysteresis." This is the name given to the gradual creeping up of the magnetisation when a magnetic force is applied with absolute steadiness to a piece of iron. This gradual creeping up may go on for half an hour or more, and amount to several per cent. of the total magnetisation.

Another important matter is that all such actions as hammering, rolling, twisting, and the like, impair the magnetic quality of annealed soft iron. Annealed wrought-iron which has never been touched by a tool shows hardly any trace of residual magnetisation, even after the application of magnetic forces. But the touch of the file will at once spoil it. Sturgeon pointed out the great importance of this point. In the specification for tenders for instruments for the British Postal Telegraphs, it is laid down as a condition to be observed by the constructor, that the cores must not be filed after being annealed. The continual hammering of the armature of an electro-magnet against the poles may in time produce a similar effect.

Fallacies and Facts about Electro-Magnets.

I will conclude this lecture by stating a few of the fallacies that are current about electro-magnets, and will add to them a few facts, some of which seem paradoxical. The refutation of the fallacies, and the explanation of the facts will come in due course.

Fallacies.—The attraction of an electro-magnet for its armature varies inversely, as the square of its distance from the poles.

The outer windings of an electro-magnet are necessarily less effective than those that are close to the iron.

Hollow iron cores are as good as solid cores of the same size.

Pole-pieces add to the lifting power of an electro-magnet.

It hurts an electro-magnet (or, for that matter, a steel magnet) to pull off the keeper suddenly. [It is the sudden slamming on that in reality hurts it.]

The resistance of the coil of an electro-magnet ought to be equal to the resistance of the battery.

A coil wound left-handedly magnetises a magnet differently from a coil wound right-handedly. [It is not a question of winding of coil, but of circulation of current.]

Thick-wire electro-magnets are less powerful than thin-wire electro-magnets.

A badly insulated electro-magnet is more powerful than one that is well insulated.

A square iron core is less powerful (as Dal Negro says, eighteen-fold!) than a round core of equal weight.

The attraction of an electro-magnet for its keeper is necessarily less strong (one-third according to Du Moncel) sideways than when the keeper is in front of the poles.

Putting a tube of iron outside the coils of an electro-magnet makes it attract a distant armature more powerfully.

Facts.—A bar electro-magnet with a convex pole holds on tighter to a flat-ended armature than one with a flat pole does.

A thin round disc of iron laid upon the flat round end of an electro-magnet (the pole end being slightly larger than the disc) the disc is not attracted, and will not stick on, even if laid down quite centrally.

If a flat armature of iron be presented to the poles of a horse-shoe electro-magnet the attraction at a short distance is greater, if the armature is presented flankways, than if it is presented edgeways. On the contrary, the tractive force in contact is greater edgeways than flankways.

Electro-magnets with long limbs are practically no better than those with short limbs for sticking on to masses of iron.

THE SHERRIN ELECTRICALLY PROPELLED BATH CHAIR.

We witnessed on Tuesday afternoon last some trials of the electrically-propelled Bath chair, devised by Mr. J. Vaughan Sherrin, to whose battery and other inventions we alluded in our editorial columns last week. The Bath chair, which weighs 200lb., is of wicker-work, and of the usual shape, and is mounted on wheels of the tricycle type. The primary cells, 18 in number, and weighing 80lb., are placed on a large tray, suspended between the wheels behind the chair. The motor, a modified two-pole Gramme machine, with laminated field magnets, weighs 38lb., and has a normal output of about ¼ horse-power. The gearing down is effected by chains. The 18 cells contain 1½ gallons of depolarising solution, costing about 6d. a gallon. With this charge the battery is capable of propelling the vehicle along ordinary roads for nine hours, at the rate of about six miles an hour; the zincs and solution then requiring to be renewed. During the runs in question the Bath chair was very easily steered and stopped, and it surmounted without much difficulty a steep and muddy incline. We also witnessed the satisfactory performances of a small rowing boat, fitted with a Sherrin motor and battery.

We append an abstract of a report by Prof. Silvanus Thompson on Mr. Sherrin's devices.

The primary battery used by Mr. Sherrin is a two-fluid battery, in which the anodes are of sheet zinc, and the kathodes are of carbon. In each cell there are three fixed kathodes and two replaceable anodes. Very light plates are used, and the particular construction adopted permits these to be placed very close together, so that the resistance to the flow of electricity internally is very small. The outer cells are of gutta-percha; in them are embedded the porous cells which surround the anodes. The liquid used in the inner cells is simply water, that placed in the outer cells around the carbon kathodes is a depolarising liquid of special composition, capable of being produced at a low cost. It is to the latter that the cells owe their high electromotive force, nearly two volts each, and their excellent staying power. In one of my tests one of these cells gave out a current of 8·75 amperes (average) for 5 consecutive hours, with an electromotive force (average) of 1·88 volts, although the cell was only about half-filled at starting. In another more complete test a cell gave a discharge lasting rather more than nine hours, of an average strength of 6·5 amperes, the average electromotive force over the whole period being 1·99 volts. The amount of zinc consumed was only 73·1 grammes, being at the rate of 1·24 grammes per ampere-hour. This demonstrates that the quantity of

Digitized by Google

zinc consumed per(gross) electrical horse-power hour will be almost exactly one pound and one-fortieth of an ounce.

In a third and more elaborate test one of these cells gave a current of the average strength of 7·85 amperes for 9½ hours; the average electromotive force over the whole discharge being 1·74 volts, of which 1·308 volts was available at the terminal as the working number of volts; the total quantity of current discharged was, therefore, about 72·6 ampere-hours. The total evolution of power was 126·17 watt-hours (or about equal to one-sixth of one horse-power for one hour), of which about 31·26 watt-hours were expended upon the internal resistance of the cell, and 94·81 watt-hours (or about one-eighth of one horse-power for one hour) were available for useful purposes. The quantity of zinc consumed during the 9½ hours' discharge was about 90 grammes, or a little less than one-fifth of a pound; and the quantity of depolarising fluid was about half a pint.

The efficiency of these cells when working at a discharge of about eight amperes is about 75 per cent. Taking this figure, and assuming that the motor used with the cells was appropriately constructed and adjusted to run at an efficiency of 60 per cent., it is clear that the total consumption of zinc for an actual net mechanical output of one horse-power would be about 2lb. 14oz. per hour. Each cell, when filled, weighs 6½lb., and yields 11 ampere hours per lb. of gross weight; or at the rate of 39½lb. gross weight per gross horse-power of electrical output.

I know of no battery, primary or secondary, which for a given gross weight of cell will yield as great an output. The economy of zinc is remarkable, the consumption being close to the theoretical limit. I estimate the net cost of electric energy from such cells at 9d. to 10d. per Board of Trade unit.

The motor consists of a modified two-pole Gramme machine, having the field magnets constructed in a special manner, which, while maintaining great mechanical strength admits of very perfect lamination of the iron. It is well designed and soundly constructed, and when properly set is remarkably free from the common vice of sparking at the commutator. The motor tested first by me weighs 40lb., and it is intended for an output of from half to three-quarters of a horse power when placed in a launch or on a tricycle. To give out its full power it should be supplied with current at a pressure of 55 volts, when it runs at a speed of from 1,500 to 2,000 revolutions per minutes, according to circumstances. Considering the size and weight of this motor, and comparing its efficiency with that of the best motors of equal weight or equal power in the market, I consider the performance of Mr. Sherrin's motor very satisfactory. For so small a motor the power is high, being at the rate of one horse-power for only 62lb. of dead weight.

The electrically-propelled Bath-chair is fitted with one of Mr. Sherrin's smaller motors, and is driven by the current derived from ten of his cells. In a short run which I took in it, on unfavourable roads and in muddy weather it ran at about six miles per hour on the level, and ascended a gradient of about one in eight at the rate of about two miles per hour. It was perfectly easy to manage, and the batteries gave no trouble either from spilling or fuming. I consider the electric chair a thoroughly practical and successful vehicle. Of the electrical tricycle I have made no trial pending certain alterations now in progress in its structure.

OBITUARY.

CHARLES HENRY GIMINGHAM.

We greatly regret to announce the death of Mr. C. H. Gimingham, the superintendent and head of the Edison and Swan Electric Light Company's Factory, at Ponder's End. For some time Mr. Gimingham's health had not been good, and by medical advice he passed the greater part of last winter in Egypt, in the hope of effecting a recovery. He returned in the spring somewhat better, but latterly his evidently failing health had given great anxiety to all his friends. His death early yesterday morning has come as a great shock to a wide circle of acquaintances, as well as to his colleagues and those who worked under him. Those of his colleagues who were more intimately acquainted with him were inspired with feelings of very strong attachment to him by his amiable disposition and character.

Mr. Gimingham was born in 1853, and educated at the City of London School. At the age of sixteen he became private assistant to Mr. William Crookes, F.R.S., with whom he remained twelve years, assisting him in his researches on the radiometer and radiant matter, also in his other researches in chemistry. In 1876 he invented his now widely used multiple tube Sprengel air pump, reading a short Paper on the subject before the Royal Society. In July, 1881, he joined the original Swan Company, and superintended the fitting up of their lamp factory at Benwell, Newcastle-upon-Tyne, and introduced his 5-tube form of Sprengel, which has since been almost exclusively used for the exhaustion of incandescent lamps. He also greatly simplified and improved the manufacture of incandescent lamps. On the formation of the Swan United Electric Light Company, in London, who bought up the Swan Company's business, he became manager of their Benwell factory. Again, on their amalgamation with the Edison Company, he was appointed resident superintendent of the Edison and Swan lamp factories at Newcastle-upon-Tyne. During the latter part of 1885 he planned and arranged a new and very extensive factory at Ponder's End for the Edison and Swan Company, and removed to London to manage the same in February, 1886. During the last four years he carried out for the Edison-Swan Company considerable extensions in their works, and up to the last was engaged in the numerous improvements in the manufacturing operations under his care.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September* 19, 1890.

The Meeting of the New York Street Railway Association.—The event of the past week was the meeting of the New York Street Railway Association at Rochester. It was notable, first, from the fact that it was almost exclusively electrical in the character of the proceedings; and, in the second place, because it was one of the most interesting, not to say amusing, symposiums of electric railway men on record. The Association is composed of the regular street railway managers and superintendents, and has a large membership. The present meeting was especially and intentionally devoted to the question of electric traction, and representatives of the Sprague, Thomson-Houston, and Short systems were present to expatiate on the relative merits of their various devices. The street railway men received the information accorded to them with great gratitude, and showed their lively interest in the matter by putting the electrical experts through about as severe a cross-examination as it has ever fallen to the lot of men to endure. The questions put were of an exceedingly searching character, and the discussion makes very interesting reading for one who desires to compare the current systems of electrical traction. The questions were not wholly confined to electrical details, very searching inquiries being also made into the business relations of the companies, as combination has been more than once broadly hinted at of late. Altogether the debate was very instructive and decidedly amusing.

Electric Light Accidents.—The morning papers were filled recently with a lurid account of an alleged electrical accident. A small boy was said to have been struck by a falling telegraph wire which was crossed by an electric light line, rendered temporarily unconscious, and badly burned. He was even reported to have remained in a dazed condition for many hours after the accident, and a burn was said to have extended clear across the front of his coat, where the "deadly wire" had struck him. On investigation, it appears that no electricity was concerned in the case. A telegraph wire falling from a considerable height with a full sweep struck the boy, cut his face slightly and knocked him down, as might be expected of a long and heavy wire. The dreadful results of electric shock were purely an effort of the imagination, and the burn across the front of the coat turned out on careful inspection to be iron rust from the broken wire which had struck him. It is not uncommon to have accidents charged to electric current which are due to very simple causes, but it is rather rare to find so amusing an example as the present one. Another and more serious accident recently was due to the electric current, but the victim owed the loss of his life to his own carelessness. The papers for several days have been full of "scare" headlines and vivid descriptions of the death of an unfortunate lineman named Kopp, who climbed an iron pole in front of an "uptown" theatre to repair the lamp on a very rainy night. He strapped himself to the pole, and attempted to manipulate the circuit with a pair of steel pliers. The rubber gloves which, by the directions of the Company, he had been instructed to wear in such cases, he had left at the station, and, as a result of his recklessness, was struck dead by the current. The circuit was an underground one, feeding arc lamps, and

Digitized by Google

the potential to which the unfortunate man was exposed was something like 1,700 volts. It was a case of reckless neglect of the most ordinary precautions.

Electric Headlights for American Railways.—An electric headlight is coming into extensive use on a number of Western railroads. It is the result of a considerable amount of experimenting, and possesses some interesting features. Only one of the electrodes, between which the arc is formed, is of carbon, the lower negative pole being a copper rod which wastes away very slowly under the action of the current, thus rendering the lamp nearly self-focussing. The dynamo, which is directly attached to a four-cylinder engine, is placed on the top of the boiler between the smokestack and the headlight. The whole apparatus occupies a very small space and weighs but 650lbs. It is controlled by a throttle valve in the cab governing the steam pipe attached to the engine. The headlight itself is of about 2,000 candle-power nominally, and throws a beam straight forward over the track to an effective distance of nearly a mile. Even in stormy weather the track is sufficiently illuminated to show the smallest obstacle, even at a distance of 1,000 or 1,200ft. In practice the apparatus has been found to require very little attention, and to operate to the great satisfaction of the railway authorities. The ability to light the track far enough ahead of the engine to allow stopping the train in case of an obstruction, is so important to safe running, particularly on roads on which the block system is not used, that the electric headlight is likely to take an important place in our railway service.

SCANDINAVIAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

COPENHAGEN, *September* 24, 1890.

It is very satisfactory to note the manner in which everything connected with the practical use of electricity is coming to the fore in Scandinavia. To all appearances, electrical engineers will find here a good, although necessarily limited, field for their energies. One large installation follows upon another, the most important being, of course, the two large central stations in Stockholm and Copenhagen. Several English firms have sent in tenders, and the result, which will, no doubt, be shortly known, is awaited with considerable interest.

Here the central station met with much encouragement from the public, the number of subscribers having proved considerably in excess of what had been anticipated. The result of this is, that the installation will have to be larger to start with than was originally intended. About 350 subscribers having applied for the electric light, with an aggregate number of about 14,000 incandescent lamps, it was decided to increase the installation from 10,000 to 20,000 lamps, and the engine-power from 1,100 to 1,400 horse-power. It was also decided to increase the capacity of the accumulator battery from 500 lamps for four hours to 1,000 lamps for eight hours. These various extensions will entail an additional expenditure of some Kr.450,000, which amount was voted by the Corporation some two or three months ago. A good many tenders have been received from prominent firms, both in England and Germany, and they correspond, on the whole, well with each other, in some cases almost surprisingly so. The lowest tender is for Kr.1,456,500, and it comprises engines, dynamos, boilers, wires, &c. To this amount will, however, have to be added, according to present calculations, Kr.33,500 for excavations, laying down cables, foundations, &c, making a total of Kr.1,622,000, which is Kr.253,000 in excess of the second and already considerably increased vote.

There has apparently been some misunderstanding or mistake in the calculations, but the great excess is, of course, principally caused by the constantly-increasing number of lamps required, which now reaches 21,600 simultaneously burning lamps, on account of which it has been necessary to increase the steam-power again, this time from 1,400 to 1,800 horse-power. These repeated extra votes are, of course, not very welcome; but, on the other hand, it must be gratifying for the Corporation to see the interest which people take in the matter; and, secondly, it must be preferable to have the extensions at such an early stage, before the actual installation has been taken in hand. The central station, as finally arranged, will be able to supply electric light to the old centre of Copenhagen, comprising the principal streets of the old town, the Amalienborg Palace, the Exchange, the new Art Museum, &c. It is proposed to light by electricity some of the principal squares. The engines will be compound, the boilers tubular, calculated to work at 10 atmospheres' pressure. The largest engines are of 500 horse-power capacity, running at 125 revolutions per minute.

The installation, as far as the Corporation is concerned, ends with the work in the streets; but the Corporation will defray the cost of the line from the streets to the meter for early applicants. From the meter the user must himself pay the installation; but the Corporation is willing to assist by supplying good lamps at wholesale prices. The price has been fixed at 8 öre (1d. = 7½ öre) per 100 watt-hours, with a slight additional charge for the meter. The price is consequently 4⅘ öre per hour for an ordinary 16-candle 55-watt incandescent lamp, the same light from gas costing 2$\frac{7}{10}$ öre per hour. In Hamburg the charge is 4 pfennig (1 pfennig = 1d.) per 50 watt-hours, or 4·4 pfennig per lamp per hour; but then there is a fixed annual charge of 5 marks per lamp. In Berlin the price is 4 pfennig per lamp-hour, with an additional charge of 6 marks per lamp.

CORRESPONDENCE.

ALLEGED MAGNETO-OPTIC E.M.F.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to your issue of 19th September, pages 537 and 559, Dr. Sheldon may have taken proper precautions to ascertain if the telephone became silent directly the beam of light was intercepted; but there is nothing in his description of the experiment to render it even probable that he has detected the effect he was looking for. Any closed circuit near vibrating machinery is likely to have induced currents excited in it.—Yours, &c.,

OLIVER J. LODGE.

ELECTRIC LIGHTING IN CHELSEA.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of September 19th, under heading "Chelsea," in the Notes, I am glad to see an extract from the surveyor's annual report to the Chelsea Vestry. It is interesting, as a healthy "sign of the times," to note that electric lighting operations are so active, and work already executed of sufficient scope to require reporting to a Vestry.

My object in writing, however, is to point out that these figures are now somewhat obsolete, so far as the Chelsea Electricity Supply Company is concerned, and that they may be misleading, as the date of the surveyor's report is not given.

Since the surveyor prepared his report, this Company's houses have increased to 182 in Chelsea alone, and including those in South Kensington represent 17,300 eight candle power lamps installed, showing a marked improvement in the natural growth of the industry within the last few months.

Indications of the same sort in other districts are doubtless being felt by many of the other supply companies.—Yours, &c.,

W. HOWARD TASKER,
Electrician to the Chelsea Electricity Supply Company.
October 2, 1890.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

TENDERS WANTED.—Mr. J. R. Chalmers, of 133, St. Vincent-street, Glasgow, will furnish particulars of tenders required for electric lighting, steam, gas engine, and boiler power for the East End Industrial Exhibition, Glasgow.

———Tenders will be received to-day (Friday) up to twelve noon for the lighting, by gas or otherwise, of the district of Sutton, in Surrey. Particulars can be had of Mr. E. W. Crickmay, Public Hall, Sutton.

———The Board of Governors of the Mullingar District Lunatic Asylum invite tenders for supplying and erecting the necessary plant and fittings for an electric light installation at the Asylum. Further particulars are given in our advertisement columns, and copies of plans and specifications and all information can be obtained from Mr. W. Kaye Parry, M.A., 35, Dame-street, Dublin. Tenders have to be addressed to the "Resident Medical Superintendent" at the Asylum on or before 10 a.m. on the 16th instant.

Digitized by Google

MESSRS. B. VERITY AND SONS.—Messrs. Verity have this week issued a very complete and comprehensive catalogue of artistic electric light fittings in polished brass or bronze and wrought iron. Many of the designs are of exceptional merit, and in addition to those given in the catalogue under notice, Messrs. Verity and Sons have in their show-rooms at King-street and Regent-street replicas of many of the finest examples of French and Italian girandoles, &c., in mercury-gilt, any of which can be used for the electric light. Amongst the designs in the catalogue which are specially striking may be mentioned 2,797, 2,776, 2,804, 2,165, 2,085, 2,666, 1,741, 1,744, 1,746, 1,803, 1,715, 1,569, 1,625, 1,276, 1,233, 1,267, 2,164, 1,371, 1,712, 1,252, 1,002, 1,029, 1,298, 1,533, 1,198 1,462, and 1,463. Of these, No. 2,066 is a repousse and pierced sconce, with a two-light branch, with hammered leaves and flowers mounted on plush; No. 1,751 is a polished bronze three-light cluster, with hammered leaves and flowers in a handsome vase; No. 1,569 is a polished and lacquered two-light bracket, with vases and scrolls in Louis XVI. style. No. 1,625 is a polished copper frame with mirror centre, arranged for two lights, and mounted on plush (this design is also made and finished in electro silver). No. 1,276 is a wall sconce in polished brass, with a one-light floral branch, mounted on plush. No. 1,298 is a handsome five-light electrolier in the Adams style, with ornamental vases, leaves, rosettes, and pierced holders. No. 1,533 is a polished and lacquered electrolier for three lights, with ornamental leaves and rosettes and pierced coronet, with glass vases, flint stars, blue jewels, and brass rosettes, and forms one of the most effective groups in the catalogue. No. 1,193 is a very chaste design, and shows more completely than anything else in the catalogue the very artistic character of much of the work executed by Messrs. Verity; it is a polished brass electrolier, with ornamental leaves scrolls, &c., for 12 lights. Nos. 1,462 and 1,463 are a pair of polished brass and lacquered portable griffin standards, the latter being a very handsome example of this class of fitting. In addition to the more artistic fittings, a large number of very serviceable brackets, pendants, suspension lights, table lights, &c., are shown, and the catalogue is one of the most complete we have yet seen, consisting of 48 large folio pages of illustrations and 14 pages of price list and explanatory matter.

REMOVAL NOTICE.—The offices of the Newcastle-upon-Tyne Electric Supply Company, Limited, have been removed to the works of the Company at Pandon Dene, Newcastle-upon-Tyne, where all inquiries should in future be addressed.

——— The International Okonite Company (Limited) have removed from 34, Cannon-street, to 98 and 100, Queen Victoria-street, E.C., to which address all communications should be sent.

MESSRS. W. H. ALLEN AND CO. — The new catalogue of this firm has just been issued, and contains illustrations and price lists of their new patent direct-acting engine and dynamo, the "Kapp" dynamo, the "Allen" dynamo, Allen's dynamo and twin engine, Allen's portable electric lighting plant, search light plant, and Allen's twin tandem combined engine and dynamo. On the last page of the catalogue, which contains 16 large quarto pages, are shown illustrations of an air compresser, direct acting fan for ventilation or forced draft, and turbine water wheel for driving dynamos. Full particulars are given of this firm's 105 volt continuous dynamos as well as of their 55 volt, 65, volt, 75 volt, and 130 volt dynamos.

MESSRS. COX AND CO. have just completed a large installation of electric bells for the Constant Springs Hotel, Jamaica, including two of their improved electric reversing annunciators of seventy-five numbers each.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

September 11, 1890.

14,313. R. ALDRIDGE. Palmer's Green. An improved electric fog signal for railways.

14,341. J. E. ROULEZ. London. Improvements in electrical apparatus for reproducing sound.

14,349. SIEMENS BROTHERS and Co. (Limited). London. An improvement in electric meters (Siemens and Halske, Germany).

14,368. L. A. THRANITZ. London. An automatic electric lighting contrivance for staircases.

September 12, 1890.

14,393. W. LUCAS and T. A. GARRETT. London. Improvements in and connected with electrical apparatus for recording the presence of watchmen, workmen, or others.

14,394. F. W. WHITE and E. F. FURTADO. London. Improvements in electric bells.

14,404. C. S. SNELL. Saltash, Cornwall. Improvements in electrical switches.

14,411. J. T. NIBLETT. London. Improvements in secondary batteries.

September 13, 1890.

14,433. A. F. LLOYD. Dulwich. Improvements relating to coin-freed electrical apparatus.

14,459. E. EDWARDS. London. Improvements in electric bells or sounding apparatus (G. Bénard, France).

14,460. E. EDWARDS. London. Improvements in electric bells (G. Bénard, France).

14,482. R. B. EVERED and T. RUDLING. London. An improved connection for electroliers or electric chandeliers.

14,484. R. B. EVERED and T. RUDLING. London. An improved combined electric switch and connecting or coupling device.

September 15, 1890.

14,536. H. J. VOIGT and J. STANDT. London. Improvements relating to means for connecting glow lamps to their holders, and for connecting together the parts of other electrical apparatus.

September 16, 1890.

14,549. S. L. WIRGAND. Glasgow. Improvements in the art of, and apparatus for, telegraphing and telephoning, and similar purposes.

14,553. R. S. HAMPSON and R. FORSTER. Halifax. Improvements in and relating to train signalling apparatus.

14,554. M. LOWE. Wigan. A magnetic and electric penholder, for the purpose of showing certain scientific phenomena.

14,603. W. R. LAKE. London. Improvements in electric signalling apparatus (the Hall Signal Company, United States).

14,604. M. W. DEWEY. London. Improvements relating to the heating of metals and other materials by electricity.

14,609. B. J. B. MILLS. London. Improvements in electrically-propelled vehicles, in the arrangement and connections of the motors and power-transmitting devices thereof, and the method of operating the same, a portion of the invention being applicable to the transmission of power for other uses (E. H. Johnson, United States).

14,613. W. ROBINSON. London. Electric-motor car.

14,624. A. S. ELMORE. London. Improvements in the manufacture of metallic articles by electrolysis, and apparatus for that purpose.

14,627. A. G. MELHUISH. Denmark Park, Surrey. Improvements in shadowless arc electric lamps.

14,634. E. F. INGLEFIELD. London. Improved apparatus for electric light signalling.

COMPANIES' MEETINGS.

The Direct Spanish Telegraph Company (Limited).

The thirty-fourth ordinary general meeting of the Company was held at Winchester House, Old Broad-street, London, E.C., on Tuesday, the 30th day of September, 1890, for the purpose of receiving the Directors' report and accounts, and for transacting the ordinary business of the Company; Sir James Anderson presiding.

Mr. CH. GERHARDI (the Manager) read the notice calling the meeting and the minutes of the last meeting, which were confirmed and signed as correct.

The CHAIRMAN: Gentlemen, you having taken the report as read, I will make such remarks as I deem to be suitable in proposing its adoption. You will remember that I foreshadowed at the last meeting that the International Telegraph Conference would soon be upon us. It has come and gone. I said at our last meeting that this Conference had a new terror in

Digitized by Google

store for us; our tariff was and is only 4½d. per word, and there were rumours of still further reductions. Well, the outcome is we have lost one halfpenny per word, and but for the good offices of Mr. Lamb, of H.M.'s Post Office, supported by the delegates from Spain, who were extremely cordial to us, I am afraid we should have lost one penny. I am bound to say, however, that there was no unfriendliness on the part of the Government delegates towards this or any other company. Yet I thought many were fairly eager to get reduced tariffs as far as possible at somebody else's expense, and we have had to let that halfpenny go. It does not seem a large amount to cry about; yet it amounts, with other adjustments, to about £3,500 per annum, and I do not feel sanguine that so small a reduction will give such impulse to our traffic as to recoup this loss. Still, I think, that we may look to some extent to its being recouped, because our traffic has been continually increasing for the past three years—and we may take comfort from the fact that it continues to increase from commercial sources alone—and that the alteration of tariff does not take place until July, 1891. I have often said at these telegraph meetings that code language was now so scientifically arranged that every year we had to lament a reduction at the rate of about one word per annum per message. Last March I told you this rate of reduction had ceased for twelve months, and I am pleased to find that the average length of messages has actually increased by a fraction for the half-year now under review; but our manager says we must not rejoice too much over that, as he suspects one or two causes other than increase of commercial traffic to account for it. I hope he is wrong; but it does seem as if we had got for the present on the ground floor of the effect of code at the low tariff of 4½d. per word. Some of the code words are 10 and 12, and even some that have been sent me are 24 and 25 words in length. I said this time last year "that for the two previous half-years we had carried more messages and made less money;" but at that date (October, 1889), we had got over that adverse condition and seemed to have turned the corner and we were making more money; but to make the £1,592 increase of revenue, as shown in our last report, we had to carry 155,192 more words, and our expenses had increased by £690. For this present half-year, to earn the increased amount of revenue shown in our report, £2,057 1s. 8d. We have transmitted 260,970 more words than in the corresponding half year, and the working expenses have increased by £391, the details of which I have before me, if you desire them. So far, then, I think we are to be congratulated. The prospect of commerce with this country and Spain has greatly improved, and we are at least justified in expecting that the increase of traffic will continue to some extent. We are not unmindful that the proprietors would naturally expect and desire a larger dividend from the increased revenue published in our report. But I would recall to your mind in substance what I said on previous occasions: "We may not as prudent Directors overlook the fact that we have a Debenture Debt of £62,000 at 6 per cent. due in 1894. Circumstances might arise to make it very difficult to renew those debentures upon easier terms—unless our reserve is so strong as to inspire confidence in the stability of our property. We have—and I earnestly congratulate the proprietors upon the fact—a reserve of £20,258: but we have only single cables, and we must forthwith duplex those cables—I wish I could say duplicate them; but we must duplex them at a cost of about £800 to meet the existing and growing traffic so as to make our speed of transmission unsurpassable; and your Directors would like to feel themselves in a position to meet any probable repairs which may be required upon our cables *without entrenching upon the reserve*. With a growing reserve and a sound commercial increase of our traffic such as now exists and has for the last three years continued, our proprietors, I believe, will gladly provide all the money required to pay off the Debenture debt in 1894, and put the 6 per cent. into their own pockets (hear, hear). This is the goal your Directors aim at, and I feel sure you will, as usual, support us (hear, hear). I do not forget that after the reduction of our capital I promised that after the Preference Shares received their 10 per cent. the Ordinary Shares should receive all the remainder of the revenue; but at that time it did not promise more than a return of 2 per cent. It was a poor look out, and having arranged for a reserve to insure the existence of our property, it seemed right to pause and see what the result would be. But since that time, mainly owing to the Treaty of Commerce between England and Spain, the outlook has changed. We must now prepare to duplex our cables, and I hope by 1894 there may exist good and sufficient reasons for duplicating one at least of our sections of cable. For the present, then, we have an increasing revenue and an increasing reserve, a 6 per cent. dividend; we have £2,500 for contingencies, our cables in good order, and I think we may confidently say that the Direct Spanish Company is fast earning a claim to be considered as one of the soundest investments in connection with submarine telegraph property in the city of London. I now move the following resolution:—

"*That the report and accounts now presented be, and are hereby, received and adopted.*"

Mr. E. ETLINGER seconded.

The CHAIRMAN invited discussion.

Mr. DYETT: What is the price of the present debentures bearing 6 per cent. interest?

The CHAIRMAN: I do not know.

Mr. DYETT: I want to know.

The CHAIRMAN, to the Secretary: Can you say?

The SECRETARY: They are not in the market.

Mr. DYETT: They were taken up by the contractors.

The CHAIRMAN: No, no. They were taken by them, but bought afterwards by the Globe Telegraph Company, who now hold them. It is not worth while discussing now.

A SHAREHOLDER: They are due in three years, I think.

The CHAIRMAN: Yes. In May, 1894. Then we shall all want to get debentures at 4 per cent.

Mr. DYETT: They are not for sale.

The CHAIRMAN: It is not worth while. We have looked the matter in the face over and over again.

The motion was then put and carried.

The CHAIRMAN: I beg to move:—

"*That the dividend at the rate of 10 per cent. per annum, less income tax, on the Preference Shares, and the dividend at the rate of 6 per cent. per annum on the ordinary shares, free of income tax, for the half-year ended 30th June, 1890, be and are hereby declared.*"

Mr. ETLINGER seconded.

The motion was carried.

The CHAIRMAN: That concludes this meeting; and I will call upon the Secretary to read the notice convening the extraordinary meeting.

The SECRETARY read the notice.

Mr. DYETT moved:—

"*That Article 71 of the Articles of Association of the Company be and is hereby repealed, and instead thereof the following be a Regulation of the Company:—The Directors shall receive as remuneration for their trouble in the execution of their office the sum of £600 per annum, or such other sum as the Company in General Meeting may from time to time determine, and such remuneration shall be apportioned by the Directors among themselves in such manner as they shall from time to time think fit.*"

He said: I have much pleasure in endorsing this.

Mr. WALTER BARNETT had much pleasure in seconding a motion for voting the Directors what they were absolutely entitled to. It was with the greatest cordiality that he seconded the proposal, as by the existing Articles of Association the Directors were entitled to claim an increased remuneration some time back, but preferred to leave the matter in the shareholders' hands.

Digitized by Google

The motion was carried.

The CHAIRMAN returned thanks for the vote. He was gratified that the shareholders should have voted them this amount, as, although the work had been heavy, their fees had not been too large in the past. There were a good many responsibilities connected with the office of a Director, more than the outside public seemed to realise. It was extremely gratifying to have such a vote from the shareholders, as it showed the confidence they reposed in the Board.

Mr. DYETT said that all parties were satisfied, both shareholders and Directors, so that it was satisfactory all round.

Mr. W. BARNETT proposed a cordial vote of thanks to the Chairman for his courteous conduct in the chair.

Mr. G. C. HAWES seconded the motion, which was carried.

The CHAIRMAN expressed his thanks, and said that it would be necessary that they should have a confirmatory meeting after 14 days to confirm the resolution that they had passed that day. Due notice would be given.

The proceedings then terminated.

NEW COMPANIES REGISTERED.

THE COMBINATION TELEPHONE AND ELECTRICAL ENGINEERING COMPANY (LIMITED).—Registered by Ernest Salaman, 65 and 66, Chancery-lane, W.C., with a capital of £20,000 in £1 shares. Object, to carry into effect an agreement made September 17 between E. F. Furtardo of the first part, Charles J. Grist of the second part, and Arthur O'Brien, as trustee on behalf of the Company, of the third part; to acquire exclusive licenses to work certain inventions of telephones, in respect of which provisional protection has been obtained for the United Kingdom, dated March 31 and May 15, and to acquire the business of Charles J. Grist, of 43, Sydney-street, Oxford-road, Manchester; to carry on the business of a telephone, telegraph and electric light company, &c. There shall not be less than three nor more than seven directors. The first are C. J. Grist and E. F. Furtardo; the others to be appointed by the subscribers to the memorandum of association. Qualification, 50 shares. Remuneration: Chairman, £120; other directors, £75 each.

ELMORE'S AUSTRO-HUNGARIAN PATENT COPPER DEPOSITING COMPANY (LIMITED).—Registered by Ashurst, Morris, Crisp, and Co., 6, Old Jewry, E.C., with a capital of £200,000 in £2 shares. Object: To carry into effect an agreement made between Elmore's Foreign and Colonial Patent Copper Depositing Company (Limited), of the first part, Woodhouse and Rawson United (Limited), of the second part, and the Company of the third part; to carry on in Austria, Hungary, and elsewhere, at such places as the Directors of the Company shall think fit, and whether as principals or agents, the business of manufacturers of and dealers in copper and other metals, and all metallic alloys or compounds of the same, and all goods and articles made of copper or other metals and alloys. There shall not be less than three nor more than nine Directors; the first to be appointed by the subscribers to the Memorandum of Association. Qualification, being a shareholder. Remuneration: Chairman, £400; Vice-Chairman, £300; other Directors, £200 each, together with 2½ per cent. upon net profits made from manufacturing and 1 per cent. upon net profits made from sales of patents, licences, or businesses.

J. E. H. GORDON AND CO. (LIMITED).—Registered by Mann and Taylor, 109, New Oxford-street, W.C., with a capital of £50,000 in £10 shares. Object, to acquire the business of J. E. H. Gordon, electrical engineer, with the leasehold premises where the business has been carried on. The first subscribers are:—

	Shares.
J. E. H. Gordon, M.Inst.C.E., 1, Queen's Gate Gardens, S.W.	1
W. J. Rivington, 21, Gledhow-gardens, South Kensington	1
Mrs. Rivington, 21, Gledhow-gardens, South Kensington	1
Mrs. Gordon, 1, Queen's Gate-gardens, S.W.	1
Mrs. Gordon, Horndon Cottage, Campden Hill	1
Miss Eva Gordon, Horndon Cottage, Campden Hill	1
H. Sinclair, 11, Pall-mall	1

J. E. H. Gordon and W. J. Rivington are appointed the first Directors. Qualification, 200 shares. Remuneration not specified.

CITY NOTES, &c.

ANGLO-AMERICAN TELEGRAPH COMPANY, LIMITED.—At a meeting of the Board of Directors of this Company, held on Friday, it was resolved to declare an interim dividend for the quarter ending September 30, 1890, of 15s. per cent. on the ordinary stock, and £1. 10s. per cent. on the preferred stock, less income tax, payable on November 1st, to the stockholders registered on the books of the Company on September 30, 1890.

BERLINER ELECTRICITATS-WERKE.—This Company is paying this year a dividend of 10 per cent, against 8 per cent. last year. According to the *Elektrotechnischer Anzeiger*, it is proposed to raise the capital from six to nine million marks.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended September 26th amounted to £4,970.

B. DELLAGANA AND CO. (LIMITED).—The Directors of this firm of electrotypers, &c., have declared a dividend at the rate of 6 per cent. per annum on the Preference shares and at the rate of 10 per cent. per annum on the Ordinary shares for the half-year to June 30, 1890.

EASTERN TELEGRAPH COMPANY (LIMITED).—This Company announces the payment on October 14th next of interest of 3s. per share, less income-tax, being at the rate of 6 per cent. per annum on the Preference shares of the Company, for the quarter ended September 30th, and the usual interim dividend of 2s. 6d. per share on the Ordinary shares, free of income-tax, in respect of profits for the quarter ended June 30th. The register of transfers will be closed from October 7th to 14th, both days inclusive.

ELMORE'S AUSTRO-HUNGARIAN PATENT COPPER DEPOSITING COMPANY, LIMITED.—The prospectus of this new subsidiary company of the Elmore group was issued on Saturday last. The Austro-Hungarian concern has a capital of £200,000, in 100,000 shares of £2 each, of which 75,000 shares were offered for subscription at a premium of 10s. per share, and 25,000 were accepted in part payment of the purchase money. Payments had to be made: 5s. on application, 15s. on allotment (which includes the premium), 15s. on Nov. 1, 1890, and 15s. on Jan. 1, 1891. The Directors are Sir John H. Morris, K.C.S.I. (Chairman), Mr. James Rock, J.P., Mr. William Elmore, Mr. John Macfarlan, and Lieut.-Gen. George Henry Fraser, R.A. (Managing Director). The consulting metallurgical chemists are Mr. Francis E. Elmore and Mr. Alexander S. Elmore; the secretary is Mr. J. Shurmer; and the offices are at 20, Bucklersbury, London, E.C. The objects of this Company are similar to those of the French company recently issued. The lists opened on Tuesday, and closed the same day for both town and country.

SUBMARINE CABLES TRUST.—Notice is given that on and after the 15th inst., the coupons due in April last will be paid in full by Messrs. Glyn, Mills, and Co., of Lombard-street, between the hours of 10 a.m. and 2 p.m. The coupons should be left with the Bankers for examination four clear days before payment. Certificate holders are requested to present the coupons for April only, and not those payable on Oct. 15th.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ending September 26, 1890, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £3,899.

CRICKET.—WOODHOUSE AND RAWSON *v.* APPLETON, BURBEY, AND WILLIAMSON.—A match was played between these elevens at Brentwood, Essex, on Saturday last, ending in an easy win for the former. Score:—Appleton, Burbey, and Williamson—Worsfold, played on, b Howel, 0; Joseph, run out, 8; Grenville, l b w, b Tasker, 27; Williamson, b Thomas, 0; Bevis, b Howell, 4; Burbey, stumped, b Howell, 0; Matthews, 0; Luff-Smith, c Howell, b Tasker, 0; Paine, b Howell, 1; extras, 1; total, 46. Appleton and Neale did not bat. Woodhouse and Rawson—L. Brockman, b Neale, 5; R. J. Jones, c Burbey, b Worsfold, 1; W. R. Long, b Bevis, 46; B. T. Thomas, c Grenville, b Neale, 97; Tasker, run out, 59; Wickens, c Grenville, b Neale, 7; Atkinson, retired, 40; Howell, run out, 17; Moore, not out, 39; Ryan, not out, 10; extras, 10; total, 331. Arthur did not bat.

THE NON-CONDUCTOR OF ELECTRICITY.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FACTORY.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

MOSSES & MITCHELL, 70, Chiswell-st., London, E.C.

JABLOCHKOFF'S DISTRIBUTION PATENT

(BEING A PATENT FOR "PRODUCING AND DIVIDING ELECTRIC LIGHT," No. 1996 of 1877.)

THE ELECTRICAL ENGINEERING CORPORATION, LIMITED

(STATTER'S) Are Proprietors of the above Patent, and Warn the Public against Infringement. (UNITED).

The following are Licensees:—

Brush Electrical Engineering Company, Limited.
Crompton & Co., Limited.
S. Z. de Ferranti.—London Electric Supply Corporation, Limited.
W. T. Goolden & Co.
Hammond & Co.
Wilson Hartnell.
Johnson & Phillips.
Laurence, Paris & Scott, Limited.
Nalder Brothers & Co.
Paterson & Cooper.
Ernest Scott & Co.
Siemens Brothers & Co., Limited.

3, PRINCE'S MANSIONS, VICTORIA STREET, WESTMINSTER. PERCY E. SCRUTTON, *Secretary.*

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 647.—Vol. XXV. FRIDAY, OCTOBER 10, 1890. Price Fourpence.

NOTES.

The views of Mr. Nikola Tesla regarding the relative merits of open-circuit and closed-circuit transformers will be read with interest. They will be found appended to an article entitled "The Hedgehog Transformer," in our present issue. It must, however, be noted that neither Mr. Swinburne nor Mr. Tesla refer to Foucault currents, which cause a waste of energy, the consideration of which is as important as that due to hysteresis or current heating. The growing importance of eddy currents, as the frequency is increased, is the probable cause of the maximum efficiency found by Mr. Tesla at a particular period; and since, according to this authority, converters of the open-circuit type are more efficient than others provided the period is sufficiently increased, it is important that eddy currents should be considered in discussing the question.

We take exception to Mr. Tesla's statement about magneto-motive force. The output of the converter depends on the flux of lines; and this, in conjunction with the frequency of the alternations and the mass of iron, determines the loss of power in hysteresis. For transformers of the same output and size of core the hysteresis will accordingly depend on the length of the iron circuit; and if this is diminished, as in open-circuited transformers, the hysteresis loss will be lessened in proportion. The increased current needed to produce the same flow of lines will cause an additional amount of waste heat; and as this, under certain circumstances, may be less than the saving effected in hysteresis, it may happen that an increase in efficiency results. Our knowledge of hysteresis losses when the currents are rapidly alternating is, however, incomplete, and very little is known of the relative magnitude of the waste due to eddy currents; so that there seems no theoretical ground for supposing that any increase of efficiency attained in this way would be of sufficient importance to outweigh the practical considerations to which Mr. Tesla refers.

The question of the efficiency of transformers is one of very great commercial importance; but the discussion of the details of actions which may or may not exist in hedgehog or other transformers would fill many columns, and since opinions differ so greatly, we do not expect to see the question settled until some efficiency tests are carried out under the conditions of ordinary use. Mr. Swinburne has, we believe, been somewhat misunderstood by Mr. Nikola Tesla, but he has at least made it clear that the consideration of an "all-day efficiency" has been overlooked by those who have merely made tests at different loads. A misunderstanding is, however, the less to be wondered at, as Mr. Swinburne's style has lately lacked lucidity. This, indeed, is shown in his Paper on testing iron, in this issue.

In a recent Note we remarked that a magneto giving, say, a hundred volts is not a sufficient test for house-wiring. We admit that we had Mr. Sidney Evershed's ohm-meter in mind; and are glad to learn from him that the portable generator which is supplied with his ingenious instrument gives a direct and continuous current at a hundred volts with seventy revolutions per minute, many users being in the habit of turning it faster and getting a hundred and fifty, to two hundred volts. We do not think that this is generally known, and hope to give a description of the generator and of the reasons which led to its design.

According to the annual report of the Queensland Post-master-General the telegraph service of that colony has had a very chequered experience during the past year, the country suffering from numerous and extensive floods, which have either swept the poles away or submerged them under water, sometimes for three or four weeks at a stretch. To maintain communication in these circumstances fresh lengths had to be bolted on to the standing poles in order to raise the lines out of the water; and this, while the wires were the refuge of snakes, and every insulator the shelter for a crowd of centipedes, was a task of no small difficulty and danger. It is not surprising, therefore, that the revenue has fallen off by £10,000, and the expenditure increased by £4,000. Some reforms are in contemplation, foremost amongst which is the adoption of an inclusive rate for all telegrams, the addresses to be charged for. Taking warning, however, probably by what has happened in this country, the Australian officials are almost unanimous in their disapproval of registered code addresses. Thirty-one new offices have been opened in the colony, and 565 miles of additional wire erected during the year, making the total miles of wire 17,193.

In another column will be found the report of the first statutory meeting of the International Okonite Company, which was held yesterday. The Okonite and Elmore concerns cannot at present be discussed apart from the Company who have promoted them, for they have not yet acquired any individuality. They differ from the Automatic Machine manufacture and from the

Digitized by Google

Kensington Stores, on account of the technical nature of the work; and for this reason the public cannot so easily judge of their value.

"From personal inspection our managers report that they are satisfied that the business is a sound and lucrative one." We remarked in a Note on July 4th, that the question is merely one of competition with the reliable products of the well-established manufactures of this country. We believe that okonite is a useful material; but, even if it had swept away and utterly superseded the use of "underwriters' wire" in America, it would not necessarily compete in this country with the almost forgotten "tape and tar," which was used eight or ten years ago. No evidence has yet been offered as to such decrease in cost, or increase in efficiency, as will ensure its reception in our markets.

As for personal inspection, that may be of some use in investigating an Automatic Machine or a Supply Store, but with okonite or Elmore copper we want actual experience. Speaking with reference to Elmore's Austro-Hungarian Patent Copper Depositing Company, the *Statist*, in a recent issue, pertinently remarks that "Before subsidiary Companies are floated in such quick succession, it would certainly have been desirable to have evidence that the parent Company was making satisfactory profits from the manufacture, and was evidencing commercial results, giving an adequate yield on the money invested. In other words, the public ought to have some proof that the purchase price of the patent rights is justified by actual results to the vendor; and proof ought to be afforded by the original vendor company, for here we have an intermediary vendor between the original patentee and the company which has the Austro-Hungarian patents. We have witnessed such disappointment from the formation of other subsidiary companies to work patents that we should very much regret to see the public rush to conclusions in this case without full investigation as to the merits."

It is probable that most of the shareholders of Woodhouse and Rawson (Limited) and of Woodhouse and Rawson United (Limited) can look after their own interests, and place their own interpretation on the report of the latter Company, which will be found in the present issue, without any assistance from the technical press. Electrical engineering and manufactures seem to be quite insignificant compared with their financial undertakings. Comments on their mode of conducting business may, therefore, be left to the financial journals, who appear to grasp the situation, and to offer some very pertinent observations thereon. The brief account which we give to-day of the extraordinary meeting of the old Company will be of interest to others than the shareholders.

The American Duty on Mica.—By the McKinley Bill a duty of 35 per cent. *ad valorem* is imposed on mica.

The Telephone in Spain.—Telephonic communication is about to be established between Madrid and the Royal Palace of La Granja, a distance of 100 miles.

Electric Traction in Berlin.—The Allgemeine Elektricitäts Gesellschaft are about to apply the Thomson-Houston-Huber system to the Wilmersdorf-Königgrätzerstrasse line.

Oswaldtwistle Local Board.—The Oswaldtwistle Local Board have agreed to the construction of an electric tramway through the township to Accrington on satisfactory terms by arrangement with Mr. Chadwick, C.E.

Madrid.—The Spanish Postal and Telegraphic Administration has requested the Telephone Company of Madrid to carry out the contract entered into with the State in regard to placing its cables underground within the term of a year.

Birmingham.—A number of members of the South Staffords shire and East Worcestershire Institute of Mining Engineer-paid a visit on Thursday last week to the electric-charging station of the Central Tramways Company at Bournbrook.

Gravesend.—The Town Council, after many discussions in committee, have at last come to a decision on the question of electric lighting, and have passed a resolution in favour of the requisite steps being taken for securing an electric lighting Order.

Experiments with the Electric Arc.—Experiments with the electric arc, when set up between carbon points in dry oxygen, show that there is a formation of a mixture of carbonic oxide and oxygen, and that the carbon is not at once burned to carbonic acid.

London Chamber of Commerce.—Among the Companies, firms and gentlemen elected members of the London Chamber of Commerce at the last Council meeting were Elmore's Patent Copper Depositing Company, Messrs. J. D. F. Andrews and Co., and Mr. Geo. Offer.

Edinburgh.—At a meeting of the Town Council on Tuesday, it was resolved, on the motion of the Lord Provost, to make application for a Provisional Order under the Electric Lighting Acts, and that the application by four companies for consent to apply for Provisional Orders should be refused.

New Cable.—The India Rubber, Gutta Percha, and Telegraph Works Company have just completed the shipment of about 2,000 miles of telegraph cable for the Central and South American Telegraph Company, to be laid from Lima to Iquique, and thence to Valparaiso, on the West Coast of South America.

The Telephone in Warfare.—According to *La Lumière Electrique*, a "telephonic bonnet" has just been adopted in the Italian garrison artillery, the idea being that the gun detachment commanders should array themselves in this headgar so as to be in constant communication with the officer commanding the battery or fort.

Barnsley.—On Tuesday last the Barnsley Town Council sat for nearly four hours discussing the desirability of carrying out the tender of the Westinghouse Electric Company, which has already been endorsed by a large majority of the Council. In the result, the Council decided by eleven votes to seven to go on with the matter.

Press Messages.—In connection with the meetings of the Church Congress at Hull last week it may be interesting to note that no fewer than 350,000 words of press messages were telegraphed during the four days from the Hull Post Office. The largest number of words transmitted on any one evening reached the figure of 100,000.

The Lighting of the City.—At the last meeting of the Commissioners of Sewers, the recommendation of the Streets Committee, that advertisements should be issued inviting tenders for lighting the western district of the City by electricity on similar conditions to those arranged for the east and central districts, was adopted without discussion.

O. S. A. Annual Dinner.—The sixth annual dinner of the Old Students' Association of the City and Guilds of London Institute will be held at the Holborn Restaurant on Friday, October 17th, at 7 p.m. Tickets, price 4s. 6d. each, may be obtained from the Secretary, 14, Garfield-road, Lavender Hill Mr. W. B. Esson is the President of the Association for the ensuing session.

Digitized by Google

Leeds.—At a special meeting of the County Council, held on Monday, to consider the report of the Electric Lighting Committee of the Corporation, it was decided, by 35 votes to 4, that it was not desirable for the Corporation itself to supply electricity for public and private lighting purposes, as, in the opinion of the Council, such a supply could be advantageously provided by private enterprise.

Personal.— Last week the electrical engineering students of Messrs. Immisch and Co., Kentish Town, presented a piece of silver plate as a token of their esteem to Mr. Charles Francis Quicke, late chief engineer and works manager, on his relinquishing that post after eight years' connection with the firm. The workmen and staff also presented on their own behalf a massive silver spirit case and an inlaid cabinet.

Reduction of Telephone Rentals.—The Directors of the National Telephone Company have decided to reduce the telephone rentals at Leeds from £15 to £10 per annum; and they are further considering the question of giving special advantages to their subscribers for trunk line service. At Glasgow the rentals are to be reduced to £10 per annum for all subscribers within a radius of half a mile of the telephone exchange.

The Lane Fox Electrical Company.—This Company, finding that all their conciliatory efforts have failed, and that the merely nominal terms which they offered have been rejected, have issued writs on the Directors and Secretary of the Kensington and Knightsbridge Company, and on Mr. Crompton as their Consulting Engineer. The Lane Fox Company have retained Sir Richard Webster, Mr. J. F. Moulton, Q.C., and Mr. Graham.

The Yorkshire College.—The Marquis of Ripon presided, and presented the prizes at the Yorkshire College on Tuesday. Lord Ripon, in the course of his address, acknowledged the handsome manner in which the public had responded to the appeal for £40,000 for the formation of an additional building fund, £32,500 having already been raised. In conclusion, he counselled his audience not to forget that that College was not only a Technical College, but a University College.

The Copper Market.—The copper statistics for the month of September show that the stock in England and France and afloat thereto amounted, on September 30th, to 69,906 tons, compared with 69,959 tons at the end of August, and 72,533 tons at the end of July. The total supplies in England and France are stated at 10,187 tons, against 9,393 tons at the end of August; while the deliveries during September were 10,240 tons, compared with 11,967 tons during the previous month.

American Electrical Units.—At the first meeting of the American Institute of Electrical Engineers for the season 1890-91, Prof. F. B. Crocker moved that the unit of self-induction be hereafter known as the "henry," after Prof. Joseph Henry, instead of as the "quadrant," the term adopted at the last Electrical Congress at Paris. The name was unanimously adopted with applause. A committee was then appointed to consider what would be the proper size of the unit, and to report at the next meeting.

Gordon Technical College (Geelong).—We have received a copy of the annual report of this institution, which has now been in existence for over five years. The only class of an electrical character is the one in which instruction is given in telegraphy. The lecture-room is fitted up exactly like a modern telegraph office, and there is every facility for students to acquire a thorough practical knowledge of telegraphy. Instruction is also given in building construction, mechanical drawing and machine construction, chemistry, photography, and general physics.

The Post Office Telegraphists.—On Saturday afternoon last the Postmaster-General notified to the staff of the General Post Office that he had, in continuation of the memorandum of July 14 last, with the sanction of the Lords of the Treasury, converted 43 of the senior class appointments into second-class assistant superintendents, at a salary commencing at £200 per annum, and increasing to £260, the *minimum* of the senior class to be £160. He had also converted some of the female first-class appointments into a higher class.

The Barking Electric Tramway.—A deputation from the Glasgow Corporation recently visited the General Electric Power and Traction Company's electric cars and installation on the Barking-road section of the North Metropolitan Tramways Company's system. At the meeting of the Glasgow Town Council on Tuesday last the Committee on Tramways recommended that application should be made to Parliament in the ensuing Session for authority to use electric and other power on the Corporation tram lines. The recommendation was unanimously approved of.

The Weight of a Cubic Inch of Water.—A re-determination of the true weight of a cubic inch of distilled water has recently been made at the Standards Department of the Board of Trade. A platinised hollow bronze cylinder, whose volume was 572·803651 inches, and whose weight in air was 183676·066 grains, was used together with a quartz cylinder and a brass sphere. After this magnificent parade of accuracy, the results differ in the fifth significant figure, and the conclusion is that the weight of the cubic inch of water at 62° Fahr. appears to be $252{\cdot}286 \pm 0{\cdot}002$ grains.

The School of Electrical Engineering and Submarine Telegraphy.—As the result of the examinations, recently held at the above School, we are informed that the following gentlemen have now obtained the Vellum Certificate of the School:—(*a*) In Electric Lighting and Power Transmission: Messrs. Claypoole, Garré, Gillies, Lawrence, Phillips, Roussel, and Waring. The examinations in these subjects were conducted by Mr. Gisbert Kapp, and included a "vivâ voce" and Practical Examination. (*b*) In Telegraphy and Telephony: Messrs. Lawrence (above named) and Salmony. This examination was conducted by Mr. H. R. Kempe.

The Rating of Telephone Poles.—An important rating case affecting telephone companies was heard at Totnes last week. The Western Counties and South Wales Telephone Company appealed against a rating of £25 made by the overseers of the parish of Kingswear upon the Company's poles and wires in the parish. It was urged by the Company that it was not deriving any income from the parish of Kingswear, as there was no exchange or call office in the parish, and in other places the Company's poles and wires were only rated at the nominal value of 5s. per mile. After hearing further arguments, the Assessment Committee decided to reduce the rateable value from £25 per annum to the nominal sum of £1 per annum.

The New York Subway Rentals.—According to the report of the Engineer of the Board of Electrical Control, the present schedule of rentals charged by the Subway Company is as follows: For 4-inch ducts, £250 per mile per annum; for 3-inch ducts, £200 per mile per annum; for 2½-inch ducts, £170 per mile per annum; for 2-inch ducts, £140 per mile per annum; for 1½-inch ducts, £110 per mile per annum; for 1¼-inch ducts, £100 per mile per annum. For distribution ducts, 1 to 4in., £200 per annum. The high-tension electric light companies generally occupy ducts of 3in. diameter. Up to January 1, 1890, 501 miles of telegraph and telephone ducts, and 515 miles of electric light and power ducts had been constructed, making a total of 1,016 miles of ducts.

Test of a Submarine Electric Light Cable.—The *India Rubber World* says the experiment was recently tried of sending an alternating current of 1,000 volts pressure through the submarine cable which connects the electrically lighted buoy off Robbin's Reef, New York harbour. The experiment was made to see if the cable would stand the stress without breaking down or developing a fault, and the result was entirely successful as far as the cable was concerned. There was no leakage and no injury to the cable. This cable is insulated with gutta percha, and was made by the Bishop Gutta Percha Company. The same company also manufactured the cables which carry current for lighting the six buoys in Gedneys Channel.

New Books.—Amongst the new scientific books about to be published are:—"The Principles of Chemistry," by D. Mendeléeff, translated by George Kamensky, of the Imperial Mint, St. Petersburg, and edited by A. J. Greenaway (Messrs

Digitized by Google

Longmans and Co.). "A Popular Treatise on Electricity and Magnetism," by Amédée Guillemin, translated and edited, with additions and notes, by Prof. S. P. Thompson; "Popular Lectures and Addresses," by Sir William Thomson, Vol. III. (Messrs. Macmillan and Co.). "A Treatise on Electricity and Magnetism," by J. Clerk Maxwell, new edition; "An Introduction to the Mathematics of Electricity," by W. T. A. Emtage (Clarendon Press). "A Text-Book of Electro-Metallurgy," by W. G. Macmillan; the complete volume of Prof. Jamieson's elementary manual of "Magnetism and Electricity" (Messrs. Charles Griffin and Co.). Messrs. Whittaker also announce a new and revised edition of Mr. Gisbert Kapp's "Electric Transmission of Energy," and a book on "Electro-Motors," by S. R. Bottone.

Exeter.—A special meeting of the City Council was held on Monday, to consider the application of the Exeter Electric Light Company and the report of the Special Committee on Electric Lighting. Mr. Andrew said he was unable to agree to the resolution of the Special Committee, who had resolved that, in their opinion, the Council should apply for a Provisional Order, and that the consent of the Council should not be given to the granting of an order to the Electric Lighting Company. He moved:—"That inasmuch as any monopoly in the supply of electric lighting is rendered impossible by the Acts of 1882 and 1888, which also safeguard the interests of the citizens in other directions, it is not desirable that the Council should take steps to obtain a Provisional Order until it is ascertained what arrangements can be made with the existing Electric Lighting Company for an optional purchase by the Council of their works within a shorter specified period than 42 years." The amendment was carried by 28 to 13 votes; and it was resolved to call a special meeting of the Council a month hence, to again consider the question of giving assent to the Electric Lighting Company's proposed order.

Electric Traction in Budapest.—The Budapest Electric Railway, which was built by Messrs. Siemens and Halske on the underground-conductor system, has proved a decided commercial success. Some 20 cars run on the line, the length of which is 7·9 kilometres. The line passes through the most fashionable streets of the town. During the month of April, 337,200 passengers were carried, being at the rate of 42,684 per kilometre of line, and 16,860 per car. The horse lines in the same town, which have a total length of 45·6 kilometres, and 329 cars, carried in the same month only 33,074 passengers per kilometre, and 4,854 per car. The earnings for the month were, for each electric car, £102; for each horse-car, £37. Since the date of this return, it is said that the differences in favour of the electric lines have been still further increased. The greater speed attained by the electric cars (11 miles per hour, as against 5) is no doubt responsible to a great extent for this flourishing state of affairs. The Town Council has also recently given permission for the building of a small electric line on the Zipernowsky single-track system. An experimental length of 3 kilometres, from Messrs. Ganz's factory to Steinbruch, is at present being laid down.

Special Edison Lamps for Series Working.—The American Edison Lamp Works are now turning out a large number of small incandescent lamps for burning in series on 110-volt circuits. These "small-series burning lamps" are made in candle-powers of 1 to 4 candles, and they require about 14 volts. Their efficiencies vary from 3 to 5 watts per candle. Some tests to determine the best efficiency to give these lamps are now being made at the Edison factory. Another lamp now being manufactured is designed for use on power circuits, and particularly for use on 500-volt street railway circuits. The lamps are made to give 16 candle-power. The voltage ranges from 95 to 100 volts, and the currents from ·60 to ·75 amperes. In designing the "railway" lamp, it was thought best to give it a stouter carbon such as would not be so easily injured by the mechanical strain to which the carbon of the lamps are subjected. Very high efficiency is not to be desired in these lamps on account of the constant variation in the E.M.F. on the circuit. The efficiency of the lamp as determined on is about four watts per candle. The voltage on the circuit can fall considerably below the 500 volt limit, as it is constantly doing on the railway circuits, without bringing the lamps to a very low incandescence; also an increase in pressure of 10 per cent. will not cause the lamps to break at an abnormal rate.

The Middleman in Electric Lighting.—Under this title an occasional correspondent writing to *The Times* reviews the question of the transference of the powers and liabilities attached to electric lighting orders obtained by local authorities. He points out, as we have frequently done in these columns, that the functions of local authorities will be those of middlemen, of prejudicially interested middlemen, in many cases with the power and the motive to farm out their order on terms more onerous than those conceded by the Electric Lighting Act of 1888; traders not in electric lighting but in an Act of Parliament. They would rather not take the risks, but the profits, should there be any; these they would like to pocket at an earlier date than the Act provides for. Can this be done without checking, without arresting altogether, it may be, the further development of electric lighting? Now, the amount that would be refunded to the Company by the sale of the undertaking on such terms as these must of necessity represent but an infinitesimal part of the total capital that would have been spent in the building up of the business. A sinking fund, large in proportion to the shortness of the tenure, must be set aside out of income for the redemption of capital. The larger the sinking fund the higher must the charge be for electricity. The conclusion is inevitable that to what extent soever you may succeed in reducing the tenure of supply authorised by the Act, to just that extent you handicap the electric light; to just that extent you lessen its attractiveness for the prudent investor. In the Lords' Select Committee of 1886, Lord Ashford and Lord Balfour of Burleigh made several efforts to exclude gas-owning Corporations from those local authorities whose consent was to be necessary to the granting of a provisional order to private undertakers. Their efforts were, unhappily, not successful. And the result has been to render the Act a dead letter in the case of all towns so governed. The truth is too often lost sight of, that private capital will not take the risk of developing a new enterprise for the simple good of the community. It is very selfish, but then the millennium has not dawned yet.

The Copenhagen Specification.—The specification for the central station at Copenhagen is a document of very uneven character, and is prefaced by a note to the effect that the Magistracy does not take upon itself any responsibility for the translation. "The first plant is to be arranged for a supply of about 14,000 contemporaneously burning incandescent lamps of 16 English candle-power each." A security of 10 per cent. of the contract sum is demanded, and a fine of one-third per cent. of the value of the work not completed, "for every beginning week which expires before the time specified." There are to be seven boilers of the Babcock-Wilcox, Steinmüller or similar make, to work at ten atmospheres, each giving 7,700lb. of steam per hour, with a maximum moisture of two per cent. Tests of the fuel, boilers, and dryness of steam are described. Four steam engines are to be provided, one of 100 effective horse-power, one of 300, two of 500, and space is to be left for two of 1,000 horse-power. They are to be compound receiver, condensing, hammer type, cranks at right angles, and coupled direct to the dynamos. The speed of the engines to be 150 and 125 respectively, and a variation of not more than 1½ per cent. is to be allowed from full load to one-eighth load. A full specification of the engine is given, and consumption tests are described. The specification of the dynamos is considerably more vague than that of the "motorial part of the plant." "During motion they must be warmed but to a slight degree . . . without using uncommonly much oiling material." "The dynamos must be capable of changing the mechanic strength transferred from the engines to the shafts, into electric energie with as small loss as possible." A switch-board for 20,000 simultaneously-burning 16 candle-power lamps, and accumulators "that without over-exertion by themselves are able to furnish 1,000 lamps" for eight hours, are to be provided. The three-wire system is to be employed in distributing, and the pressure is to be such that two arc lamps in series can burn steadily, but it must not exceed 110 volts. A fall of 1·4 volt is allowed on a pair of distribution mains at full load, and 14 volts on the feeders.

MAGNETISM IN IRON AND OTHER METALS.*—XXXII.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 579.*)

§ 118. Hysteresis in the Relation of Magnetic Susceptibility to Temperature.—Although no hysteresis appears in the experiments which have just been described, the magnetic condition depending, apparently, only upon the actual temperature and not upon past temperatures, it is still possible to experiment under conditions which show hysteresis in the relation of magnetic quality to temperature. Hysteresis of this kind is found when the range through which the temperature is varied is sufficiently wide to include the critical region, in which magnetic quality disappears during heating and reappears during cooling. The disappearance and reappearance do not occur at the same temperature. There are two critical temperatures: one is the point at which magnetic quality is lost during heating, and this is higher than the other, namely, the point at which magnetic quality is regained during cooling.

In ordinary iron and steel the difference between these two critical temperatures is not great—perhaps ten or twelve degrees in soft iron—and the direct measurement of it is a matter of some difficulty. That there is a difference, however, admits readily of easy experimental proof,† and may, indeed, be inferred from the phenomenon of recalescence. It is known that in recalescence there is, superposed upon the process of cooling, a real rise of temperature, and it is known that the change of magnetic state occurs simultaneously with the recalescence. If the change of constitution which then takes place depended upon the actual temperature alone, and not upon preceding temperatures, this rise would be impossible, for it would undo the very change which causes it. To make it possible the altered state of the material must be able to stand some elevation of temperature without changing back again; in other words, the change of constitution must show hysteresis with respect to temperature.

Osmond,‡ who has made a very full investigation of the temperatures at which perturbations take place during the processes of heating and cooling, finds that with electrolytically deposited iron there is a marked evolution of heat during cooling, about 855°C., and a marked absorption of heat during heating—about 867°C. There is no reason to doubt that it is at and about these temperatures that the changes from the non-magnetic to the magnetic state and from the magnetic to the non-magnetic state respectively occur.

In hard steel Osmond's experiments show a wider difference between the two critical temperatures. The principal evolution of heat during cooling occurs at 674°C., and the corresponding absorption of heat during heating occurs at 705°C. At any temperature between these limits we should expect to find this steel magnetic if the immediately preceding temperature had been lower, but non-magnetic if the immediately preceding temperature had been higher.

A much more remarkable difference of the same kind is found in what is called nickel-steel. Hopkinson has examined several alloys of iron and nickel, and has discovered, by direct magnetic tests, that in some of them the metal may retain either a magnetic or a non-magnetic condition throughout an extraordinarily wide range of temperature.‖ His results as to other physical properties of these alloys, as well as their magnetic properties, are of the highest interest.

§ 119. Hopkinson's Experiments with Nickel-Iron Alloys.—The samples were tested ballistically, in the form of rings, the temperature being inferred from the resistance of the secondary coil. A sample containing 4·7 per cent. of nickel and 0·22 per cent. of carbon, gave a magnetisation curve, at the temperature of the atmosphere, resembling the curves given by ordinary mild steel. When heated, the magnetic quality being tested by reversals of a magnetising force of 0·12 C.-G.-S., it was found to lose susceptibility between 750°C. and 800°C., and not to regain it on cooling until the temperature had fallen to 650°C. or 600°C. Fig. 90 shows the changes which took place during heating and cooling; it gives the induction B produced by reversing the force H of 0·12, in terms of the temperature. It will be seen that there is a clear range of about

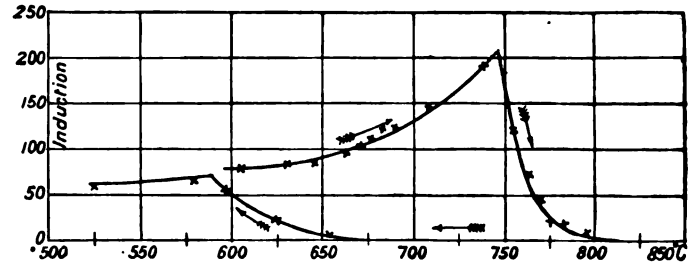

FIG. 90.—Steel with 4·7 per cent. Nickel. Magnetising Force 0·12.

150° within which the metal may exist in either of two states; in one state it is as susceptible as ordinary mild steel; in the other it is practically non-magnetisable, the permeability being, in fact, only about 1·4. Under stronger magnetising forces the magnetic quality appears and disappears at about the same two points. Further, an experiment in which the time rate of heating and of cooling were observed showed that the same two temperatures were marked by perturbations such as occur at the critical temperature in iron, the higher temperature being associated with an absorption of heat in the process of heating, and the lower temperature with an evolution of heat in the process of cooling. The heat which is liberated in cooling, at the temperature where magnetic quality returns, was found to be about 150 times the quantity which would raise the temperature of the piece by one degree.

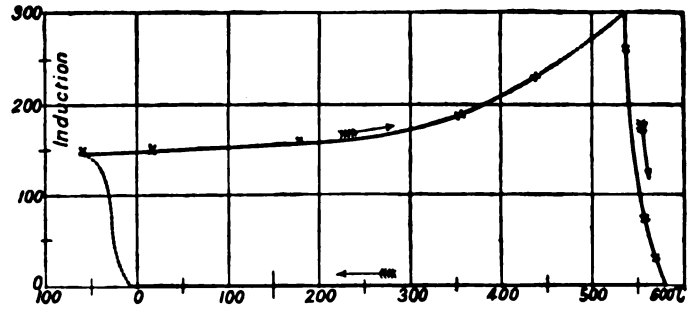

FIG. 91.—Steel with 25 per cent. Nickel. Magnetising Force 6·7.

Still more striking results were obtained with a specimen containing 25 per cent. of nickel. This was non-magnetisable at ordinary temperatures in its primitive state, but on being cooled in a freezing mixture it became magnetisable at a temperature a little below the freezing point. Rendered magnetisable in this way, it retained its magnetic quality on being warmed until the temperature rose to 580°C. At that temperature it became again non-magnetisable, and remained so on cooling down to the ordinary temperature of the air. Within a range of about 600 degrees this steel is capable of existing, quite stably, in either state. Figs. 91 and 92 show the induction B (produced by reversals of magnetic forces equal to 6·7 and 6·4 respectively) in terms of the temperature. In the non-magnetisable state the permeability is only 1·4; in the

* All rights are reserved.

† A very pretty experiment, showing that the change of state which iron undergoes in passing a red heat occurs at different temperatures during heating and during cooling, has been described by Mr. Newall and by Mr. F. T. Trouton. A lamp flame, held under an iron wire which is in circuit with a galvanometer so that a short portion of this wire becomes red hot, is made to travel slowly under the wire, and it is found that a current appears in the galvanometer, the direction of the current depending on the direction in which the flame travels. The current is due to difference in thermo-electric quality between the red hot and the cold iron, and depends on the fact that on the side which is being heated the change of state is occurring at a higher temperature than on the side which is being cooled.

magnetisable state the permeability resembles (but falls rather short of) that of hard nickel. The curve of magnetisation (at 13°C.) is copied in Fig. 93. Hopkinson has also shown that other physical properties of this alloy change along with its magnetic properties. The electrical conductivity is markedly different in the two states: at 0°C., for instance, the specific resistance is only 0·00052 if the substance has been brought into its magnetisable state by applying a freezing mixture, but is 0·00072 if it has been brought into the non-magnetisable state by previous heating above 600°C.

Equally pronounced differences are found with regard to extensibility and strength. In the non-magnetisable state this metal is comparatively soft; wires show an elongation of 30 per cent. or more before rupture, and break with a load of about 50 tons per square inch. In the magnetisable state it is much harder; there is only 7 or 8 per cent. of extension, and the strength is no less than 85 tons per square inch, or even more.

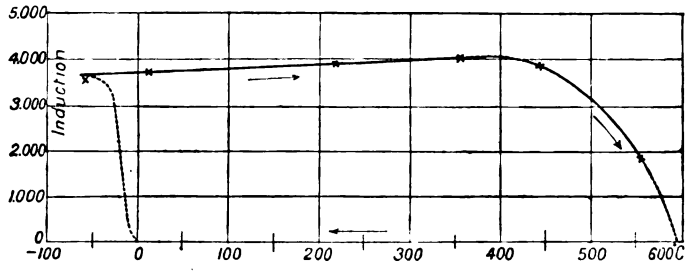

Fig. 92.—Steel with 25 per cent. Nickel. Magnetising Force 6·4.

"If," says Hopkinson, "this material could be produced at a lower cost these facts would have a very important bearing. As a mild steel the non-magnetisable material is very fine, having so high a breaking stress for so great an elongation at rupture. Suppose it were used for any purpose for which a mild steel is suitable on account of this considerable elongation at rupture: if exposed to a sharp frost its properties would be completely changed—it would become essentially a hard steel until it had actually been heated to a temperature of 600° C." It is interesting to notice that specimens of the non-magnetisable metal when broken in the testing machine pass into the magnetisable state; the change occurs along with the mechanical hardening which the metal suffers in being drawn out.

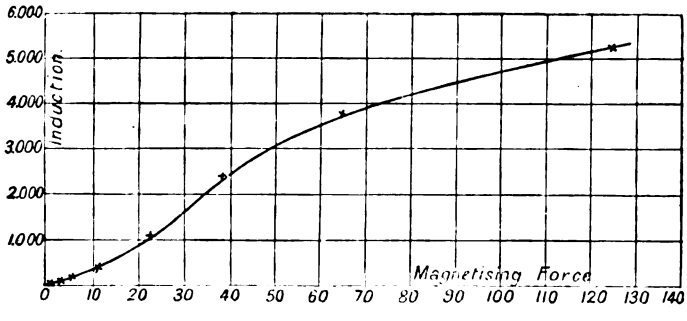

Fig. 93.—Steel with 25 per cent. Nickel. Curve of **B** and **H**.

This remarkable power of assuming one or other of two widely different physical states is less noticeable when the percentage of nickel in the alloy is further increased. Two other nickel iron alloys, containing respectively 30 per cent. and 33 per cent. of nickel, were found by Hopkinson to be much more permeable, and to show very much less hysteresis with respect to temperature in changing between the magnetisable and non-magnetisable states, and to change at a comparatively low temperature. Fig. 94 shows the results of magnetising the 33 per cent. sample with a force **H** of 1·0. The curves, which correspond to rising and falling temperatures, are not far apart, and the change takes place at temperatures lying near 200°C. In the 30 per cent. sample the critical temperatures are lower about 140°C. in heating and 125°C. in cooling). Finally, a sample containing 73 per cent. of nickel showed no material difference between the critical points for heating and cooling; its critical temperature was 600°C.

These observations make it not unlikely that a substance such as manganese steel, which is nearly non-magnetic in all conditions of temperature in which it has hitherto been tested, would become magnetic if the temperature were sufficiently

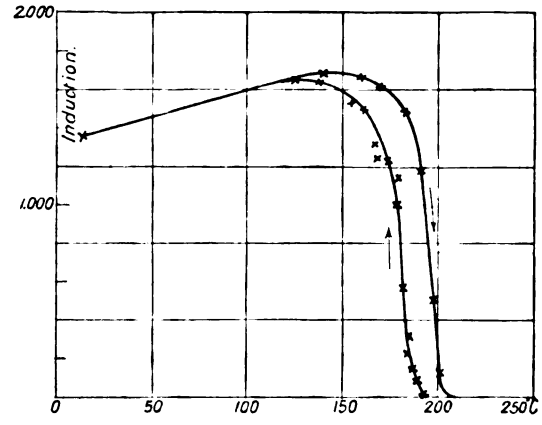

Fig. 94.—Steel with 33 per cent. Nickel. Magnetising Force 1·0.

lowered. And it is even possible that other metals than iron, nickel, and cobalt are non-magnetic only because all our dealings with them are at temperatures above a "critical point."

ON THE ELECTRO-DYNAMICS OF STATIONARY BODIES.*

BY H. HERTZ.

(Continued from page 581.)

Conservation of Energy.—Let us denote by S the electro-magnetic energy in a given volume τ, an element of whose surface is represented by $d w$. From (10) and (11), by multiplying the equations respectively by L, M, N, X, Y, Z, adding, and integrating throughout the volume considered, we deduce, in the same manner as in equation (4), the result

$$4\pi A \frac{dS}{dt} = -4\pi A \int (u X + v Y + w Z)\, d\tau + \int \begin{vmatrix} \cos(n,x) & \cos(n,y) & \cos(n,z) \\ X & Y & Z \\ L & M & N \end{vmatrix} dw \quad . \quad . \quad (23)$$

and if the volume τ includes a complete electro-magnetic system, so that the forces disappear at the surface, this equation reduces to

$$\frac{dS}{dt} = -\int (u X + v Y + w Z) d\tau. \quad . \quad . \quad . \quad (24)$$

This equation leads us to the conclusion that each unit of volume is a source of energy, and producing it at the rate denoted by $(u X + v Y + w Z)$. Experience tells us in what form this energy shows itself in particular cases. In the interior of good conductors the quantity of energy generated per unit volume in a unit of time, is, according to both theory and practice, given by either of the equivalent expressions

$$\lambda (X^2 + Y^2 + Z^2) = \frac{1}{\lambda} (u^2 + v^2 + w^2).$$

Where $\frac{1}{\lambda}$ is the specific resistance, X, Y, Z, are the components of the electromotive force, and u v and w the components of the electric current. These expressions are in perfect accordance with (24) since for such conductors we have $u = \lambda X$, $v = \lambda Y$, $w = \lambda Z$.

Again at the bounding surface of isotropic homogeneous bodies the quantity of energy produced in the separating layer per unit volume, per unit time, is given by the expression

$$u X' + v Y' + w Z'.$$

* An abstract of a paper published in the "Nachrichten von de Kœniglichen Gesellschaft, der Wissenschaften," for March, 1890; and reprinted in *La Lumière Électrique*, July, 1890.

Digitized by Google

An integration extended from one side to the other of the separating layer shows that the rate of increase of energy per unit of separating surface is equal to

$$(u\cos(n,x)+v\cos(n,y)+w\cos(n,z))\,\phi_{12}$$

or proportional to the current of electricity across the surface. Experience shows that a similar expression holds true in practice. Its value may be positive or negative, and, according to circumstances an augmentation or diminution of energy may be denoted by it. If this energy takes the form of heat, it corresponds with the Pelter effect, and we call the electromotive force acting a thermo-electric one. If we have to consider the chemical energy as well as the heat energy, we call the electromotive force a chemical one.

Finally, let us consider a limited portion of the system, and calculate the rate at which the total energy is increased. This rate is given by the expression

$$\frac{dS}{dt}+\int(uX+vY+wZ)\,d\tau.$$

Since it must exceed the rate of increase of electro-magnetic energy by the quantity denoting the rate at which energy is being dissipated. By reference to (23) it is thus apparent that the variation of the energy accumulated within any space can be exactly calculated by supposing that the energy travels across the bounding surface in such a way that the energy current per unit of area of the bounding surface is equal to

$$\frac{1}{4\pi A}\begin{vmatrix}\cos(n,x) & \cos(n,y) & \cos(n,z)\\ X & Y & Z\\ L & M & N\end{vmatrix} \quad . \; . \; 25$$

Investigation of this expression shows that the energy current thus defined flows at right angles to the direction of both the electric and magnetic forces, and that its value is equal to the product of the two forces, multiplied by the sine of the angle between them and divided by $4\pi A$.

In discussing this hypothesis of an energy current, it must be noticed that the way in which the integral has been split up is quite arbitrary, and that the results to which it leads are not always probable. For example, when a magnet is placed near an electrified body, the energy in the neighbouring space must, according to this view, be continually in motion in closed cycles. It seems to me that, in the actual state of our knowledge, we must accept with caution the idea of the localisation of energy, and its motion from one point to another. No analogous principles have as yet been introduced into the study of rational mechanics.

(To be continued.)

ON THE AIR CONDENSERS OF THE BRITISH ASSOCIATION.*

(Continued from page 619.)

BY R. T. GLAZEBROOK (WITH A NOTE BY DR. A. MUIRHEAD).

It remains, then, to give an account of the experiments undertaken for the purpose of comparing mica or paraffin condensers, as ordinarily used with the air condensers, and of investigating some of the effects of absorption.

The two well-known methods of De Sauty and Sir William Thomson have both been employed.

The arrangements are shown in Figs. 5 and 6.

The first of these is not really suitable for use in cases in which there is absorption, though with care a fairly accurate measure of the instantaneous capacity can be found. The resistances, R_1, R_2, can always be arranged so that the effect of the charge rushing into the air condenser shows itself, as a sharp kick of the spot of light—to the left, say—followed by a slower deflection in the other direction due to the absorption charge soaking into the mica or paraffin. The resistance for which this sharp kick practically disappears is fairly definite, and from it the instantaneous capacity can be found, while an observation of the resulting kick due to the absorption enables us to calculate the increase of capacity which arises from that cause. This can be done in various ways; the simplest, perhaps, is to disconnect the condensers from the circuit, and replacing the mica condenser by a variable condenser of small capacity, observe the kick this produces in the galvanometer, when charged with the same battery. From this the capacity to which the absorption is equivalent can be approximately calculated.

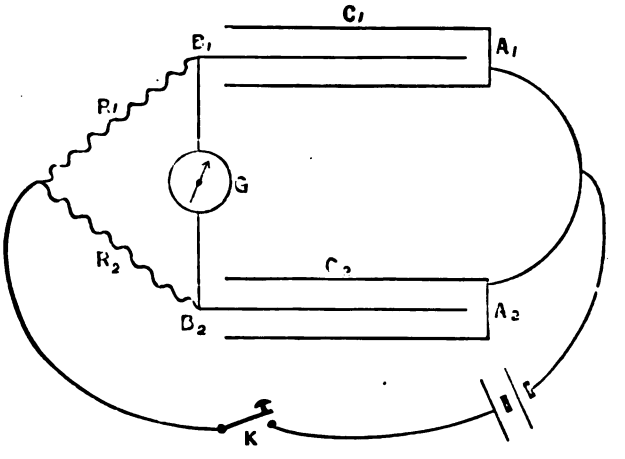

FIG. 5.—Comparison of Mica or Paraffin Condensers with Air Condensers (1st Method).

Thus, a condenser of about ·1 microfarad was compared with Dr. Muirhead's three condensers combined. Taking C_2, R_2, to refer to the air condenser, we had

$$C_2 = \cdot 009506$$
$$R_2 = 898650 \text{ ohms},$$

and with $R_1 = 89300$ there was a slight tremor to the left and a movement of 5 divisions to the right; on changing R_1 by 100 ohms, the change in the motion of the spot was marked.

This gives for the instantaneous capacity $C_1 = \cdot 09550$ the value found by the commutator at frequency 64 was ·09543 microfarads.

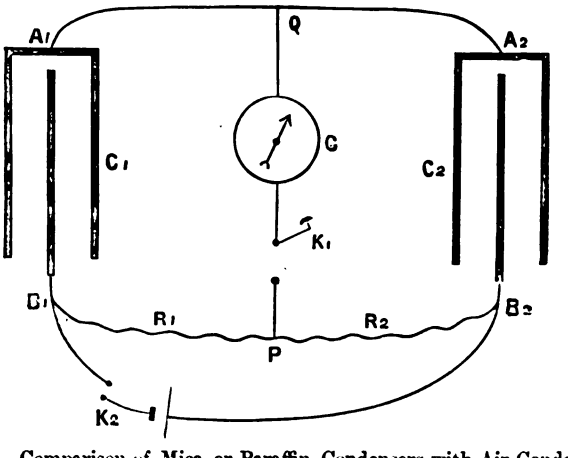

FIG. 6.—Comparison of Mica or Paraffin Condensers with Air Condensers (2nd Method).

To evaluate the 5 divisions, the air condenser was disconnected, and the mica condenser replaced by one of capacity ·001 microfarads; the kick observed was 4·8 divisions, while with ·002 microfarads it was 9 divisions, thus a kick of 5 divisions corresponds to about ·0011 microfarad capacity. Hence the capacity of the mica condenser, including the full effect of absorption, is ·0966 microfarads.

The second method, about to be described, in which the absorption effect is included, gave ·0965 microfarads.

Let us now consider the second method. The current from a battery flows through a large resistance, R_1+R_2, B_1 P B_2 (Fig. 6). One plate of each condenser is in contact with B_1 and

* Paper read before the British Association in Section A, Leeds, September, 1890, being an Appendix to the Report of the Committee on Electrical Standards.

Digitized by Google

B_2 respectively, let V_1, V_2 be the potentials at these points. The other plates, A_1, A_2, are insulated and connected together and to the galvanometer G the other pole of the galvanometer can be connected to P, through the insulated key K_1. The galvanometer can be replaced by an electrometer. Let R_1 be the resistance, P_1 B, R_2 the resistance, P B_2. Suppose the point, P, be put to earth, the rest of the circuit being insulated. Then if C_1, C_2, be the capacities it is easy to see that there will be no current through the galvanometer on making the key K_1, if $C_1 R_1 = C_2 R_2$.

Now, in the case of a mica or paraffin condenser the capacity is a function of the immediate past history of the condenser, and different values will be found for the R_1, R_2, according to the time the charging has lasted. Dr. Muirhead, however, who uses the method largely, has shown how to obtain the instantaneous capacity from the observations. His method is described in the following extract from a letter to myself.* In the method as described, one pole of the battery is to earth instead of the point P of Fig. 6.

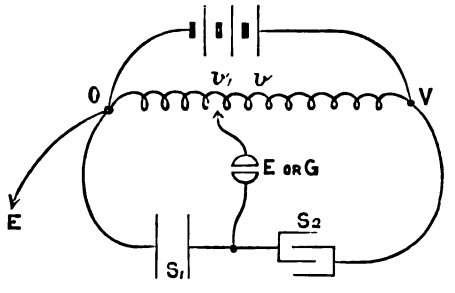

Fig. 7.—Comparison of Condensers (Dr. Muirhead's Method).

Dr. Muirhead writes:—"I have ·05 microfarad nearly in all condensers, and a series of mica condensers of ·1, ·2, ·3, ·331 (original one-third) and ·498 (original ·5) mf. capacity, all enclosed in a double air-tight box to keep the temperature as uniform as possible. The capacity of these standards is determined periodically by both the tuning-fork method (using a revolving commutator instead of the tuning fork), and by the ballistic galvanometer method. One can make comparisons of these condensers among themselves and with other condensers by the method I adopt to an accuracy of 4 in 10,000. The temperature coefficient of shellacked mica condensers is about ·018 per degree centigrade and of paraffined mica ·034 per cent.

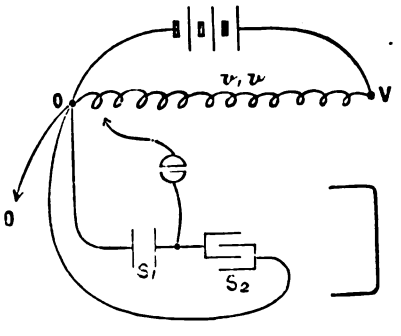

Fig. 8.—Comparison of Condensers (Dr. Muirhead's Method).

Let S_1 (Fig. 7) be the capacity of the air condensers,
" S_2 " " condenser to be compared with air condensers.

After making battery contact, supposing the charging of the condensers to be instantaneous and the absorption *nil*, then we have

$$v S_1 = (V - v) S_2$$

where v is the potential of the junction of the two condensers. Should there be any delay in obtaining the balance, the position of r on the slides will vary—say to v_1—then the charges on the two condensers will be

$$v_1 S_1 \text{ and } (V - v_1)(S_2 + \sigma)$$

respectively where σ is the apparent increase of capacity of S_2 due to absorption or soaking in of charge. On disconnecting the armature of S_2 from the slides and putting it to O (Fig. 8), or earth, the potential falls from V to O, and immediately afterwards the potential of the junction of the two condensers becomes, say, v_2, so that

$$S_1 v_1 + S_2 (v_1 - V) = (S_1 + S_2) v_2.$$

Hence
$$v_1 (S_1 + S_2) - V S_2 = (S_1 + S_2) v_2.$$

or
$$S_2 = S_1 \cdot \frac{v_1 - v_2}{V - (v_1 - v_2)}.$$

V and v_1 are known, and v_2 is indicated at once on an electrometer, or when a galvanometer is used it can be measured quickly, thus:—As soon as v_1 has been observed, break the galvanometer contact and move the index of the slides down to O, then directly after bringing the armature of S_2 from the full potential of the slides to zero, close the galvanometer circuit and observe the throw, a, which is a measure of v_2, the potential of the junction of the two condensers."

In my own experiments, which were made after consultation with Dr. Muirhead, I adopted a method practically the same as his; but before describing it it will be better to consider rather more the effects of absorption. Let us suppose, at first, that the leakage from either condenser is inappreciable. If there be no absorption, each condenser is charged to its full potential practically instantaneously, and it does not matter when or in what order the keys, K_1 K_2, are put down; the position of P on the slide is not affected.

Suppose, now, that C_1 shows absorption, the capacity increases with the time of charging. We can get the instantaneous capacity by depressing—first, the key K_1 and then K_2; but in this case we are troubled with the effect of the slow after charging as in the other method. Still the resistance, for which the kick due to the initial charging disappears, is, with the condensers I employed, fairly marked, and a value for the instantaneous capacity can be thus fairly accurately obtained.

If, now, K_2 be made for 1 second and then K_1 depressed, a different position will be found for P. With this interval of charge the apparent capacity differs appreciably from its instantaneous value, and the after effects of the absorption can still be observed. The same is true for intervals of 2, 3, or 4 seconds, the value obtained for the capacity increases, and the after effect is still noticeable; but with the condensers and battery I used, if the time of charging was prolonged to 5 seconds, the after effect was inappreciable, and the position of P on the slide, and hence the apparent value of the capacity, were hardly affected by further increasing the time of charge. In the experiments on a cable recorded in Dr. Muirhead's Paper, already referred to, the absorption effects continue much longer. In the observations recorded below, then, unless the contrary is stated, the key, K_2, was held down for 5 seconds, and then, K_1 being depressed, the position of P determined, for which the galvanometer remained unaffected. The value of the capacity deduced, then, is the full capacity for the potential to which the condenser is charged. It is, of course, possible, though further experiments would be wanted to prove it, that the full effect of absorption is not merely to increase by a definite amount, independent of the potential, the apparent instantaneous capacity, but that the increase may depend on the potential to which in each case the condenser is being charged. It will, of course, depend on the purposes for which the condenser is to be used whether the instantaneous capacity or the full capacity is required; and it probably will be best, when issuing certificates, to state both the instantaneous capacity and the maximum increase due to absorption—mentioning at the same time the potential used in the experiments for determining this correction, and also the time of charging in which this maximum increase is practically attained.

The method I employed in determining the correction due to absorption was the following:—Suppose the plates, A_1 A_2, to be at potential zero and uncharged. Make the battery key, K_2, and after keeping it made for some little time break it again. If there be no absorption A_1 and A_2 will still be at zero potential and uncharged; but let there be absorption in one of the two, A_1, and let B_1 be the positive pole of the battery; then, while the battery is on, negative electricity is being

* See also *The Electrician*, Sept. 5, 1890.

Digitized by Google

absorbed by the dielectric near A_1, and positive electricity is left free over the plates, A_1 A_2, and the wires connecting them. When the battery is broken the negative electricity begins to soak out, but the process takes time. Hence, if immediately on breaking the battery key, K_2, the galvanometer key, K_1, is made for an instant, there is a throw of the galvanometer needle indicating the passage to the earth of the positive set free by the absorption. If, after a time, the galvanometer key be again depressed, there is an equal throw in the opposite direction caused by the passage of the negative which has again soaked out of the condenser. The required correction is obtained from either of these throws.

For, let i be the current between B_1 and B_2; let C_1 be the instantaneous capacity of the one condenser and C_2 of the other; and let Q be the quantity of electricity absorbed. Then the quantity of negative electricity on the plate A_1 is $C_1 R_1 i + Q$, and the quantity of positive electricity on the plate A_2 is $C_2 R_2 i$, if we assume the potential of these plates to be still zero.

Therefore, $$C_1 R_1 i + Q = C_2 R_2 i$$

$$\therefore \frac{C_1}{C_2} = \frac{R_2}{R_1} - \frac{Q}{C_2 R_1 i}.$$

If E be the E.M.F. of the battery, then, neglecting the battery resistance,

$$i = \frac{E}{R_1 + R_2}$$

$$\therefore \frac{C_1}{C_2} = \frac{R_2}{R_1} - \frac{Q}{C_2 E}\left(1 + \frac{R_2}{R_1}\right).$$

Now, we have seen that with the galvanometer as I used it, if γ is the throw produced by the passage of a quantity Q, then $Q = \gamma \times 10^{-10}$.

The battery consisted of 36 small storage cells, which, when fully charged, had an E.M.F. of about 75 volts, so that

$$E = 75 \times 10^8.$$

Also, $$C_2 = \cdot 021 \text{ microfarads}$$
$$= 21 \times 10^{-18}.$$

Hence, with these numbers,

$$\frac{C_1}{C_2} = \frac{R_2}{R_1} - \frac{\gamma}{1575}\left(1 + \frac{R_2}{R_1}\right).$$

Or, writing it as a correction to C_1,

$$C_1 = \frac{C_2 R_2}{R_1} - \frac{\gamma}{75}\left(1 + \frac{R_2}{R_1}\right)10^{-18}.$$

Examples of the method of applying this correction will be given shortly.

It will be noticed that a leak in one of the condensers may be corrected for in the same way. For, suppose the mica condenser to leak, then a quantity of Q^1 of positive electricity passes through to the plate, A_1, while the battery current is on, and the condition that the galvanometer should not be deflected is,

$$C_2 R_2 i - C_1 R_1 i = Q^1,$$

the same equation as previously.

There will, however, be this difference: on depressing the key, K, after breaking the battery circuit, a positive charge will in both cases pass from A to B through the galvanometer; if this charge be due to absorption, there will, when the key is again depressed after an interval, be a current through the galvanometer in the opposite direction; while if the first charge be due entirely to a leak, there will be no effect when the key is the second time depressed. In practice, the leak and the absorption may exist together either in the same or different condensers. In the second case the leak will tend to produce opposite effects to those caused by the absorption; the quantity, Q^1, however, increases nearly in the ratio of the time of charging, while Q increases for the first few seconds, but soon reaches a maximum and then remains constant.

These considerations are illustrated by some experiments in which the condensers I. and II. were compared with various mica condensers. The battery key was in each case made for 30 seconds; it was then broken, and the galvanometer key was made for an instant, the resulting throw was the sum of those due to (1) the leak in the mica condenser (λ) say; (2) the absorption in that condenser (α) say; and (3) the leak in the air condenser, which produces an effect in the opposite direction $-\lambda^1$, say.

After about 30 seconds more the key was again depressed, the resulting throw is due to the absorbed electricity which has again leaked out, and this will give us $-\alpha$.

The following table gives the results; each observation entered is the mean of three or four.

Condenser compared with standard.	——	I.	II.
·05	$\lambda + \alpha - \lambda^1$	2·3	−7·3
	$-\alpha$	−3	−2·6
·1	$\lambda + \alpha - \lambda^1$	2·2	−9
	$-\alpha$	−3	−3
·1	$\lambda + \alpha - \lambda^1$	2·2	−7
	$-\alpha$	−2·2	−3·5
·5	$\gamma + \alpha - \lambda^1$	3·3	−4
	$-\alpha$	−3·3	−2·5
	$\lambda + \alpha - \lambda^1$	4	−3·2
	$-\alpha$	−5	−5·7

If we take the comparisons with condenser I. first, it appears that throughout $\lambda - \lambda^1$ is small. For the ·05 and ·1 microfarad it may be about −·5 divisions, while α is about 3 divisions; for the ·5 microfarad, α is rather larger being about 3·3 and $\lambda - \lambda^1$ is zero, while for the 1 microfarad α the absorption effect is distinctly larger, being 5 divisions, and $\lambda - \lambda^1$ is about −1. All this is, of course, quite consistent with the fact that condenser I. and the mica condensers insulate well while there is absorption by the mica.

When, however, we come to the condenser II. the results are quite different. While the absorption effects are comparable, as, of course, they ought to be, with those obtained in the comparison with I. the leakage effects are very large.

The values of $\lambda - \lambda^1$ in order are as follows: −9, −12, −10·5, −6·5, −8. Now we know that the mica condenser shows very little leak effect, the above leaks are therefore almost entirely in the air condenser II. If we suppose the total leak to be proportional to the time, then for the 5 second charges used in the experiments the corresponding values of γ in the corrections to be introduced for leakage will be one-sixth of the above, and thus we get the following results:—

Condensers.	Value of γ.	Correction to capacity in microfarads for the leak.
·05	1·5	·00007
·1	2	·00016
·5	1	·0003
1·0	1	·0007

It is clear that the corrections are in all cases small, being not much over 1 in 1,000, but they serve to illustrate the method. The above corrections are only those for the leak, the correction for absorption could be found in the same way.

With a view to testing the method in a case in which a leak only existed without absorption, a number of comparisons of I. and II. were made.

In these experiments the resistance with I. was 296,240. The resistances with II. and the deflection due to the leak obtained by breaking the battery and then making the galvanometer, are given below together with the ratio of the two capacities corrected for the leak.

Interval between battery and galvanometer contacts.	Resistance.	Leak in scale divisions.	$\frac{R_1}{R_2}$	Correction.	$\frac{C_2}{C_1}$
0″	275,980	0	1·0734	0	1·0734
5″	275,180	2·5	1·0765	−·0032	1·0733
30″	271,380	14·5	1·0916	−·0184	1·0732
60″	267,180	22·5	1·1088	−·0286	1·0802

Digitized by Google

The last three lines of the table give the results of a series of comparisons between II., which had a leak, and a condenser of ·1 microfarad, which showed absorption. The resistance with II. was 394,930 ohms.

In the first four lines the corrections are negative, for the capacity of the leaky condenser is being found in terms of the standard. In the next three lines they are positive, for the ratio of the mica condenser to the leaky standard II. is being found.

A comparison of the fourth and sixth columns shows the results of the correction. In the fourth line it is clear that the correction is not large enough. This probably arises from the difficulty of making contact with the galvanometer circuit sufficiently soon after the battery is broken to ensure that the whole of the charge accumulated by the leak should pass through the galvanometer.

The leak correction was also tested with similar results by putting an artificial leak in I.

We will now give some specimens of the observations made to compare I. with a mica condenser in order to show the accuracy attained. Condenser I. compared with ·1 microfarad; resistance with I., 493,560 ohms; resistance with ·1 microfarad, 105,800 + a; variable resistance given below.

In the table in which the effect of the galvanometer is shown by the letters R, L, in the last column, R means there was a deflection to the right, L to the left.

Interval between galvanometer and battery contact.	Variable resistance to be added above.	Effect on galvanometer.
5″	700	R
	400	L
	500	Very small R
2″	400	L
	700	R
	600	L
0″	1,200	L
	1,300	Tremor L, then swing to R
	1,400	R

Thus in this case the effect of an alteration of 100 in the resistance, *i.e.*, one one-thousandth of the whole, is very marked, and we may take the following values for the resistance:—

5″ interval	105,800 + 500
2″ „	105,800 + 650
0″ „	105,800 + 1,300

Other series of observations showed that the resistance for 10 seconds interval was the same as for 5 seconds; if the interval was prolonged to 30 seconds a very small increase in capacity was noticeable. Thus the effect of absorption is to increase the capacity of the ·1 microfarad by about 8 in 1,000, or ·008 of the whole, of this ·0065 shows itself in the first 2 seconds of charging, and ·0015 afterwards, the increase after 5 seconds, if any, being extremely small.

When comparing I. with ·5 microfarad the resistances used were 592,290 and 24,910 respectively. In this case an alteration in the latter resistance of 10 ohms, or one two thousand five hundredths, was easily seen. The following are the results:—

Interval.	Resistance.
10″	24,900
5″	24,900
2″	24,930
0″	25,060

Showing again that the absorption effect disappears after 5 seconds, and that the effect of absorption in 2 seconds is about ·0052, and in 5 seconds about ·0064 of the whole capacity.

When comparing with 1 microfarad, the resistances were 592,290 and 12,580, the last number being accurate to about 5 ohms, or about the same proportion as before.

The results of the various observations are given in the following table, the observations made with II. have been corrected for the leak as already explained.

Table *giving the Capacities of certain Mica Condensers as compared with the Air Condensers.*

Date.	Value from I.	Value from II.	Value found by commutator at frequency 64.
Aug. 19	·04934	·04938	
„ 23	·04934	·04936	·04867
June 17	·09772	·09780	—
Aug. 14	·09751	—	·09638
„ 18	·09773	·09786	—
„ 21	·09773	·09781	—
„ 18 (M)	·5005	·5008	—
„ 18 (A)	·5007	·5009	—
„ 21	·5006	·5010	—
„ 18	·9910	·9912	—
„ 21	·9913	·9912	—

It will be noticed that, for either condenser I. or II., the results are in very close accordance; with the exception of one observation, on August 14th, the differences are barely as great as 1 in 5,000, and the method is clearly capable of giving the value of a mica condenser in terms of the air condenser, to this accuracy.

The reason for the low result on August 14th is to be found in the fact that, on that day, the leak in I. was considerable, being, as we have seen, over 1 per cent. per minute. Full observations for the correction were not taken; it would, however, amount to about ·0002, judged by the correction required to observations on II., when leaking at a similar rate.

The results from II. are equally consistent among themselves, but all slightly greater than those from I. This would indicate that the correction applied for the leak in II. is rather too large.

The capacities given in the table are those found with a five seconds interval, by which time, as we have seen, the absorption in the mica condenser used is practically complete. We have already discussed the method of determining the instantaneous capacity, and a table of the corresponding values could easily be given.

For our present purpose it is hardly necessary to do this, and indeed for many purposes for which condensers are employed a knowledge of the full capacity is more useful than one of the instantaneous one. In the last column the values of the capacities found by the commutator are given; the differences in both cases amount to about 1·3 per cent. of the capacity.

During the forthcoming year condenser II. will be again set up and tested, and the permanent arrangements for rapidly comparing condensers and for issuing certificates will, I hope, be completed.

ALTERNATING VERSUS CONTINUOUS CURRENTS IN RELATION TO THE HUMAN BODY.*

By H. Newman Lawrence, M.I.E.E., and Arthur Harries, M.D.

The present Paper is supplementary to a preliminary Paper on the same subject read before the Institution of Electrical Engineers on 27th March, 1890.† In that Paper it was stated (*Society Journal*, Vol. LXXXVI., 1890) that "Our experiments have not been made with the powerful currents dealt with in electric lighting and distribution of power;" and this admission, together with the difficulties inseparable from the accurate measurement of alternating coil currents, are points in connection with our Paper which have given rise to much discussion in the electrical and other journals. In the present instance, however, we have endeavoured, as far as possible, to obviate criticism on these grounds:—(1.) By using currents directly from lighting circuits—both alternating and continuous. (2.) By using currents directly from a dynamo whose rate of alternation could be accurately ascertained. (3.) By using currents of high E.M.F. (4.) By using an instrument for the measurement of alternating currents whose accuracy at the reading of our former Paper was theoretically

* Paper read before the British Association in Section G, Leeds, September, 1890.

† See *Electrician*, April 4, 1890, p. 551.

Digitized by Google

questioned by one or two speakers, but which has since been tested and proved to give correct readings by an eminent practical electrician (see *Society Journal*, Vol. LXXXVI., 1890), thus confirming the accuracy of the readings formerly recorded by the instrument, as well as those which are contained in our present Paper.

Another practical point to which special attention has been given in this Paper is that our experiments have been made chiefly with the skin in a state of nature, so that the conditions of experiment as nearly as possible resemble those which might be expected to exist under accidental circumstances, that is to say, under circumstances when contact with conductors was unexpected, and therefore unprovided for. With so much brief preface, we proceed to give in detail the results of several series of observations made under the conditions explained at each step.

Resistance.

In dealing with the resistance of the human body many difficulties present themselves, and render it by no means easy to arrive at definite data thereon. The complicated structure of the body at once prohibits any attempt to regard it as an ordinary inanimate conductor. Several methods have been tried or suggested. The Wheatstone Bridge method, which we previously adopted, was shown to be inaccurate by Mr. Otto T. Bláthy, in the *Electrician* of April 25, 1890, and the unsatisfactory nature of comparisons made between resistance measurements taken with the E.M.F. of a few battery cells, and those likely to result from the use of an E.M.F. such as is common in light and power circuits, has been pointed out by several of our critics. We have therefore thought it best to obtain our resistance measurements by passing the current direct from a light circuit through two or more bodies in series, and then, by noting the current strength passed and the E.M.F. used to pass it, to calculate the resultant resistance.

For this purpose we used in the first case dynamo-generated continuous current taken from the lamp leads at the Institute of Medical Electricity, which is supplied by the St. James's and Pall Mall Electric Light Company. Having disconnected a lamp the voltage was tested, and found by a Cardew voltmeter to be 104. We then connected up two metal electrodes of 45 square centimetres area each, which could be grasped in the hand, putting in series therewith only a milliampere meter having 755 ohms resistance and a key. Two persons joined hands, and each grasped one of the electrodes with his free hand. Circuit was then completed, and the reading taken.

The results are set forth in the following tables :—

Table A.—*Resistance to Continuous Current.*

Group.	E.M.F. in volts.	Current strength in milliamperes.	Total resistance.	Resistance of milliampere meter in ohms.	Resultant resistance of each person.
*1	104	7·5	13,866	755	6,555
*2	,,	5·75	18,086	,,	8,666
*3	,,	7·25	14,345	,,	6,795
*4	,,	9.25	11,243	,,	5,244
*5	,,	9·5	10,947	,,	5,096
*6	,,	8·0	13,000	,,	6,122
*7	,,	10·0	10,400	,,	4,822

Average, 6,185 ohms.

* Two persons.

In the second case we used a dynamo-generated alternating current taken from a Siemens' dynamo at the School of Electrical Engineering, Hanover Square, which was kindly placed at our disposal by the managers (Mr. Wm. Lant Carpenter and Mons. Leon Drügman). The arrangements for connection were exactly the same as those described above for the continuous current, except that groups of four and five persons joined hands, instead of only two. The same Cardew voltmeter, the same milliampere meter, the same electrodes were used.

The voltage varied from 115 to 137, and the alternations from 60 to 75 per second.

Table B.—*Resistance to Alternating Currents.*

Group.	E.M.F. in volts.	Current strength in milliamperes	Total resistance.	Resistance of galvanometer.	Resultant resistance of each person.
1. 5 persons	115	4	28,750	755	5,599
2. ,,	120	5	24,000	,,	4,649
3. ,,	123	7	17,571	,,	3,363
4. ,,	124	7	17,714	,,	3,391
5. ,,	124	6	20,666	,,	3,982
6. 4 persons	123	8	15,375	,,	3,655
7. ,,	137	9·5	14,421	,,	3,416

Average, 4,008 ohms..

These observations show results widely differing from those obtained by other methods, and indicate that while under these conditions the resistance to the two forms of current more nearly approximate to one another, yet that to continuous current is still considerably greater than that to alternating. It is interesting to note that the average resistance to alternating current obtained by this method closely corresponds to that obtained by Mr. Bláthy, and mentioned in his letter above referred to. He makes it from 4,000 to 5,000 ohms, and our results show an average of 4,008 ohms. We may state then, in round figures, that we find the resistance of the human body, under the conditions named to continuous current, to be 1·5 times that to alternating current.

We next endeavoured to find how far variations of the contact area would affect the result, and obtained the following readings :—

Table C.—*Variations in Current due to Alterations in Contact Area, E.M.F. being Constant.*

(Continuous dynamo current at 104 volts.)

Total contact area in square centimetres.*	Current strength in milliamperes.				
	Sub. 1.	Sub. 2.	Sub. 3.	Sub. 4.	Average.
90·0	10·0	10·0	10·0	10·0	10·0
45·0	7·25	5·25	7·0	5·25	6·19
22·5	6·0	4·75	5·75	...	5·5
†9·0	5·75	3·25	4·0	...	4·3

* Two electrodes each having same area, one being grasped in each hand.
† Electrodes held by thumb and finger only.

From this it appears that, in round numbers, a reduction in the contact area of 50 per cent. reduces the current strength by 40 per cent., a reduction in the contact area of 75 per cent. reduces the current strength by 45 per cent., and a reduction in the contact area of 90 per cent. reduces the current strength by 60 per cent.

It is manifest that to arrive at anything like a definite law on the subject a great number of readings must be taken; but we think the above results form a useful indication of the important bearing contact area has in determining the seriousness or otherwise of accidents in light and power circuits.

Sensation.

In this part of our Paper we propose to compare the results obtained when electrodes connected respectively with dynamo-generated continuous currents and dynamo-generated alternating currents are brought into and kept in contact for an appreciable time with the human skin in a natural state; that is to say, in the state normal to the person experimented upon at the time of testing. In order that this series might be complete, it would possibly have been better to give barometric, thermometric, and hygrometric readings, of which we have taken many; but these data belong rather to a complicated side issue, and do not affect the main question to which this Paper must necessarily be confined, so we have considered it best to omit them altogether—taking it that the subjects experimented on were in an average condition of health at the time, and that the atmospheric conditions were more or less like those to be expected in a climate similar to that of England.

Digitized by Google

The results are tabulated as follows:—

Table D.

Conditions.—Metal-handle electrodes grasped in the hands (surface area 45 square centimetres each), in connection with dynamo-generated continuous current, taken from lamp-lead as before mentioned (Table A.).
E.M.F. 104 volts, by Cardew's voltmeter.

Subject.	Discomfort point.	Fixation point.
	Milliamperes.	
1.....	18	not any.
2.....	15	not any.
3.....	20	not any.
4.....	22	not ony.
5.....	15	not any.
6.....	20	not any.
	Average, 18·3	

In each instance, burning sensation under the electrodes became unbearable after about 30 seconds; this was the only objectionable feature, though electrolytic action was sufficiently marked to induce slight blistering in two of the cases. We have to call special attention to the fact *that in no case was muscular fixation, or any sensation approximating thereto, reached with the continuous current*, nor have we at present any reason to suppose such a result possible.

Table E.

Conditions.—Metal-handle electrodes grasped in the hands (surface area 45 square centimetres each).
Alternating Current from Siemens' dynamo.
E.M.F. 110 volts, by Cardew's voltmeter.
Number of Alternations per Second, 23.

Subject.	Current strength.	
	Discomfort point.	Fixation point.
	Milliamperes.	Milliamperes.
1.....	3·0	6·0
2.....	3·5	7·25
3.....	4·5	6·5
4.....	3·5	8·5
5.....	4·0	7·25
	Average, 3·70	Average, 7·10

Table F.

Alternating Current from same dynamo as last table.
Electrodes as last table.
E.M.F. 85 volts.
Alternations per Second, 68.

Subjects as before.	Current strength.	
	Discomfort point.	Fixation point.
	Milliamperes.	Milliamperes.
1.....	3·5	6.0
2.....	4·5	8·75
3.....	3·75	8·0
4.....	4·75	8·75
5.....	4·25 not reached at	8·0
	Average, 4·15	Average, 7·90

In Table E. it will be observed that the average discomfort point is 3·7, the average point of muscular fixation 7·10. In Table F. the average discomfort point is 4·15, the average fixation point 7·90, the mean of the two sets being 3·9 for discomfort point, and 7·5 for fixation point.

We wish to differentiate clearly between what we have termed *discomfort point* in connection with both varieties of current, and that which we have called the point of muscular fixation, which we have only been able to discover in experiments with the alternating current. This is the more necessary because herein lies one of the great differences in the danger of accidental contact with the two systems respectively. To put it plainly, *we have found no point at which it is impossible to release personal contact with a continuous-current circuit, while it is easy with a comparatively low-current strength to find a limit beyond which it becomes a physical impossibility to disengage oneself from contact with the alternating-current circuit. A little consideration will show that this cannot be too strongly emphasised, for while with the one personal effort will suffice to release the sufferer, with the other the agency of a second person must be called into play before the dangerous action of the current can be stopped.* Many of the critics of our former Paper appear to have failed to recognise this most important distinction, and to have regarded muscular fixation as synonymous with discomfort-point.

Tables E. and F. were constructed from observations made on the same patients in the same order with the same machine, though with an interval of two days; in the first table the E.M.F. was greater (110 volts), and the rate of alternation less (23 per second) than in the second table, when the E.M.F. was 75 volts, while the alternations were 68 per second. In Table E. fixation needed nearly twice as much current strength as discomfort, and in Table F the same sort of relation obtains, though in the latter instance the alternations were just three times as frequent. During the discussion on the Paper at the Electrical Engineers on March 27th, Dr. Harries in his reply stated that "The more rapid the alternations the more nearly did the conditions resemble those present with continuous current *as regards sensation*." Putting aside for the moment the difference of E.M.F. in the two sets of experiments (25 volts) a comparison of Tables E. and F. will fully bear out this statement, for we find that both average discomfort point and average fixation points are higher, though the alternations are so much more frequent in Table F.

It may not be out of place here to note that observations made with a Wheatstone's transmitter in another series of experiments at about the same time showed that a higher rate of alternations with same E.M.F. and current strength reduced the sensation. It is conceivable and probable that nerve impulses travel as waves at a given average rate of speed (90ft. per second. Helmholtz). But sensations may follow one another so rapidly and so irregularly that one set of waves may impinge upon and modify the next preceding set, thus altering the total effect which would be produced upon cortical centres by a given number of sensations in a given time. Alternations may be so rapid and irregular that these conditions are present in such wise that the total effect of a series of shocks given at a certain rate of speed is less than the total effect of a similar number of shocks given at a lower rate of speed. And it is only in this way that we are able to account for the power to bear larger current strength at a high rate of alternation, *i.e.*, when the rapidity is over 50 or so per second.

Shock.

With continuous-current shocks (sudden make or break) from dynamo-generated continuous lighting circuit with a current strength of 10 to 20 milliamperes, the sensation was that of a sudden jerk, followed by feeling of heat at the points of contact with the electrodes, increasing until the sensation became unbearable. The make jerk was distinctly more marked and more unpleasant than the break jerk, though the latter was followed by an increase in the sensation of heat in the neighbourhood of the points of contact, the increase persisting for two or more seconds after contact was broken.

Shocks of alternating current, from Siemens' dynamo-generated alternating circuit, were also taken by the subjects concerned in Tables A., B., C., &c. A tingling sensation was felt, which rapidly increased to muscular contraction, becoming more and more unpleasant, and accompanied by a sensation of heat in the neighbourhood of the electrode, though not immediately under the site of contact, as in the case of the continuous current. It was noticed that the maximum effect was *not immediately* felt, an increase being apparent for one or two seconds, the hands being still in contact with the electrodes. This effect was most apparent with small currents (two to three milliamperes). As the current strength increased, the maxi-

Digitized by Google

mum effect was more rapidly produced. When eight milliamperes were passed, the effect seemed immediate. Considerable heating of the parts in contact with the electrodes and of contiguous parts was noted on both make and break shocks. This continued to invade adjacent parts during the period of continued closure of the circuit, and the general effect included muscular fixation in most of the subjects experimented on.

In our previous Paper we concluded by deducing a danger ratio. This showed the danger of serious consequences on contact with the alternating current to be 41·5 times greater than that to continuous currents. So high a ratio was thought by many to be excessive, and the more recent experiments now set forth prove it to be so, *if we calculate it on exactly the same lines as before.* We find, however, that there are other factors which should be included in calculating the danger ratio in addition to those used in the former Paper, viz., "Differences in Resistance and Sensation." The difference in resistance obtained by the method we have now adopted and set forth in Tables A. and B. is 1·5, instead of 8·3 as obtained by the former method. The difference in sensation set forth in Tables D., E., and F., on the other hand, is 4·7, or only 0·3 less than that obtained previously. This would give a danger ratio of 7·0. Such a ratio, though far below that obtained with small battery and coil currents, would be sufficiently serious to demand very careful attention from electrical engineers, *if it represented the whole state of the case; but it does not* (as mentioned above) *cover the whole ground*, for we have also to consider two other factors, viz., Difference in Initial Shock and Difference in Continued Contact. On these two heads comparative values cannot be given. As regards initial shock, in which the time period of contact is a minimum, we have made many tests on various individuals, who one and all declare that the initial shock of alternating current of a certain strength is far worse to bear than the initial shock of continuous current of the same strength. This, from the nature of the experiments, can only be tested with small currents; and it is conceivable that with large currents such marked differences may not be observable, the time factor being left out of consideration. The second, however (continued contact), is a matter of far greater importance, as we have already pointed out in discussing muscular fixation. The time period of contact being appreciable with continuous current, we have no muscular fixation, and the subject of accidents would be able to release himself. On the other hand, an appreciable time of contact being made with an alternating-current circuit, the subject would be absolutely fixed *in situ* until released by extraneous aid, being exposed during the whole time to the full effect of the current passing through him. Further than this, the act of muscular contraction might and probably would increase the contact area, and so increase the current allowed to pass. When, therefore, we take these last-named factors into account it is manifest that the danger ratio of 41·5 to 1 named in our former Paper, is by no means too high. We do not now name another figure, because it appears to us impossible to express in terms that could be used for calculation the difference in initial shock and in continued contact.

It may perhaps be expected that we should make some reference to the quantity of current which constitutes a fatal dose, but this can only be arrived at by careful observation of all the electrical conditions prevailing at fatal accidents or executions. The difficulty of obtaining such information is unfortunately very great as regards accidents, but surely not as regards executions. That the authorities in charge of Kemmler's execution failed to take measurements of the E.M.F. and current strength used, is almost incredible, and in view of the fact that they possessed so excellent an opportunity such neglect seems quite inexcusable. For some time past we have been hoping that some information would be forthcoming; but the article by Mr. C. Huntly in the *Electrical World*, reproduced in the current number of the *Electrical Review*, seems conclusive; for it says, "No data of either the electrical or mechanical apparatus were taken." Mr. Perry, in his recent articles in American electrical journals, arrives at the conclusion that one ampere is an undoubtedly fatal current, provided it actually passes through the victim. This estimate we see no reason to differ from, though we hardly think sufficient evidence has been obtained on which to base really definite conclusions.

We will now briefly summarise our conclusions; and in doing so desire to draw attention to the fact that they are based upon certain conditions, and while we believe them to be sufficiently accurate and reliable under these conditions we in no sense claim them as true under all conditions.

Conclusions.

A. When the human body, with the skin in its normal unmoistened condition, comes into contact for an appreciable time with bare metal conductors of a dynamo-generated continuous current passing at about 100 volts in such a way that the current passes from hand to hand, and the total contact area is about 90 sq. centimetres:

(1.) A current of about 0·016 ampere will pass through it.

(2.) This current can be borne without discomfort for 15 to 30 seconds.

(3.) After about 30 seconds, unpleasant burning sensations become marked and quickly increase.

(4.) The subject is perfectly able to release himself at will during any portion of the time of contact.

B. When the human body comes into contact with dynamo-generated alternating currents, alternating at about 60 to 70 per second, under the same conditions as above:

(1.) A current of about 0·025 ampere will pass through it.

(2.) This current is six times greater than that which produces discomfort.

(3.) Instantly the subject is fixed by violent muscular contraction and suffers great pain.

(4.) The subject is utterly unable to release himself, but remains exposed to the full rigour of all the current that may be passing.

C. When circuit from electric light or power conductors is accidentally completed through the human body, the danger of serious consequences is many times greater when alternating than when continuous currents are passing at equal voltage, and this is still to a large extent true if the voltage of the continuous current be double that of the alternating.

D. (1.) With both forms of current a reduction of contact area materially reduces the amount of current strength that passes.

(2.) With the alternating current, if the rate of alternation be reduced below 50 per cent., the sensations of pain accompanying muscular fixation will be increased, while if the rate of alternation be increased the pain will be diminished.

Finally, we would remind those gentlemen who so commonly speak as if voltage were the chief or only factor in the danger of accidental contact, that *current strength is the important item*, and that according to Ohm's law current strength is dependent not only upon E.M.F. but upon the total resistance in circuit at the time of accidental contact. To make statements based upon voltage only, such as newspaper reports of a recent execution have contained, is not only distinctly misleading, but calculated to induce the uninitiated to form erroneous conclusions.

Thunderstorm Observations.—In a Paper recently communicated to the Hungarian Academy, M. Hegfroky gives the results of a study of five years' thunderstorms (1882-86) on the Hungarian plain. Days on which thunder was observed formed 16·4 per cent. of all days from April to September. Nearly half of the season's rainfall was on days of thunderstorm. Hail fell on 11 days, on one of which there was no thunderstorm. There were most thunderstorms in June (59 out of 199). The June of 1886 had as many as 26. The commencement of a thunderstorm occurred most often from 2 to 5 p.m. The author accepts Sohncke's theory that the electricity of thunderstorms is due to friction of water-drops on ice.

Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xv.) are accepted up to 5 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1890 Edition consists of about 850 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

Orders for the 1890 issue should be forwarded AT ONCE *to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.*

ELECTRICAL BOOKS AND PUBLICATIONS.

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.*

CONTENTS OF THE CURRENT NUMBER.

TECHNICAL EDUCATION.

LORD DERBY, at Liverpool, and Mr. GLADSTONE, in different parts of the country, have been singing the praises of manual skill and of what has been called "the sacrament of physical work;" and in both cases their theme has been. "More technical schools, more technical education, and increased facility for the artisan class in obtaining a practical acquaintance with the more important truths of science and the accuracy and definiteness of scientific thought." Until quite recently we have never, as a nation, been conspicuous for the excellence of our State education, technical or otherwise; in fact, compared with other countries, we have been decidedly backward. As early as 1642, only ten years after the landing of the "Mayflower," the colonists of Massachusetts passed a law requiring every citizen, under a penalty of twenty shillings, to teach his children and apprentices, or have them taught, to read perfectly the English language; while not so very long afterwards a regulation was made that in every township of over 500 householders a school was to be opened to teach, among other subjects, book-keeping, surveying, geometry, natural philosophy, chemistry, and botany; a curriculum which, though not, strictly speaking, technical, at any rate embodies elements that could not fail to be of great service in everyday life. In France at the present day elementary instruction may be given at the State schools in agriculture, surveying, and levelling; while the excellence of the German technical schools needs no comment. In this respect, indeed, England will bear no comparison with her neighbours, and for the last few years the deficiency has been dwelt upon by politicians of every description save one. The strike agitators know better than to encourage skilfulness and intelligence. Since they are for the most part shrewd men, they are quite alive to the fact that a first-class skilled workman can nearly always command both a fair and a steady wage; and that as the main advantage which the trade unions offer over the many friendly and other insurance societies is a fund upon which he may sometimes be permitted to draw when he is out of work, they fail, as far as this is concerned, to attract thoroughly competent men. The dock labourers and other bodies who are ignorant enough to believe that there is an inherent antagonism between capital and labour are from lack of training devoid of the skill that will command six or

Digitized by Google

seven shillings for a day's work at a vice, or prefer from indolence or want of ambition to continue in their unintelligent occupations. If the technical education that is being talked about will enable these classes to contribute to the never-failing market for skilled and intelligent labour to such an extent that their numbers will be diminished, and that the value of unskilled labour will rise, it will be the better for all; for we sympathise with no trade that cannot afford to pay a decent wage. This kind of education, however, is quite different from that which would enable the skilled artisan to acquire habits of systematic exactness of thought and of a grasp of scientific methods and processes.

These matters may be acquired while learning the elements of science which are taught at such admirable institutions as those of the City and Guilds of London and its many branches throughout the country, and at the numerous technical colleges of leading provincial towns.

We must remember, however, that the absence of State schools of this description is only an example of the policy of individual freedom hitherto adopted in all English internal administration, a policy which has come to the front most prominently under the phase of "Free Trade," and which always finds plenty of ability to support it. In no country save England is education almost entirely "run" by private individuals, nor is it usual for the great universities of a country to be as absolutely unconnected with the State as are our own. But in passing from the general question of State education to the particular branch in question, that of technical schools, it is instructive to observe the different results that its advocates anticipate from them. According to Lord DERBY their establishment is to inaugurate an era of breadth of mind and scientific accuracy of thought which will dissipate and neutralise the loose talk and inconclusive argument so painfully prevalent at the present day; while to Mr. GLADSTONE they are to be the panacea for the over-competition and low pay from which the present generation of clerks are suffering. Technical schools, he says, are to make things easier and brighter for the care-worn clerk who knows only English, and has to compete with the foreigner versed in two languages besides his own, and who works withal at a lower rate; but how they are to counterbalance the immigrants, who swarm over here in such numbers, Mr. GLADSTONE does not show. Nor are we struck by the honesty of his logic when he, in the first place, points out that the mechanic gets good pay because so many of his class rush off to be clerks, and thereby leave the field vacant to him, and then advises the clerks to throw down their pens and become mechanics because of the better remuneration offered. Mr. GLADSTONE occasionally seems to forget that if you give to one you take from another, and that no amount of such manipulation can add to or decrease the wage fund of a trade or of a country.

We have said enough to show that technical education is a subject the scope of which is not quite easy to grasp, owing to the loose manner in which the term has been used, especially when it is dragged in as a platform panacea for low wages and over-competition. Technical education of a certain sort there always has been and always must be; the young artisan now, as ever, learns his trade as a factory apprentice, according to many authorities the most profitable and most practical manner in which he could do so. Apprenticeship, indeed, is not what it was in the time of ELIZABETH, when seven years was the minimum term, and the apprentice was, in a manner, under the tutelage of his master; but still the workman when he has served his time has, to all intents and purposes, learnt his trade.

There is, however, a point at which serious fault may be found with the present system. As long as the trade or handicraft to be learnt is one of comparative simplicity, and consists merely in the development of manual skill, an empirical training is sufficient; but as soon as a higher level is reached it is imperative that the workman, if he is to produce really high-class work in his own department, should also have a fair knowledge of the collateral branches of the industry, and a tolerable acquaintance with the principles on which the creative skill of the factory is based, as well as a due appreciation of his share of the work. It is evident that to no industry do these remarks apply so forcibly as to that of electrical engineering. Yet how many of the workmen employed in making a dynamo, though highly skilled in their own department—that of manual labour—are acquainted with the most elementary principles of its design, or have even a hazy idea of the manner in which the current is generated? In work of this description there is true need for a general and suitable scientific education for the skilled workman, in addition to the manual dexterity he already possesses. We are scarcely so sanguine as Lord DERBY, who expects the artisan after this scientific course to have acquired either habits of accuracy in matters of fact, or a mastery of scientific methods. A truly great advance will have been achieved if he is able to form a more fitting estimate of the part he plays himself in the construction of the finished product, and if he takes a more generous and sympathetic view of the scientific labour of his masters.

REVIEWS.

Screw Threads, and Methods of Producing them, with numerous Tables and complete Directions for Screw Cutting Lathes. By PAUL N. HASLUCK. London: Crosby Lockwood. 1890.

This little pocket-book, which has now reached a third edition, contains a considerable amount of very useful information, and a number of well-arranged tables. It is not easy to decide on what should, and what should not, find a place in a pocket-book. The most common mistake is the use of matter which is really suitable for a text book.

A considerable portion of this pocket-book consists of information which is of the text book character, and is therefore out of place in a pocket-book. Elementary portions about the wrapping of a right-angled triangle round a cylinder; the difference between right and left-handed screws; descriptions of the commonest form of screwing tackle and of the screw cutting lathe are altogether unnecessary. It is doubtful if it is worth while to read about such matters even in a text book, since there is little to be said about them that cannot be more easily and surely learned in the workshop.

The description of standard threads and the tables containing the dimensions of the threads, of Whitworth nuts and bolts, and taps, are good; but they only occupy eight pages. For these tables and for sundry information in other sections, the book, which is only 3½in. by 2¼in. by ¼in., is worth having; but there are several matters which we might expect to find in a work, however small, on screw threads, which has run to a third edition. Among these are a table of change wheels for screw cutting, in place of part of the chapters which are devoted to the explanation of the principle and method of calculating the ratios, and a table and formulæ giving the strength of Whitworth bolts, &c. There is an amateur flavour in this little work which may account for the omission of the latter, for most amateurs seem to be interested in the mysteries of mandrel noses and of Holtzapffel's threads, and few ever think of calculating or even inquiring into the strength of a bolt. A page should be given to the design of nuts, and room could be found for a few wrinkles about impromptu taps, extracting broken screws, blacksmith's dodges for making vice screws, Archimedian drills, &c.

ELECTRICAL DISTRIBUTION BY TRANSFORMERS FROM CENTRAL AND ECCENTRIC STATIONS.*

BY DR. J. A. FLEMING, M.A.

(Continued from page 604.)

§ 13. **Westinghouse Transformers.**—The transformers or converters employed are illustrated in Fig. 34. The iron cores of the transformer consist of a pile of sheet-iron stampings, which are built up to encase the primary and secondary coils.

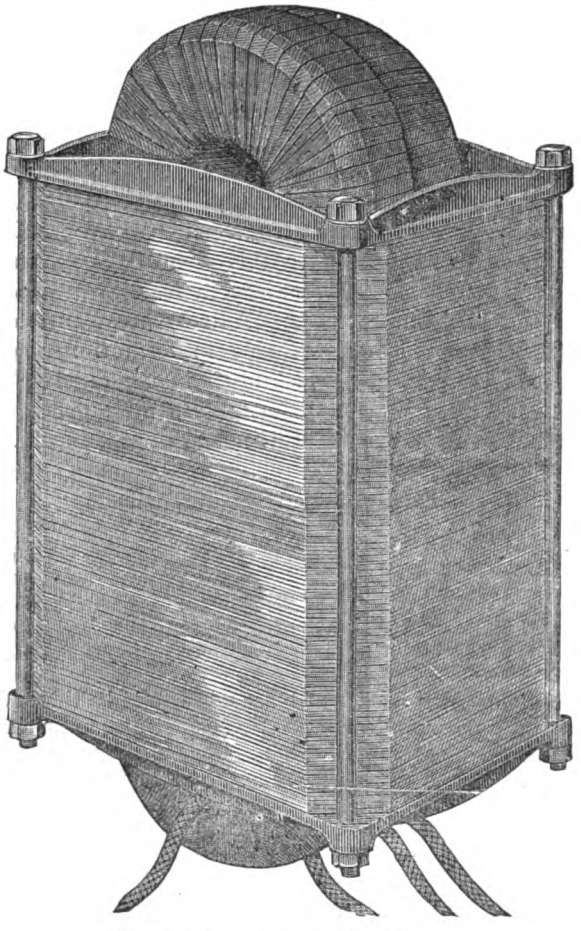

FIG. 34.—Westinghouse Transformer.

The sheet-iron stampings are shown in Fig. 35. The cross-piece, or tongue, is bent back when the rectangle is slipped over the coils, and re-bent back into place, so as to fill up the centre aperture of the coils. Each of these coils is composed of double covered wire, coated with an insulating compound,

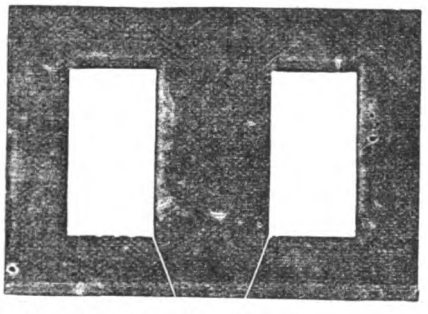

FIG. 35.—Sheet Iron Stamping of Westinghouse Transformer.

each layer of wire being insulated from its neighbour by additional insulation, and the completed coil covered with three separate and distinct coverings of insulating cloth. The contact between the primary and secondary coil is prevented by distance-pieces of insulating materials. The iron stampings are then piled up in and around the two coils (*see* Fig. 36), and the whole compressed by end-plates and tie-rods. The com-

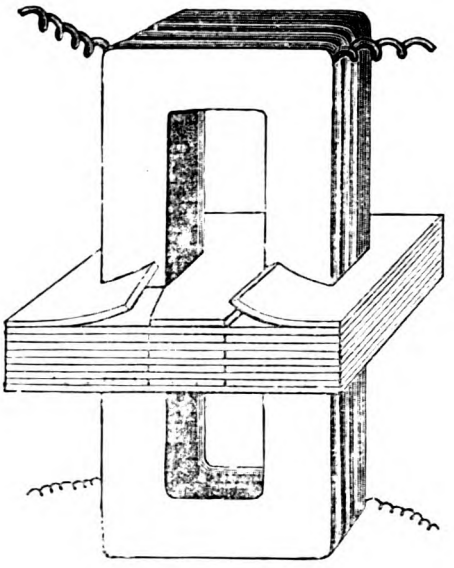

FIG. 36.

pleted converter is enclosed in a cast-iron box, the two halves of which are bolted together with a waterproof joint (*see* Figs. 37 and 38). The ends of the primary and secondary coils are brought out to face plates under swing lids. There are the

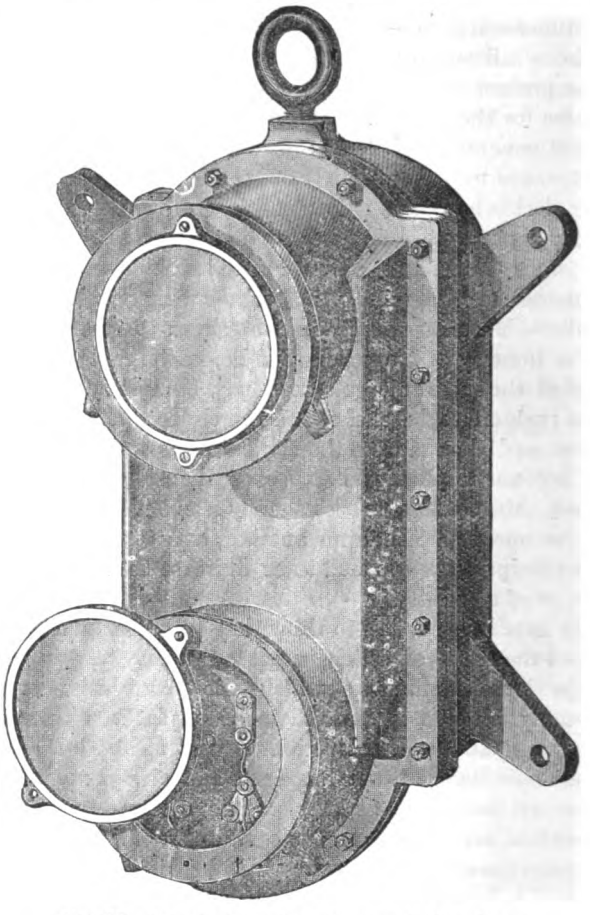

FIG. 37.—Westinghouse Transformer in Iron Case.

usual primary and secondary fuses, these being covered in with glass plates. The converter case has a ring and lugs by which it is attached to walls of buildings or to posts. A very usual practice is to affix the converter to the cross-arm of the

post carrying the primary wires or to the walls of a building (*see* Figs. 39A and 39B).

The converters are manufactured in four sizes for 500, 1,000, 1,500, and 2,000 Watts output, or for 10, 20, 30, 40, 50-volt 16 candle-power lamps. It is generally the custom to employ

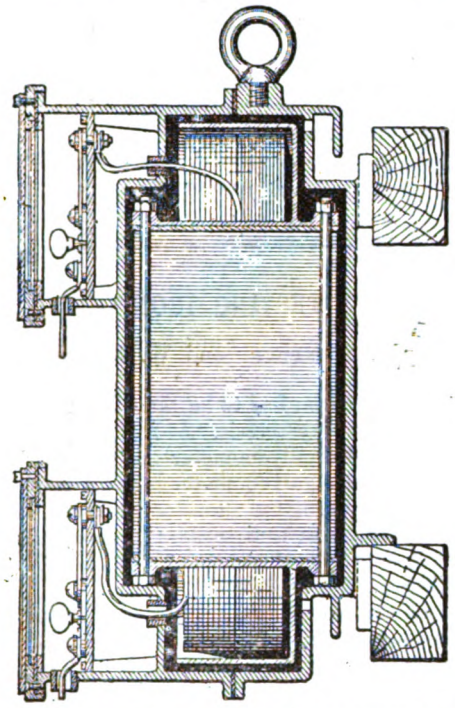

FIG. 38.—Section of Westinghouse Transformer in Case.

the converters singly on separate secondary circuits, and not to bank them with secondaries in parallel on the same circuit, as it is considered that if the primary fuse of one condenser "blows," the additional load thrown on the other converters is apt to break down the whole set. The transformer generally used lowers

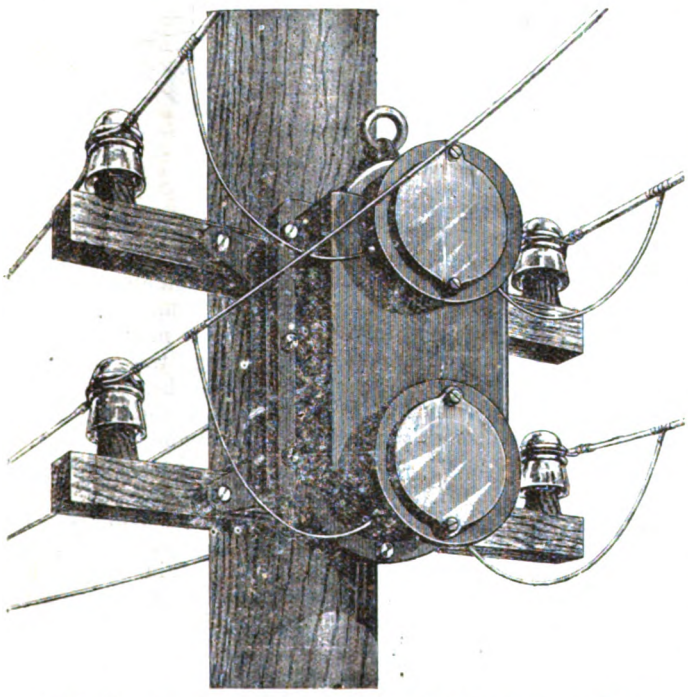

FIG. 39A.—Westinghouse Transformer affixed to cross-arm of post.

pressure from 1,000 volts to 50 volts. Although the converters are very light, and have a smaller quantity of iron in the cores than might be considered desirable, they appear to be efficient in performance. Comparative tests made by the calorimeter method at the Electrical Testing Bureau of the Johns Hopkins University, U.S.A., in 1889, gave results as follows for the electrical efficiencies of these transformers at various loads:—

Efficiency of Westinghouse Converters.

Capacity of transformer in 50-volt 16 candle-power lamps.	Power in watts supplied to primary circuit.	Output in watts on secondary circuit.	Watts lost.	Efficiency, in per cent.
	Full Load.

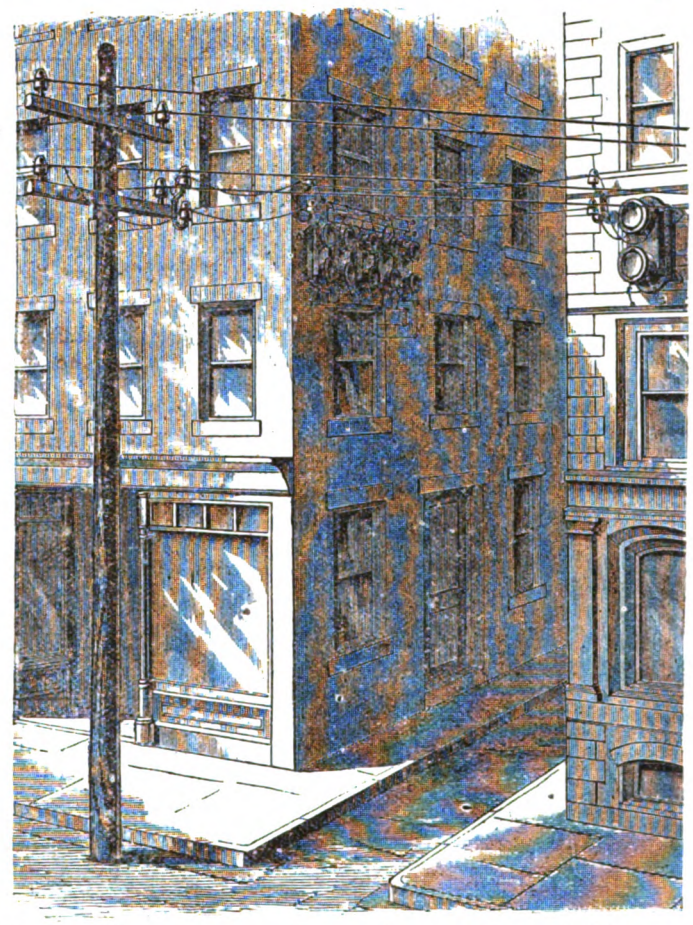

FIG. 39B.—Westinghouse Transformers affixed to exterior of buildings

Prof. G. Forbes, employing the same calorimeter method on a 30-light transformer, obtained an efficiency of 95 per cent. at half-load. The calorimeter method is, however, one somewhat difficult to carry out with accuracy, and such discrepancies in results are not unlikely to occur even between careful observers. Tests made by Mr. N. Marshall, under direction of Prof. Cross, at the Institute of Technology, Massachusetts, employing the calorimeter, and using a 20-light converter, gave an efficiency at full load of 93 per cent.* In this case the alternations were 14,530 per minute. Probably the most complete tests on the efficiency of these transformers are those of Dr. Louis Duncan and Mr. W. F. C. Hasson, made in 1890 at the testing laboratory of the Johns Hopkins University, on a 750-light Westinghouse plant.† The dynamo was driven through a Tatham dynamometer by an Armington and Sims engine. Engine,

* *Electrical World*, Vol. XV., January 18, 1890, p. 46.
† *Electrician*, Vol. XXIV., p. 593, 1890.

Digitized by Google

dynamo, and dynamometer, were bolted down to heavy timbers, and the current conveyed to a bank of transformers of the 40-light size. These transformers supplied incandescent lamps. The efficiency of these converters was separately determined by a calorimeter method, by placing them in a metal box, with double walls, between which water was allowed to flow. The temperatures of the water at exit and entrance were observed, as well as the weight of water which passed through; at the same time the current and potential difference in the secondary circuit of the converter was measured. A series of corrections had to be applied for radiation. A 40-light and a 20-light converter were tested, with the results as under :—

Efficiency of a Westinghouse Converter, 40-Light.

No. of lamps on.	Volts of lamps.	Watts in secondary circuit.	Loss in watts in transformer.	Loss in iron in watts.	Efficiency, in per cent.
40	50·0	2,000	109	...	94·8
0	50·9	0	84	84	...

Efficiency of a Westinghouse Converter, 20-Light.

No. of lamps on.	Volts of lamps.	Watts in secondary circuit.	Loss in watts in transformer.	Loss in iron in watts.	Efficiency, in per cent.
20	48·8	952	106·0	95 2	90·0
15	52·2	817	114·8	108·9	87 6
10	50·3	506	101·7	99·2	83·3
5	51·44	264	109·4	108·7	70·7
0	52 3	0	110·5	110·5	0·

Experiments at slightly different primary potential differences showed that the loss in the iron varied very nearly as the square of the voltage.

The efficiency of the converters being determined, that of the dynamo alone could be found. A series of experiments was made, in which the power supplied to the pulley of the dynamo was compared with the electrical power taken up in the lamps on the secondary circuits of the transformers, and as a result the net or over-all efficiency of the system determined. The lamp load was taken at $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$ and full load, and the power determined.

Table of Efficiency of 750-Light Westinghouse Plant at Various Loads.

Load	Exciter.		Primary Circuit.		Secondary circuit.		Horse-power in lamp circuit.	Power supplied to dynamo.	Loss in transformation.	*Net* Efficiency, in per cent.
	E.M.F.	Current.	E.M.F.	Current.	E.M.F.	Current.				
¼	105	9·4	1107	10·0	49·5	153·9	10·21	21·83	11·62	46 8
½	104	10·5	1107	18·9	49·6	338·4	22·5	34·4	11·9	65·4
¾	101	11·0	1113	28·6	50·0	520·7	34·9	48·0	13 1	72 7
Full	112	11·5	1125	38·1	50·9	739·8	50·48	64·44	13 96	78·3

Looking at these figures, we see that there is even at no load only a small loss in the converters themselves, but there is a very considerable loss in the dynamo armature. The twenty 40-light converters supplying the 750 lights at full load absorb only some 2,000 watts, or about 3-horse power, when the secondary circuits are open; but since the total loss is at full load equal to 13-horse power, it follows that there is a loss of 10-horse power in the dynamo at full load. From the above figures it appears, however, that at full load the commercial efficiency of the alternating dynamo in itself reaches somewhere about 86 per cent. Taking a commercial load diagram for the 24 hours, and reckoning the average diurnal or "all day" efficiency of such a 750-light plant, we find it to be about 60 per cent. That is to say, that if such a plant were continuously supplying incandescent lamps in ordinary houses, 60 per cent. of the energy given to the dynamo in the 24 hours would be represented by electrical energy in the lamp circuits, and the rest would be dissipated in the machine and converters. In actual central-station work good arrangements and proper selection of the size of unit machine would keep the working dynamo plant very nearly fully loaded at the various hours of the day, and a considerably higher average efficiency might be attained in the all-day use of such properly divided plant. Further reference will be made to the question of the reduction of the diurnal waste as far as regards the transformers and the relative advantages of transformer centres and large and small transformers.

(To be continued.)

TESTING IRON.*

By J. Swinburne and W. F. Bourne.

In practical work iron has to be tested as to its permeability and as to the loss by hysteresis. As regards permeability tests, the ordinary ballistic galvanometer method can, of course, be used; but a ballistic galvanometer is not a convenient instrument, and the method is too slow for practical use. It may, therefore, be of interest to describe the apparatus we use commercially. It is the development of a method devised in 1886. (See *Phil. Mag.*, July, 1887.)

The various samples of iron are obtained in the form of wire, and made up into rings, being wound on a former kept for the purpose, so that all the rings are alike as to dimensions. Before winding, the specific gravity of the iron is taken by weighing, and the specific resistance is measured. The ring is weighed to get the volume of iron, and is then wound with suitable primary and secondary wires.

The arrangement is shown diagrammatically in the annexed figure :—

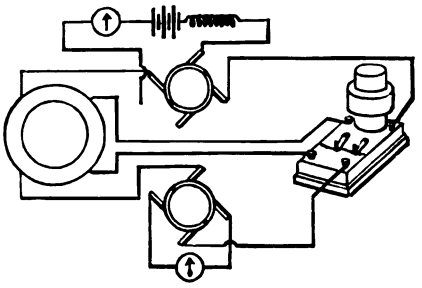

Diagram of Arrangements.

The circuit from secondary cells is led through an adjustable resistance, then through an ammeter to a commutator, resembling Brillouin's, which is driven by a belt from any shafting that may be near. The circuit is led through the primary to an induction box to the ring under test, and then back to the commutator. The circuit is then led back to the cells. The induction box consists of a primary coil, standing on end, and a number of secondary coils arranged so that the mutual induction is the same for all of them. The secondary coils are led to buttons, and the switches include them by ones or tens, making the readings in steps of one per cent. of the highest. The primary of the sample ring is in series with that of the induction box. The secondaries are coupled so as to oppose each other, and arranged in circuit with a second commutator; a Varley, or, as it is more often called, a Deprez d'Arsonval galvanometer, being inserted in the circuit. The two commutators are, of course, on the same spindle. The adjustment of the induction box was carried out as follows: The coils were roughly calculated to give a mutual induction a little in excess of a convenient round number per turn of secondary. A cylinder of a known diameter with a known number of turns per centimetre in the primary, and a known number of turns in the pilot coil was taken, and

*Paper read before the British Association in Section A, Leeds, September 1890.

Digitized by Google

put in the place of the sample ring, and its mutual induction measured with the induction box. To allow for the error due to the shortness of the cylinder of the standard coil, it was slipped out of the pilot coil, and moved exactly half its length in a direction along its axis, and a new reading taken. This reading gave the error due to the ends of the cylinder. A shunt was then put across the primary induction box, so as to make the readings come out in microhenrys.

To test a sample of iron all that is necessary is to alter the mutual induction by steps, and to bring the galvanometer to zero for each step by means of the adjustable resistance. As the galvanometer is dead-beat, the readings can be taken in a few minutes.

The importance of loss by hysteresis in alternate-current work is only now beginning to be fully realised. There are several ways of measuring the loss in transformers, but none of them seem satisfactory. Sometimes the transformer is put in a calorimeter, or else it is assumed that the pressure and even the exciting current vary harmonically, and have a so-called "angle of lag." The published efficiencies of most transformers are got by finding the loss from the copper resistances, and neglecting the loss in iron altogether. There is still another method, and that is taking the curves of pressure and current. Prof. Ryan has been singularly successful in this with a modification of Joubert's method.

Tests of transformers by means of lag angles and calorimeters have been published by Profs. Ferraris and Ayrton, and Major Cardew. As the loss in a transformer can be divided into the loss in the copper which varies as the square of the load, and the loss in the iron by hysteresis and Foucault currents which remains constant, these results can be checked. The results published, as obtained by these experimenters, show inaccuracies that make them quite valueless. The loss in the iron in Prof. Ayrton's experiments varies 160 per cent. of its smallest value, while Prof. Ferraris' cores give out power working as refrigerators. (See article "On Induction and other Things," *Electrical Review*, October, 1887.)

There is really little reason for measuring the loss in a transformer; it is much simpler to measure the loss in the iron. No one would think of measuring the loss in the copper by means of a calorimeter or angle of lag method. All that is needed is to measure the effective current and multiply its square by the resistance, the resistance being determined from the specific resistance of copper, or by direct measurement. Similarly, in the case of the iron, it is best to determine the qualities of the iron once for all, and then the efficiencies of all transformers made of it can be foretold.

We use the same rings as for the permeability test, but do not employ the secondary wires. The loss of power at various frequencies and inductions is taken with a wattmeter. It is sometimes supposed that a wattmeter cannot be made with little enough self-induction to read accurately. If there is much self-induction in the pressure or shunt circuit, the reading will be lower than that with a direct current if there is no self-induction in the circuit in which the waste of power is to be measured; but if the current is behind the pressure, as in measuring the loss in iron, the wattmeter may even read too high. We therefore designed a special instrument, which was made for us by pupils of the London College of Electrical Engineers. The current coils are fixed, and the moving coil is suspended by a fine wire, with a fine spring at the foot, to take the electricity out again. The moving coil has few turns and little self-induction, and a large non-ductively wound resistance is in series with it. This wattmeter can be read with a mirror, if desired; but with 2,900 ohms in series with the pressure coil, it gives a torsion of 2° per watt on a non-inductive resistance. The series resistance is not wound with a looped wire as is usual in resistance boxes, because this method is not good, the insulation being apt to break down. A single wire was therefore used. When one layer was wound, the bobbin was reversed in the lathe, and the next layer wound in the opposite direction, a thin layer of insulation being put between the layers. This method secures absence of self-induction, and good insulation, as the beginning and end of the coil are kept well apart. The readings are taken by bringing the index back to zero by turning the suspension, so that the mutual induction of the coils is zero, as the coils are at right angles.

The self-induction of the pressure coil was not directly measured, as that would give us no useful information, as we do not know the variation of the current and pressure of air dynamos. They certainly do not vary harmonically, and at full load the pressure rises slowly and falls suddenly in each half period.

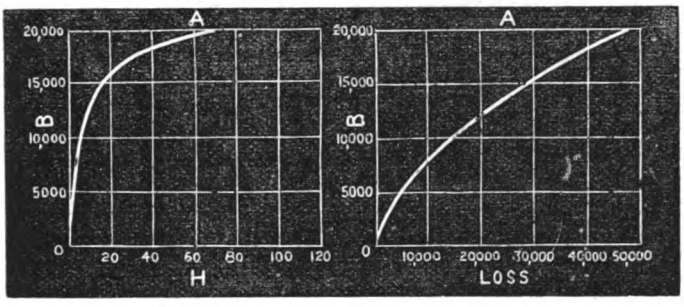
The wattmeter was therefore subjected to a severe test. Readings were first taken with direct currents on a resistance; readings were then taken on the same resistance with an alternate current. This resistance had very little self-induction, so that any self-induction in the pressure coil should lessen the reading, by making the current in the pressure coil lag, and also by reducing it. The reading with the alternate current was 2·1 per cent. less than with the direct. This figure is entered in the note-books, but though it is too small to matter in our work, it is larger than it ought to be. The next test was to measure the power taken by a coil with the same current and same pressure, but with no resistance and large self-induction. It is difficult to make up a coil with no iron core to take 50 volts and 10 amperes with no appreciable loss by resistance; we therefore took a hedgehog transformer, and measured the power taken by it. The reading was taken with 50 volts and 4·2 amperes. If the pressure coil had any appreciable self-induction, the reading would be considerable; it might, in fact, be anything up to about 200 watts. The least self-induction would increase the reading enormously. The reading was 11 watts, and the calculated loss by copper and iron in the transformer with only 50 volts on its secondary was 10·3; so the wattmeter is practically correct. Let it be supposed, however, that the loss in iron was really less than this, and that the loss was two watts less than the reading. This is an extreme assumption; but we may see how much such an error would affect our readings of the sample rings. The assumed error is 1 per cent. of the product of the pressure and current. Now, in the case of a closed iron circuit the power is about half the product; so this would lead to an error of 2 per cent. in the loss in the iron. In a closed-circuit transformer the loss in iron is, roughly speaking, 10 per cent. at full load, and about 40 per cent., to take a low figure, taken over the day; so that the error would be 0·2 per cent. and 1 per cent. In the hedgehog form the loss in iron is about 1·5 per cent. at full, and 15 per cent. at all day loads; so the errors are ·03 and 0·3 per cent. respectively, which are too small to matter. As a matter of fact, they are much less than the various errors of observation that creep into such work. Measuring the power in an open-circuit transformer is also a most difficult case, for the least self-induction then gives rise to the largest error; in measuring the power in a closed circuit ring the errors are less.

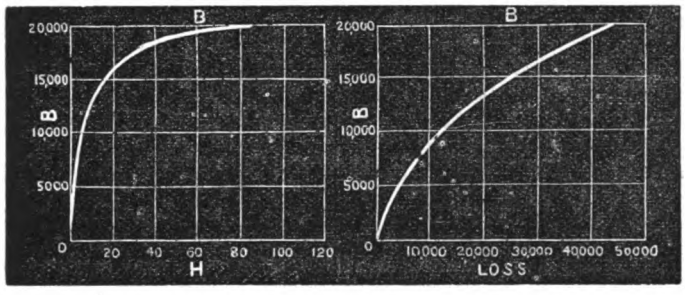
We give a number of curves of permeability and of $\int E\,dQ$ per cubic centimetre for different samples of iron. These are practically the same as curves of $\int I\,dH$; but $\int E\,dQ$ seems a better way of writing it, as $\int I\,dH$ can scarcely be said to have any physical meaning, and has even had the effect of not suggesting that the reversal involves waste of energy; indeed, it seems to have rather disguised the fact.

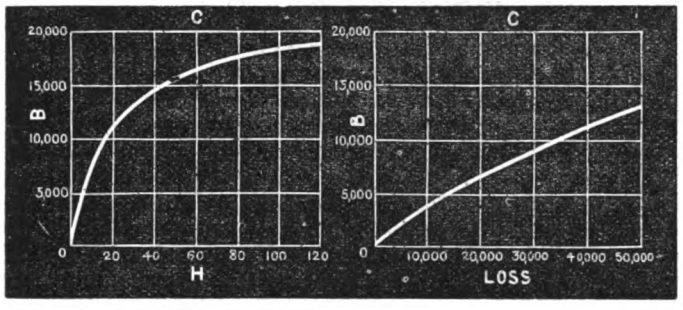
In completing these curves some corrections have been made. The wattmeter absorbs some power itself, as the pressure coil circuit is led through the current coils. We might have compensated for this in one of the ways described to Section A by one of us in 1887, but in this case did not think it worth while. The Foucault current losses are also corrected. The losses in the wires themselves can be calculated with rigid accuracy, as explained in a Paper on "Transformer Design," which one of us had the honour of reading before Section G last year. There might also be some loss by Foucault currents, due to imperfect insulation between the wires of the core. The insulation is, however, too good to allow this; in fact, the resistance between two wires, about an inch apart, runs into ohms, the measurement being seven ohms in the particular example taken. The losses by Foucault currents are frequently over-estimated by writers on the subject. If the specific resistance of the iron is known, they can nearly always be calculated with much greater

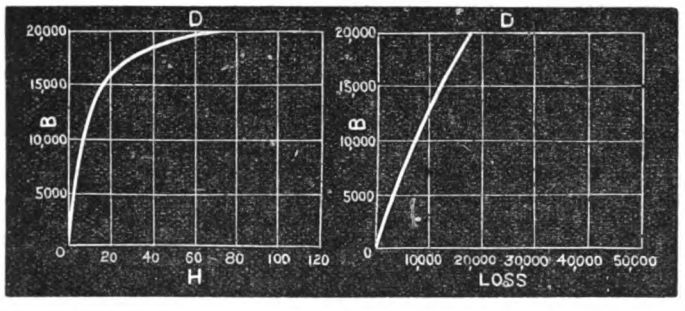
Digitized by Google

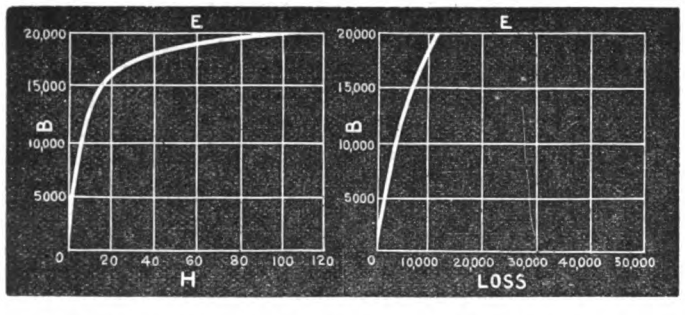
accuracy than they can be measured. The loss by the copper resistance is also allowed for in the curves. Though it is generally the practice to give all the steps in a Paper like this, we think it better to give the results only; for, though the Paper then looks less imposing than if full of curves and calculations, it is more likely to be useful.











We have not yet tested the same sample at very different frequencies to see if there is any time lag. From the comparatively small loss at high frequencies it is not probable there is any appreciable time lag.

BRITISH ASSOCIATION.

DISCUSSION ON ELECTRICAL STANDARDS.

The following is a report of the discussion which arose at the recent meeting of the British Association at Leeds on the reading of the Report of the Committee on Electrical Standards (see *The Electrician*, September 26, p. 587), and the four Appendices thereto (see *The Electrician*, October 3, p. 608, p. 613, p. 615, p. 616, and p. 637 of present issue).

Prof. G. F. FITZGERALD, referring to the specimens of copper which gave a very abnormal density, and had an abnormally low conductivity, asked whether they had been annealed, or whether annealing would alter them, and also where the copper came from.

Mr. H. A. TAYLOR said that he supplied one of the specimens referred to—No. VII. of the Table. The conductivity was increased 2·2 per cent. by thorough annealing; and the peculiar feature of the hard-drawn copper was that it had never been heated.

Mr. JAMES SWINBURNE asked whether the Association was thinking of doing anything with regard to Joule's equivalent. In some American books, Wood's "Thermo-Dynamics," for instance, the figure of 784 was given as the most recent determination. If there was any chance of there being an error in that, surely it was a very important thing that it should be determined again.

Dr. J. A. FLEMING said the question of the secular changes in resistance coils was rather important. He was inclined to think that it would perhaps be better to use some form of liquid paraffin, rather than to use paraffin wax, as was generally done. The members of the committee, he was sure, thoroughly appreciated the great value of the work Mr. Glazebrook was doing in keeping a very careful watch upon these coils. These seven or eight coils constituted the prime standards of electrical resistance for all the world, and they were practically like the standard pound or the standard yard preserved at the Board of Trade. It was most important that most careful watch should be kept upon them, in order to detect any secular changes in the alloys. It was an unfortunate fact that nearly all those substances which were the most suitable for the construction of standards of resistance were more or less complicated alloys. The simple metals which would probably be better fitted for permanent standards had very large temperature coefficients. Some experiments had recently been made in the United States on two rather interesting alloys, one of which had actually a negative co-efficient of change of resistance for temperature. They were alloys consisting of copper, nickel, and ferro-manganese; and the interesting part about them was this—that one of these alloys, in one particular condition of annealing, was just like carbon and the electrolytes: it had a negative co-efficient. It had been found that by a suitable combination of these two alloys it was possible to have an alloy which did not change its resistance at all for variation of temperature. It was not at all impossible that we might one day arrive at a suitable alloy of this kind, which perhaps would be of sufficient permanence. But, unfortunately, these ferro-manganese alloys were not at all likely to be used, from the fact that they were found to change their resistance somewhat, even under the small currents that are used for measuring them. His acquaintance with the Cambridge coils had ceased for some time; but he seemed to recollect that the gold-silver coil at one time gave them some anxiety as to a change of standard temperature, but if he followed Mr. Glazebrook it was the platinum-silver coil now that gave them anxiety. As Mr. Glazebrook said, it was rather a serious matter that a coil of platinum-silver having a small temperature coefficient should have changed so much. All these things seemed to point to the fact that a more complete and very careful investigation of the change of resistance of alloys with time required to be made. With regard to the method of testing the capacity of the condensers by the revolving commutator, he made a great many experiments on that method about two years ago, with fairly satisfactory results. The method was to drive a commutator by a small electro-motor. The commutator had an arrangement by which he could alter the duration of the contacts. He wanted to see what was the influence of the duration of the contacts on the capacity—to see how long the contact must be made in order to avoid cutting off the tails of the discharges. He found that when the duration of the contact was about eight or ten times that of the time-constant of the condenser circuit the discharge was complete. He made a number of very careful comparisons between condensers in his own possession and some standard condensers—micro-farads—which showed that this method could be employed with very considerable accuracy. It could also be employed very well for the measurement of the capacity of small condensers like Leyden jars by using a differential galvanometer. By putting a current through a resistance in series with one coil of a differential galvanometer and then a current from the condenser through the other coil, he was able to make very easily determinations as to the capacities of Leyden jars of different sizes. The method seemed to afford considerable facility for dealing with these small capacities, and he had no doubt that for comparisons between the condensers to be employed as standards, it would be about as good a method as any that could be adopted.

Sir W. THOMSON said he was very glad that Dr. Fleming had called attention to the alloys having negative temperature coefficients. It would be interesting to electricians to know that the subject was under examination in Helmholtz's new research laboratory. He had been informed (though he was not quite certain of this) that arrangements were being made for giving out wire in which there would be no temperature variation. At all events, as the matter was being investigated by very able

Digitized by Google

hands in Berlin, as well as in America, they might soon hope to see coils in which they would not be troubled with any temperature error for measuring electrical resistances, that they would be able to have an instrument with a slight negative temperature coefficient to absolutely compensate the effect of the positive temperature coefficient.

Mr. A. P. TROTTER said that as the committee were dealing with the question of the resistance of copper, it might be important to determine exactly what they meant by "copper." Then, again, annealing and tempering were said to introduce a very large change; and the phrase, "thorough annealing" was used. Surely, if annealing did produce any change, they ought to know what was meant by "thorough annealing." Another variety of copper is known in America, though not in this country, as "tempered copper." It was perfectly well known that ordinary commercial copper contained a considerable quantity of oxygen; and a question arose as to whether electro-deposited copper was entirely free from occluded gas. The question was not purely a chemical one, and it was important that it should be determined, if copper was to be used.

Sir W. THOMSON said it was important to know the time occupied in "thorough tempering." Thorough tempering might extend over days or weeks, and might produce very different results according to the duration of the process.

Prof. G. F. FITZGERALD said there seemed to be a difference in the effect on alloys and on pure metals.

Sir W. THOMSON: It is just possible that the pure metals may be worse. I do not know of any alloy which is so liable to great differences, in consequence of very small impurities, as is pure copper.

Mr. R. T. GLAZEBROOK said the way in which the annealing was done was to enclose the wire in a copper case, to pack it tightly with asbestos, and lampblack, and shut it up, then to heat it thus for some hours with a Bunsen burner, and then leave it to cool slowly by gradually turning down the flame for something like from 24 to 36 hours. In several cases there had been more than one annealing.

Sir W. THOMSON suggested, with reference to the use of lampblack, that the presence of carbon might have a very great effect. He well remembered some experiments made about 25 years ago on the elastic fatigue of wires. It was found that copper wires heated very hot in powdered charcoal, kept hot for a considerable time and, then allowed to cool very slowly, became very brittle. The subject was not pursued, but it seemed that there was an effect from the powdered charcoal. The lampblack, with the asbestos, might have the same effect; and it might, therefore, be desirable to try annealing with asbestos alone, with charcoal powder, and then with asbestos and lampblack, as in the present case.

Prof. G. F. FITZGERALD said that if the copper was at all impure on account of the mixture of oxide, the superficial layer would form carbon monoxide, and that would probably diffuse in the inside and would reduce the oxide of copper that was in the inside.

Prof. OLIVER J. LODGE pointed out that it must not be assumed for certain that there was anything the matter with the platinum-silver alloy, which was only one ingredient in the changed coils; he further asked whether Mr. Glazebrook, in speaking about coil F having changed much, meant more than one in ten thousand or thereabouts; and lastly, what sort of squared paper had been used for the diagrams.

Prof. JOHN PERRY said that, when experimenting on spiral springs, on taking out two or three lengths of platinum-silver wire very near one another, which were, as far as he could judge, flattened and twisted in the same way, he had found that perhaps one out of every three was utterly different in its behaviour from the others, and was no longer elastic. Two pieces would be perfectly elastic, but the third seemed to be of quite a different material.

Lord RAYLEIGH said that in connection with the errors in copper containing minute traces of impurity, it was worth mentioning an experience he had last summer. He was passing pure hydrogen over copper. The copper wire was of the kind ordinarily used for electrical apparatus of high conductivity. He found that the hydrogen, after passing over, contained sulphuretted hydrogen; it seemed impossible to get any copper which did not give off sulphur, and give it off apparently for an almost indefinite time. Some of the wires were heated for hours nearly every day for weeks, but they yielded sulphuretted hydrogen at the end. When they were taken out they were found to be absolutely brittle; suggesting the idea, at any rate, that the removal of the sulphur, and possibly of oxygen, had been fatal to their mechanical properties.

Mr. SEARLE, in describing the commutator employed in the Cavendish Laboratory, said there was a tuning-fork acting in the well-known manner, with two slits on the prongs, and through those slits there was viewed a stroboscope disc on a wheel attached to the commutator. It was driven by a water motor by a fine fishing-line joined with a splice —a knot was no good at all; every time a knot went over the man at the galvanometer called out. They did not govern the commutator by the bands driving the commutator, but by a small secondary band going from the water-motor to a pulley within easy reach of the observer. In that way they got rid, not only of the inertia of the commutator itself, but also of that of the fly-wheel of the water-motor, which was very considerable; and they were by that means able to keep the speed pretty constant. The stroboscopic disc enabled them to get considerable variations of speed bearing definite relations one to another. As to what Dr. Fleming was saying about the probability of measuring extremely small capacities by means of this commutator, Prof. Thomson was able to measure the capacities of ordinary small copper wire. The capacities of the connecting wires of the various condensers had been, of course, carefully allowed for.

Mr. R. T. GLAZEBROOK, replying to the discussion, said, in regard to the annealing and the preparing of the copper, he was afraid that in his endeavour to be brief he had not been quite just to the very great care which Mr. Fitzpatrick had taken with regard to a large number of these points. There was an almost unanimous feeling among copper manufacturers that small quantities of oxide are necessary to give tenacity to the copper, and that there is a certain amount of oxide in all the copper wire. The reason why it was annealed in charcoal was to get rid of that oxide; and he thought that in almost all cases the wire did come out brittle, as Sir William Thomson had described, but at the same time it came out with a very much reduced resistance. In the preparation of the copper by Mr. Fitzpatrick himself he should have stated that the hydrogen was passed over the copper for hours while in a finely-divided state at a considerable temperature. Mr. Fitzpatrick had now a specimen of copper which he had prepared entirely by chemical means, not by electrolytic deposition at all. He had hoped to have been able to give the results of the observations to the Section; but, unfortunately, a tube suitable for reducing the copper could not be obtained in England, and the last of a stock which Mr. Fitzpatrick had obtained from Germany broke three days before he (Mr. Glazebrook) came away. Mr. Fitzpatrick had another stock on order (indeed, it had been on order for months), but the tubes had not arrived; and so the copper was there awaiting its final chemical reduction and purification. He fancied that the copper did become distinctly brittle and lose its tenacity when one got rid of the last traces of oxide, and possibly also of sulphur, as Lord Rayleigh had mentioned. The table gave in most cases the results of annealing. Regarding the temperature coefficients, he knew Matthiessen's formula, and it was given in the paper. The number he had put upon the blackboard was only intended to be approximate. He thought that number was obtained by observations ranging from 16°C to nearly 100°C; and where he had criticised it was in extending that formula down from 16°C to 0°C. He had not been able to find any observations of Matthiessen's at a lower temperature than 16°C. If Mr. Taylor had numbers lower than 16°, and near 0°C, they would be of extreme value to the report. Dr. Fleming referred to the point he had raised about the effects of mechanical strain. It might be within the recollection of the Section that in the last clauses of the Report he asked for further resistance coils. It was his intention to wind those coils entirely free from paraffin. He had not yet made up his mind as to the exact form, and he should be very glad to talk the matter over, and have Dr. Fleming's very valuable assistance. As to alloys with negative temperature coefficients, he hoped to have some specimens of the wire before very long, and possibly next year to make a communication to the Section upon it. As regards the platinum-silver alloy, his own impression was that the effect alluded to was not a change in the alloy, but a mechanical change produced in the alloy by the effects of the strain. He hoped that any electricians who were present and who had old coils of the Association would kindly lend them to him again, as was done a couple of years ago, in order that he might compare them, and see whether there was any evidence of change in them. The amount of change for the coil F was a rise of ·00063; the fall for G was ·0002; the fall for H was ·0001 B.A. units. Prof. Perry's remarks about the platinum-silver alloy entirely bore out some observations of his own as to the very different nature of coils of platinum-silver wire, taken from the same bobbin, which showed quite a different constitution. He did not mean, however, that there was a large difference in the temperature coefficient. The squared paper was ordinary wall-paper; and Mr. Griffiths, when he sent it, hoped that it would not remind the Section too much of the bath-rooms. In reference to the value of Joule's equivalent, he entirely agreed with Mr. Swinburne that it was worthy of very careful consideration. Probably the best results were those of Prof. Rowland, and, no doubt, those were what Mr. Swinburne quoted.

THE HEDGEHOG TRANSFORMER.

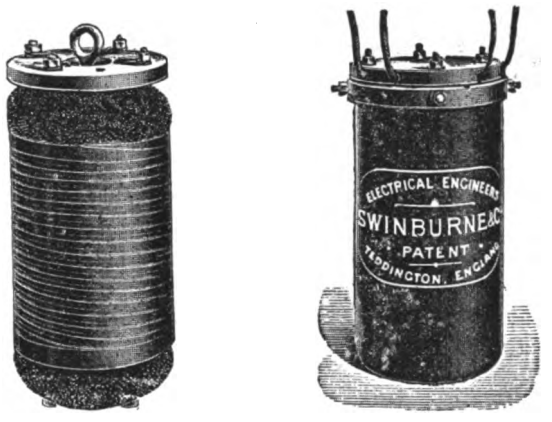
At the British Association meeting of last year, Mr. Swinburne contended that an open iron circuit could be made more efficient than any form of closed iron-circuit transformer. In calculating the efficiencies of transformers, the loss in the iron has generally been left completely out of account, and the loss in copper alone considered. If the loss by hysteresis is taken into account the loss in iron in closed-circuit transformers, as usually designed, is some 10 per cent. of the full load. As the loss in iron goes on all the time a transformer is in circuit this is very serious. The proportion of actual to possible output of energy per day varies in different districts, but in most stations the average use of lamps is less than two hours a day, including all the lamps installed. The transformer must be large enough to feed all the lamps installed, so it runs, say, an average of two hours of full load a day. If there is a loss of 10 per cent. of full load in the iron, this gives an actual efficiency of 45·5 per cent., even neglecting the loss in copper. In the hedgehog form (see Figure) the proportion of iron is very much reduced. The result is, that even in small transformers the iron loss is under 1 per cent. of the full load. One per cent. of the full load gives 89 per cent. all day, neglecting copper loss, against the 45 per cent. of the closed circuit. This is neglecting copper, however, and the copper loss is greater in the hedgehog form, so this is an exaggerated comparison. Such a transformer really has an efficiency of about 87 per cent. all day.

If a closed iron circuit is used, the iron circuit must be long to embrace the copper coils. The only way to shorten it is to make the copper coils smaller. This means using a higher current density, which is wasteful, or fewer turns of copper. Fewer turns

Digitized by Google

of copper demand either a higher induction in the iron, or a greater cross-section, and both of these mean greater loss by hysteresis. If the iron circuit is opened, the sides of the embracing core can be removed, so the loss by hysteresis is divided by three. As there is now plenty of room for copper, the turns and cross-section can be increased, and the iron reduced still further. The object of introducing the closed-iron circuit was to reduce the magnetic resistance. An open-circuit transformer has much higher magnetic resistance. The question of magnetic resistance is not so important as might at first sight appear. Its increase demands more excitation or more magneto-motive force, and this increases the loss in copper. The best form is thus a compromise. The hedgehog ends are to reduce the magnetic resistance. In a conductive circuit the resistance is low if the current density is low in all parts where the specific resistance is high. Similarly, in a composite magnetic circuit of iron and air, the magnetic resistance is low if there is never a high magnetic current density or induction in the air, which has high specific magnetic resistance. The magnetising current in a hedgehog is high, but as it is a quarter of a period behind the primary current in phase, and as the primary wire has to be large enough to carry the primary current, the loss in watts is small. As this loss goes on all day, however, it is by no means unimportant, and has to be included in getting out the efficiencies of these transformers.

The construction of these transformers, as carried out by Messrs. Swinburne and Co., of Teddington, is very simple. A gun-metal casting of cross-shaped section forms the backbone. It is spread out at each end, forming legs at one and taking the circular terminal board at the other. It also carries insulating flanges, which form the ends of the coils. Into the four recesses in the core are put four bundles of soft iron wire. These are taped over, and the secondary is wound on. The secondary is



Swinburne's Hedgehog Transformer.

then covered with two layers of ebonite, and the flanges are also faced with the same material. The primary is then wound on in two compartments, separated with ebonite, after the manner invented by Gramme so that both ends come outside, and as far removed from each other as possible. The ends of the core are then spread out, and the transformer tested under 4,000 or 5,000 volts; the insulation in megohms being read by an instrument which measures the effective resistance under an alternating current. As iron cases cannot be used, as they would be magnetised by the transformer, and as any metal would have Foucault currents generated in it, stoneware jars, specially made for the purpose, are used for cases. These have lids bolted down with holes for the leads.

Mr. Nikola Tesla criticises Mr. Swinburne's arguments in the *Electrical Engineer* of New York. The hysteresis loss occurring in closed-circuit transformers at full load is asserted to be, instead of 10 per cent., no more than 6 per cent., provided the iron is good, and the converter is intelligently used. The proportion of actual to possible daily output of energy is said to be larger than Mr. Swinburne asserts, when due care is taken in distributing the load, and when, as in many cases, entire circuits are shut off when not required. The open-circuit form of converter is subject to many disadvantages when operated at the usual period; and in comparing the hysteresis loss with that occurring in the closed-circuit type, the fact that the loss depends, within certain limits, upon the square of the magneto-motive force, may easily be overlooked. The diminution of the amount of iron, it is true, lessens the hysteresis, but the increased magneto-motive force needed to produce the same output partially counteracts the effect. Four Swinburne transformers joined so as to form a closed magnetic circuit would probably be more efficient than one alone. The magnetic resistance would be less, and the exciting current could be diminished. The electric heating depends on the square of the current flowing, and this amount of waste heat may be by no means insignificant.

Mr. Tesla asserts that the tendency to shorten the magnetic circuit in transformers is due principally to practical considerations, the extra efficiency gained by reducing the magnetic resistance being of minor importance. Whether the open-circuit transformer is an improvement or not will depend principally on the period. The experience of most engineers has resulted in the adoption of the closed-circuit form; and Mr. Tesla, who claims to have been the first to advocate the open-circuit type of converter, states that to improve the efficiency he found it necessary to use a higher period, and that at usual periods the closed-circuit form was preferable.

If an anchor ring of iron is wound *all over* with primary and secondary wires, the best result is got at a particular period. If another ring of the same material and cross section, but of double the circumference, is similarly wound, the maximum effect occurs at the *same period*, and the efficiency is the same. Thus a transformer of any capacity can be made, provided the primary and secondary coils completely cover the core. If only a fraction of the ring is covered by the wires, the smaller transformer is more efficient, and it thus becomes important to shorten the magnetic circuit. Practical considerations have prompted the best makers to enclose the wires as much as possible with laminated iron.

THE ELECTRO-MAGNET.*

BY PROF. SILVANUS P. THOMPSON.

(Continued from page 624.)

General Principles of Design and Construction.—Principle of the Magnetic Circuit.

To-night we have to discuss the law of the magnetic circuit in its application to the electro-magnet, and in particular to dwell upon some experimental results which have been obtained from time to time by different authorities as to the relation between the construction of the various parts of an electro-magnet, and the effect of that construction on its performance. We have to deal not only with the size, section, length, and material of the iron cores, and of the armatures of iron, but we have to consider also the winding of the copper coil, and its form; and we have to speak in particular about the way in which the shaping of the core and of the armature affects the performance of the electro-magnet in acting on its armature, whether in contact or at a distance. But before we enter on the last more difficult part of the subject, we will deal solely and exclusively with the law of force of the magnet upon its armature when the two are in contact with one another; in other words, with the law of traction.

I alluded in a historical manner in my first lecture to the principle of the magnetic circuit, telling you how the idea had gradually grown up, perforce, from a consideration of the facts. The law of the magnetic circuit was, however, first thrown into shape in 1873 by Prof. Rowland, of Baltimore. He pointed out that if you consider any simple case, and find (as electricians do for the electric circuit) an expression for the magnetising force which tends to drive the magnetism round the circuit, and divide that by the resistance to magnetisation reckoned also all round the circuit, the quotient of those two gives you the total amount of flow or flux of magnetism. That is to say, one may calculate the quantity of magnetism that passes in that way round the magnetic circuit in exactly the same way as one calculates the strength of the electric current by the law of Ohm. Rowland, indeed, went a great deal further than this, for he applied this very calculation to the experiments made by Joule more than 30 years before, and from those experiments deduced the degree of magnetisation to which Joule had driven the iron of his magnets, and by inference obtained the amount of current that he had been causing to circulate. Now this law requires to be written out in a form that can be used for future calculation. To put it in words without any symbols, we must first reckon out from the number of turns of wire in the coil, and the number of amperes of current which circulates in them, the whole *magneto-motive force*—the whole of that which tends to drive magnetism along the piece of iron—for it is, in fact, proportional to the strength of the current, and the number of times it circulates. Next we must ascertain the resistance which the magnetic circuit offers to the passage of the magnetic lines. I here avowedly use Joule's own expression, which was afterwards adopted by Rowland, and, for short, so as to avoid having four words, we may simply call it the *magnetic resistance*. Mr. Heaviside has suggested as an advisable alternative term, magnetic *reluctance*, in order that we may not confuse the resistance to magnetism

* A series of four Cantor Lectures delivered before the Society of Arts, January—February, 1890.

Digitized by Google

in the magnetic circuit with the resistance to the flow of current in an electric circuit. However, we need not quarrel about terms; magnetic reluctance is sufficiently expressive. Then having found these two, the quotient of them gives us a number representing—I must not call it the strength of the magnetic current—I will call it simply the quantity or number of magnetic lines which flow round the circuit; or, if we could adopt a term which is used on the Continent, we might call it simply *the magnetic flux*; the flux of magnetism being the analogue of the flow of electricity in the electric law. The law of the magnetic circuit may then be stated as follows:—

$$\text{Magnetic flux} = \frac{\text{magneto-motive force}}{\text{reluctance}}.$$

However, it is more convenient to deal with these matters in symbols, and therefore the symbols which I use, and have long been using, ought to be explained to you. For the number of spirals in a winding I use the letter S; for the strength of current, or number of amperes, the letter i; for the length of a bar, or core, I am going to use the letter l; for the area of cross-section, the letter A; for the permeability of the iron which we discussed in the last lecture, the Greek symbol μ; and for the total magnetic flux, the number of magnetic lines, I use the letter N. Then our law becomes as follows:—

$$\text{Magneto-motive force } \frac{4\pi S i}{10};$$

$$\text{Magnetic reluctance.. } \Sigma \frac{l}{A\mu};$$

$$\text{Magnetic flux ..... } N = \frac{\frac{4\pi \cdot S i}{10}}{\Sigma \frac{l}{A\mu}}.$$

If we take the number of spirals and multiply by the number of amperes of current, so as to get the whole amount of circulation of electric current expressed in so many ampere-turns, and multiply it by 4π, and divide by 10, in order to get the proper unit (that is to say, multiply it by 1·257), that gives us the magneto-motive force. For magnetic reluctance, calculate out the reluctance exactly as you would the resistance of an electric conductor to the flow of electricity, or the resistance of a conductor of heat to the flow of heat; it will be proportionate to the length, inversely proportional to the cross-section, and inversely proportional to the conductivity, or, in the present case, to the magnetic permeability. Now, if the circuit is a simple one, we may simply write down here the length, and divide it by the area of the cross-section and the permeability, and so find the value of the reluctance. But if the circuit be not a simple one, if you have not a simple ring of iron of equal section all round, it is necessary to consider the circuit in pieces as you would an electric circuit, ascertaining separately the reluctance of the separate parts, and adding all together. As there may be a number of such terms to be added together, I have prefixed the expression for the magnetic reluctance by the sign Σ of summation. But it does not by any means follow because we can write a thing down as simply as that, that the calculation out of it will be a very simple matter. In the case of magnetic lines we are quite unable to do as one does with electric currents to insulate the flow. An electric current can be confined (provided we do not put it in at 10,000 volts pressure, or anything much bigger than that) to a copper conductor by an adequate layer of adequately strong—and I use the word "strong" both in a mechanical and electrical sense—of adequately strong insulating material. There are materials whose conductivity for electricity as compared with copper may be regarded perhaps as millions of millions of millions of times less; that is to say, they are practically perfect insulators. There are no such things for magnetism. The most highly insulating substance we know of for magnetism is certainly not 10,000 times less permeable to magnetism than the most highly magnetisable substance we know of, namely, iron in its best condition; and when one deals with electro-magnets where curved portions of iron are surrounded with copper, or with air, or other insulating material, one is dealing with substances whose permeability, instead of being infinitely small, compared with that of iron, is quite considerable. We have to deal mainly with iron when it has been well magnetised. Its permeability compared with air is from 1,000 to 100 roughly; that is to say, the permeability of air compared with the iron is not less than from one one-hundredth to one one-thousandth part. That means that it is quite possible to have a very considerable leakage of magnetic lines from iron into air occurring to complicate one's calculations, and prevent an accurate estimate being made of the true magnetic reluctance of any part of the circuit. Suppose, however, that we have got over all these difficulties, and made our calculations of the magnetic reluctance; then dividing the magneto-motive force by the reluctance gives us the whole number of magnetic lines.

There, then, is in its elementary form the law of the magnetic circuit stated exactly as Ohm's law is stated for electric circuits. But as a general rule one requires this magnetic law for certain applications, in which the problem is not to calculate from those two quantities what the total of magnetic lines will be. In most of the cases a rule is wanted for the purpose of calculating back. You want to know how to build a magnet so as to give you the requisite number of magnetic lines. You start by assuming that you need to have so many magnetic lines, and you require to know what magnetic reluctance there will be, and how much magneto-motive force will be needed. Well, that is a matter precisely analogous to those which every electrician comes across. He does not always want to use Ohm's law, in the way in which it is commonly stated, to calculate the current from the electromotive force and the resistance; he often wants to calculate what is the electromotive force which will send a given current through a known resistance. And so do we. Our main consideration to-night will be devoted to the question how many ampere-turns of current circulation must be provided in order to drive the required quantity of magnetism through any given magnetic reluctance. Therefore, we will state our law a little differently. What we want to calculate out is the number of ampere-turns required. When once we have got that, it is easy to say what the copper wire must consist of; what sort of wire, and how much of it. Turning, then, to our algebraic rule, we must transform it, so as to get all the other things besides the ampere-turns, to the other side of the equation. So we write the formula:—

$$Si = \frac{N \cdot \Sigma \frac{l}{A\mu}}{1{\cdot}257}$$

We shall have then the ampere turns equal to the number of magnetic lines we are going to force round the circuit multiplied by the sum of the magnetic reluctances divided by 1 257. Now this number, 1·257, is the constant that comes in when the length, l, is expressed in centimetres, the area in square centimetres, and the permeability in the usual numbers. Many persons unfortunately—I say so advisedly because of the waste of brain labour that they have been compelled to go through—prefer to work in inches and pounds and feet. They have, in fact, had to learn tables instead of acquiring them naturally without any learning. If the lengths be specified in inches, and areas in square inches, then the constant is a little different. The constant in that case, for inches and square inch measures, is 0·3132, so that the formula becomes:—

$$Si = N \times \Sigma \frac{l''}{A''\mu} \times 0{\cdot}3132.$$

Here it is convenient to leave the law of the magnetic circuit, and come back to it from time to time as we require. What I want to point out before I go to any of the applications is, that with the guidance provided by this law, one after another the various points that come under review can be arranged and explained, and that there does not now remain—if one applies this law with judgment—a single fact about electro-magnets which is either anomalous or paradoxical. Paradoxical some things may seem in form, but they all reduce to what is perfectly rational when one has a guiding principle of this kind to tell you how much magnetisation you will get under given circumstances, or to tell you how much magnetising power you require in order to get a given quantity of magnetisation. I am using the word "magnetisation" there in the popular sense, not in the narrow mathematical sense in which it has sometimes been used (*i.e.*, for the magnetic moment per unit cube of the material). I am using it simply to express the fact that the iron or air, or whatever it may be, has been subjected to the process which results in their being magnetic lines of force induced through it.

Now let us apply this law of magnetic circuit in the first place to the traction—that is to say, the lifting power of electro-magnets. The law of traction I assumed in my last lecture, for I made it the basis of a method of measuring the amount of permeability. The law of magnetic traction was stated once for all by Maxwell, in his great treatise, and it is as follows:—

$$P\,(\text{dynes}) = \frac{B^2 A}{8\pi},$$

where A is the area in square centimetres. This becomes

$$P\,(\text{grammes}) = \frac{^2A}{8\pi \times 981}.$$

That is, the pull in grammes per square centimetre is equal to the square of the magnetic induction, B (being the number of magnetic lines to the square centimetre), divided by 8π, and divided also by 981. To bring grammes into pounds you divide by 453·6; so that the formula then becomes:—

$$P\,(\text{lbs.}) = \frac{B^2 A}{11{,}183{,}000};$$

Digitized by Google

or if square inch measures are used :—

$$P\ (\text{lbs.}) = \frac{B^2{}_{''}\,A''}{72{,}134{,}000}.$$

To save future trouble we will now calculate out from the law of traction the following Table ; in which the traction in grammes per square centimetre or in pounds per square inch is set down opposite the corresponding value of B.

Table VI.—*Magnetisation and Magnetic Traction.*

B lines per sq. cm.	$B_{''}$ lines per sq. inch.	Dynes per square centimetre.	Grammes per square centimetre.	Kilogrs. per sq. centim.	Pounds per sq. inch.
1,000	6,450	39,790	40·56	·0456	·577
2,000	12,900	159,200	162·3	·1623	2·308
3,000	19,350	358,100	365·1	·3651	5·190
4,000	25,800	636,600	648·9	·6489	9·228
5,000	32,250	994,700	1,014·0	1·014	14·39
6,000	38,700	1,432,000	1,460·0	1·460	20·75
7,000	45,150	1,950,000	1,987·0	1·987	28·26

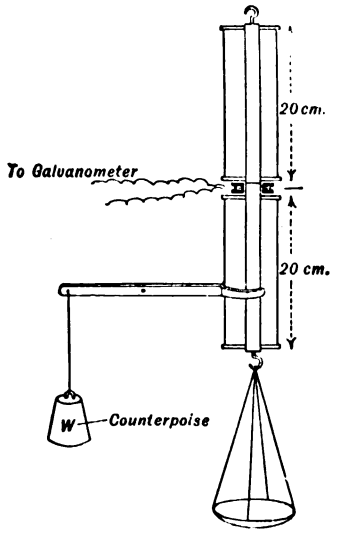

Fig. 22.—Bosanquet's Verification of the Law of Traction

This simple statement of the law of traction assumes that the distribution of the magnetic lines is uniform all over the area we are considering ; and that, unfortunately, is not always the case. When the distribution is not uniform, then the mean value of the squares becomes greater than the square of the mean value, and consequently the pull of the magnet at its end face may, under certain circumstances, become greater than the calculation would lead you to expect—greater than the average of B would lead you to suppose. If the distribution is not uniform over the area of contact, then the accurate expression for the tractive force (in dynes) will be—

$$P = \frac{1}{8\pi}\int B^2 dA,$$

the integration being taken over the whole area of contact.

This law of traction has been verified by experiment. The most conclusive investigations were made about 1886 by Mr. R. H. M. Bosanquet, of Oxford, whose apparatus is depicted in Fig. 22. He took two cores of iron, well faced, and surrounded them both by magnetising coils, fastened the upper one rigidly, and suspended the other one on a lever with a counterpoise weight. To the lower end of this core he hung a scale-pan, and measured the traction of one upon the other when a known current was circulating a known number of times round the coil. At the same time he placed an exploring coil round the joint, that exploring coil being connected, in the manner with which we were experimenting last week, with a ballistic galvanometer ; so that at the moment when the two surfaces parted company, or at the moment when the magnetisation was released by stopping the magnetising current, the galvanometer indication enabled him to say exactly how many magnetic lines went through that exploring coil. So that, knowing the area, you could calculate the number per square centimetre, and you could therefore compare B^2 with the pull per square centimetre obtained directly on the scale-pan. Bosanquet found that even when the surfaces were not absolutely perfectly faced the correspondence was very close indeed, not varying by more than 1 or 2 per cent. except with small magnetising forces, say forces less than five C.G.S. units. When one knows how irregular the behaviour of iron is when the magnetising forces are so small as this, one is not astonished to find a lack of proportionality. The correspondence was, however, sufficiently exact to say that the experiments verified the law of traction, that the pull is proportional to the square of the magnetic induction through the area, and integrated over that area.

Now the law of traction being in that way established, one at once begins to get some light upon the subject of the design of electro-magnets. Indeed, without going into any mathematics, Joule had foreseen this when he in some instinctive sort of way seemed to consider that the proper way to regard an electro-magnet for the purpose of traction was to think how many square inches of contact surface it had. He found that he could magnetise iron up until it pulled with a force of 175lb. to the square inch, and he doubted whether a traction as great as 200lb. per square inch could be obtained.

In the following Table Joule's results (*see* Table I.) are re-calculated, and the values of B deduced :—

Table VII.—*Joule's Results Re-calculated.*

Description of electro-magnet.	Section. sq. in.	Section. sq. cm.	Load. lbs.	Load. kilos.	lbs. per sq. in.	kilos. per sq. cm.	B	Ratio of load to weight.

I will now return to the data on Table VI., and will ask you to compare the last column with the first. Here are the various values of B, that is say, the amounts of magnetisation you get into the iron. You cannot conveniently crowd more than 20,000 magnetic lines to the square centimetre of the best iron, and, as a reference to the curves of magnetisation shows, it is not expedient in the practical design of electro-magnets to attempt, except in extraordinary cases, to crowd more than about 16,000 magnetic lines into the square centimetre. The simple reason is this : that if you are working up the magnetic force, say from 0 up to 50, a magnetising force of 50 applied to good wrought iron will give you only 16,000 lines to the square centimetre, and the permeability by that time has fallen to about 320. If you try to force the magnetisation any further, you find that you have to pay for it so greatly. If you want to force another 1,000 lines through the square centimetre, to go from 16,000 to 17,000, you have to add on an enormous magnetising force ; you have to double the whole force from that point to get another 1,000 lines added. Obviously, it would be much better to take a larger piece of iron, and not to magnetise it too highly—to take a piece a quarter as large again, and to magnetise that less forcibly. It does not, therefore, pay to go much above 16,000 lines to a square centimetre—that is to say, expressing it in terms of the law of traction, and the pounds per square inch, it does not pay to design your electro-magnet so that it shall have to carry more than about 150lb. to the square inch. This shall be our practical rule : let us at once take an example If you want to design an electro-magnet to carry a load of one ton, divide the ton, or 2,240lb., by 150, and that gives the requisite number of square inches of wrought iron, namely, 14·92, or, say, 15. Of course, one would work with a horseshoe-shaped magnet, or something equivalent—something with a return circuit—and calculate out the requisite cross-section, so that the total area exposed might be sufficient to carry the given load at 150lb. to the square inch. And, as a horse-shoe magnet has two poles, the cross-section of the bar of which it is made must be 7½ square inches. If of round iron, it must be about 3½in. in diameter ; if of square iron, it must be 2¾in. each way.

That settles the size of the iron, but not the length. Now, the length of the iron, if one only considers the law of the magnetic circuit, ought to be as short as it can possibly be made. Reflect for what purpose we are designing. The design of an electro-magnet is to be considered, as every design ought to be, with a view to the ultimate purpose to be served by that which you are designing. The present purpose is the actual sticking on of the

Digitized by Google

magnet to a heavy weight, not acting on another magnet at a distance, not pulling at an armature separated from it by a thick layer of air; we are dealing with traction in contact. The question is—how long a piece of iron shall we need to bend over? The answer is—take length enough, and no more than enough, to permit of room for winding on the necessary quantity of wire to carry the current which will give the requisite magnetising power. But this latter we do not yet know; it has to be calculated out by the law of the magnetic circuit—that is to say, we must calculate the magnetic flux, and the magnetic reluctance as best we can; then from these calculate the ampere-turns of current; and from this calculate the needful quantity of copper wire, so arriving finally at the proper length of the iron core. It is obvious the cross-section being given, and the value of B being prescribed, that settles the whole number of magnetic lines, N, that will go through the section. It is self-evident that length adds to the magnetic reluctance, and, therefore, the longer the length is, the greater have to be the number of ampere-turns of circulation of the current; while the less the length is, the smaller need be the number of ampere-turns of circulation. Therefore you should design the electro-magnet as stumpy as possible—that is to say, make it a stumpy arch, even as Joule did when he came across the same problem, and arrived, by a sort of scientific instinct, at the right solution. You should have no greater length of iron than is necessary in order to get the windings on. Then you see we cannot absolutely calculate the length of the iron until we have an idea about the winding, and we must settle, therefore, provisionally, about the windings. Take a simple ideal case. Suppose we had an indefinitely long, straight iron rod, and we wound that from end to end with a magnetising coil. How thick a coil, how many ampere-turns of circulation per inch length, will you require in order to magnetise up to any particular degree? It is a matter of very simple calculation. You can calculate exactly what the magnetic reluctance of an inch length of the core will be. For example, if you are going to magnetise up to 16,000 lines per square centimetre, the permeability will be 320. You can take the area anything you like, and consider the length of one inch; you can therefore calculate the magnetic reluctance per inch of conductor, and then you can at once say how many ampere-turns per inch would be necessary in order to give the desired indication of 16,000 magnetic lines to the square centimetre. And knowing the properties of copper wire, and how it heats up when there is a current; and knowing also how much heat you can get rid of per square inch of surface, it is a very simple matter to calculate what minimum thickness of copper the fire insurance companies would allow you to use. They would not allow you to have too thin a copper wire, because if you provide an insufficient thickness of copper, you still must drive your amperes through it to get a sufficient number of ampere turns per inch of length; and if you drive those amperes through copper winding of an insufficient thickness the copper wire will over-heat, and your insurance policy will be revoked. You therefore are compelled, by the practical consideration of not over-heating, to provide a certain thickness of copper wire winding. I have made a rough calculation for certain cases, and I find that for such electro-magnets as one may ordinarily deal with, it is not necessary in any case of practical work to use a copper wire winding, the total thickness of which is greater than about half an inch; and, as a matter of fact, if you use as much thickness as half an inch, you need not then wind the coil all along, for if you will use copper wire winding, no matter what the size, whether thin or thick, so that the total thickness of copper outside the iron is half an inch, you can, without over-heating, using good wrought iron, make one inch of winding do for 20in. length of iron—that is to say, you do not really want more than $\frac{1}{40}$th of an inch of thickness of copper outside the iron to magnetise up to the prescribed degree of saturation that indefinitely long piece of which we are thinking, without overheating the outside surface in such a way as to violate the insurance rules. Take it roughly, if you wind to a thickness of half an inch, the inch length of copper will magnetise 20in. length of iron up to the point where B equals 16,000. If then we have a bar bent into a sort of horse-shoe in order to make it stick on to a perfectly-fitting armature also of equal section and quality, we really do not want more than one inch along the inner curve for every 20in. of iron. An extremely stumpy magnet, such as I have sketched in Fig. 23, will therefore do, if one can only get the iron sufficiently homogeneous throughout. If, instead of crowding the wire near the polar parts, we could wind entirely all round the curved part, though the layer of copper winding would be half an inch thick inside the arch, it would be much less outside. Such a magnet, provided the armature fitted with perfect accuracy to the polar surfaces, and provided a battery were arranged to send the requisite number of amperes of current through the coils, would pull with a force of one ton, the iron being but 3$\frac{1}{2}$ins. in diameter. For my own part, in this case I should prefer not to use round iron, one of square or rectangular section being more convenient; but the round iron would take less copper in winding, as each turn would be of minimum length if the sections were circular.

Now, this sort of calculation requires to be greatly modified directly one begins to deal with any other case. A stumpy, short magnetic circuit with great cross-section is clearly the right thing for the greatest traction. You will get the given magnetisation and traction with the least amount of magnetising force when you have the area as great as possible, and the length as small as possible. You will kindly note that I have given you as yet no proofs for the practical rules that I have been using; they must come later. Also I have said nothing about the size of the wire, whether thick or thin. That does not in the least matter; for the ampere-turns of magnetising power can be made up in any desired way. Suppose we want on any magnet 100 ampere-turns of magnetising power, and we choose to employ a thin wire that will only carry half an ampere, then we must wind 200 turns of that thin wire. Or, suppose we choose to wind it with a thick wire that will carry 10 amperes, then we shall want only 10 turns of that wire. The same weight of copper, heated up by the corresponding current to an equal degree of temperature, will have equal magnetising power when wound on the same core. But the rules about winding the copper will be considered later.

Now, if you look in the text-books that have been written on magnetism for information about the so-called lifting power or portative force of magnets—in other words, their traction—you will find that from the time of Bernoulli downwards, the law of portative force has claimed the attention of experimenters, who, one after another have tried to give the law of portative force in terms of the weight of the magnets, usually dealing with permanent magnets, not electro-magnets. Bernoulli gave* a rule, something of the following kind, which is commonly known as Häcker's rule—

$$P = a\sqrt[3]{W};$$

where W is the weight of the magnet, P the greatest load it will sustain, and a a constant depending on the units of weight chosen,

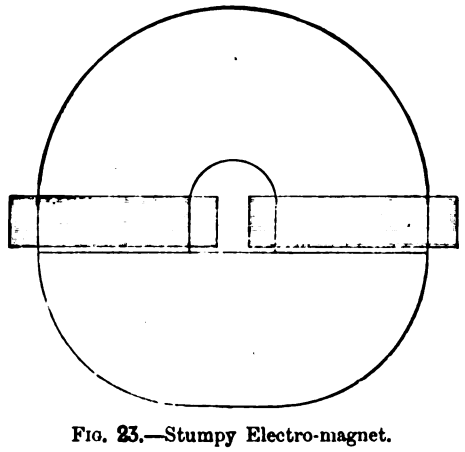

Fig. 23.—Stumpy Electro-magnet.

on the quality of the steel, and on its goodness of magnetisation. If the weights are in pounds then a is found, for the best steels, to vary from 18 to 24 in magnets of horse-shoe shape. This expression is equivalent to saying that the power which a magnet can exert—he was dealing with steel magnets; there were no electro-magnets in Bernoulli's time—is equal to some constant multiplied by the three-halfth root of the weight of the magnet itself. The rule is accurate only if you are dealing with a number of magnets all of the same geometrical form, all horse-shoes let us say, of the same general shape, made from the same sort of steel similarly magnetised. In former years I pondered much on Häcker's rule, wondering how on earth the three-halfth root of the weight could have anything to do with the magnetic pull; and having cudgelled my brains for a considerable time, I saw that there was really a very simple meaning in it. What I arrived at† was this. If you are dealing with a given material, say hard steel, the weight is proportional to the volume, and the cube root of the volume is something proportional to the length, and the square of the cube root forms something proportional to the square of the length—that is to say, to something of the nature of a surface. What surface? Of course, the polar surface. This complex rule, when thus analysed, turns out to be merely a mathematician's expression of the fact that the pull for a given material magnetised in a given way is proportional to the area of the polar surface; a law which in its simple form Joule seems to have arrived at naturally, and which in this extraordinarily academic form was arrived at by comparing the weights of magnets with the weight which they would lift. You will find it stated in many books that a good magnet will lift 20 times its own weight. There never was a more fallacious

* "Acta Helvetica," Vol. III., p. 233, 1758.

† *Philosophical Magazine*, July, 1888.

Digitized by Google

rule written. It is perfectly true that a good steel horse-shoe magnet weighing 1lb. ought to be able to pull with a pull of 20lb. on a properly-shaped armature. But it does not follow that a magnet which weighs 2lb. will be able to pull with a force of 40lb. It ought not to, because a magnet that weighs 2lb. has not poles twice as big if it is the same shape. In order to have poles twice as big you must remember that three-halfth root coming in. If you take a magnet that weighs eight times as much, it will have twice the linear dimensions and four times the surface ; and with four times the surface in a magnet of the same form, similarly magnetized, you will have four times the pull. With a magnet eight times as heavy you will have only four times the pull. The pull, when other things are equal, goes by surface, and not by weight, and therefore it is ridiculous to give a rule saying how many times its own weight a magnet will pull. It is also narrated as a very extraordinary thing that Sir Isaac Newton had a magnet, a loadstone, which he wore in a signet ring, which would lift 234 times its own weight. I have had an electro-magnet which would lift 2,500 times its own weight, but then it was a very small one, and did not weigh more than a grain and a-half. When you come to small things, of course the surface is large proportionally to the weight ; the smaller you go, the larger becomes that disproportion. This all shows that the old law of traction in that form was practically valueless, and did not guide you to anything at all, whereas the law of traction, as stated by Maxwell, and explained further by the law of the magnetic circuit, proves a most useful rule.

From this digression let us return to the law of the magnetic circuit. I gave you in my first lecture, when speaking of permeability, the following rule for calculating the magnetic induction B :—Take the pull in pounds, and the area of cross section in square inches, divide one by the other, and take the square root of the quotient ; then multiplying by 1,317 gives B ; or multiplied by 8,494 gives $B_{\prime\prime}$. We have therefore a means of stepping from the pull per square inch to $B_{\prime\prime}$, or from $B_{\prime\prime}$ to the pull per square inch. Now the other rule of the magnetic circuit also enables us to get from the ampere turns down to $B_{\prime\prime}$, for on p. 891, we have the following expression for the ampere-turns :—

$$S\,i = N \times \Sigma \frac{l''}{A''\mu} \times 0{\cdot}3132,$$

and N, the whole number of magnetic lines in the magnetic circuit is equal to $B_{\prime\prime}$ multiplied by A″, or

$$N = B_{\prime\prime} A''.$$

From these we can deduce a simple direct expression, provided we assume the quality of iron as before, and also assume that there is no magnetic leakage, and that the area of cross-section is the same all round the circuit, in the armature as well as in the magnet core. So that l'' is simply the mean total path of the magnetic lines all round the closed magnetic circuit. We may then write

$$S\,i = \frac{B_{\prime\prime}\, l''}{\mu} \times 0{\cdot}3132 ;$$

whence—

$$B_{\prime\prime} = \frac{\mu \times S\,i}{l'' \times 0{\cdot}3132}.$$

But by the law of traction, as stated above,

$$B_{\prime\prime} = 8494 \sqrt{\frac{P\ (\text{lbs.})}{A\ (\text{sq. in.})}}.$$

Equating together these two values of $B_{\prime\prime}$, and solving, we get for the requisite number of ampere-turns of circulation of exciting currents :—

$$S\,i = 2661 \times \frac{l''}{\mu} \times \sqrt{\frac{P\ (\text{lbs.})}{A\ (\text{sq. in.})}}$$

This, put into words, amounts to the following rule for calculating the amount of exciting power that is required for an electro-magnet pulling at its armature, in the case where there is a closed magnetic circuit with no leakage of magnetic lines. Take the square root of the pounds-per-square-inch ; multiply this by the mean total length (in inches) all round the iron circuit ; divide by the permeability (which must be calculated from the pounds-per-square-inch by help of Table VI. and Table II.) ; and finally multiply by 2,661 : the number so obtained will be the number of ampere-turns. One goes then at once from the pull per square inch to the number of ampere-turns required to produce that pull in a magnet of given length, and of the prescribed quality. In the case where the pull is specified in kilogrammes, the area of section in square centimetres, and the length in centimetres, the formula becomes

$$S\,i = 3951. \frac{l}{\mu} \sqrt{\frac{P}{A}}.$$

As an example, take a magnet core of round annealed wrought iron, half an inch in diameter, 8in. long, bent to horse-shoe shape. As an armature, another piece, 4in. long, bent to meet the former. Let us agree to magnetise the iron up to the pitch of pulling with 112lb. to the square inch. Reference to Table VI. shows that $B_{\prime\prime}$ will be about 90,000, and Table II. shows that in that case μ will be about 907. From these data calculate what load the magnet will carry, and how many ampere-turns of circulation of current will be needed.

Ans.—Load (on two poles) =43·97lbs.
Ampere-turns needed =372·5

N.B.—In this calculation it is assumed that the contact surface between armature and magnet is perfect. It never is ; the joint offers additional resistance to the magnetic lines, and there will be some leakage. It will be shown later how to estimate these effects, and to allow for them in the calculations.

Here let me go to a matter which has been one of the paradoxes of the past. In spite of Joule, and of the laws of traction, showing that the pull is proportional to the area, you have this anomaly—that if you take a bar-magnet having flat ended poles, and measure the pull which its pole can exert on a perfectly flat armature, and then deliberately spoil the truth of the contact surface, rounding it off, so making the surface gently convex, the convex pole, which only touches at a portion of its area instead of over the whole, will be found to exert a bigger pull than the perfectly flat one. It has been shown by various experimenters, particularly by Nicklès, that if you want to increase the pull of a magnet with armatures, you may reduce the polar surface. Old steel magnets were frequently purposely made with a rounded contact surface. There are plenty of examples. Suppose you take a straight round core, or one leg of a horseshoe, which answers equally, and take a flat-ended rod of iron of same diameter as an armature ; stick it on endwise, and measure the pull when a given amount of ampere-turns of current is circulating round. Then,

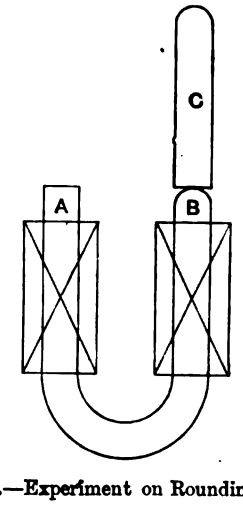

Fig. 24.—Experiment on Rounding Ends.

having measured the pull, remove it and file it a little, so as to reduce it at the edges ; or take a slightly narrower piece of iron, so that it will actually be exerting its power over a smaller area, you will get a greater pull. What is the explanation of this extraordinary fact ? A fact it is, and I will show it to you. Here, Fig. 24, is a small electro-magnet, which we can place with its poles upwards. This was very carefully made, the iron poles very nicely faced, and on coming to try them it was found they were nearly equal, but one pole, A, was a little stronger than the other. We have, therefore, rounded the other pole, B, a little ; and here I will take a piece of iron, C, which has itself been slightly rounded at one end, though it is flat at the other. I now turn on the current to the electro-magnet, and I take a spring-balance, so that we can measure the pull at either of the two poles. When I put the flat end of C to the flat pole A, so that there is an excellent contact, I find the pull about 2½lb. Now try the round end of C on the flat pole, A ; the pull is about 3lb. The flat end of C on the round pole B is also about 3lb. But if now I put together two surfaces that are both rounded, I get almost exactly the same pull as at first with the two flat surfaces. I have made many experiments on this, and so have others. Take the following case :—There is hung up a horseshoe magnet, one pole being slightly convex and the other absolutely flattened, and there is put at the bottom a square bar armature, over which is slipped a hook, to which weights can be hung. Which end of the armature do you think will be detached first ?

If you were going simply by the square inches, you would say this square end will stick on tighter ; it has more gripping surface. But, as a matter of fact, the other sticks tighter. Why ? We are dealing here with a magnetic circuit. There is a certain total magnetic reluctance all round it, and the whole number of magnetic

Digitized by Google

lines generated in the circuit depends on two things—on the magnetising force, and on the reluctance all round ; and, saving a little leakage it is the same number of magnetic lines which come through at B as go through at A. But here, owing to the fact that there is at B a better contact at the middle than at the edges of the pole, the lines are crowded into a smaller space, and therefore at that particular place B_n, the number of lines per square inch runs up higher, and when you square the larger number, its square becomes still larger in proportion In comparing the square of the smaller B_n with the square of greater B_n, the square of the smaller B_n over the larger area turns out to be less than the square of the larger B_n integrated over the smaller area. It is the law of the square coming in.

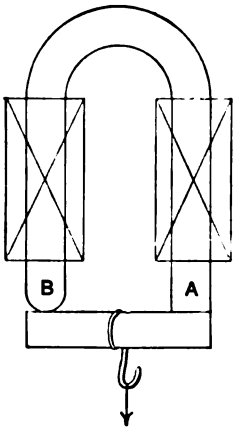

FIG. 25.—Experiment of Detaching Armature.

As an example, take the case of a magnet pole formed on the end of a piece of round iron 1·15in. in diameter. The flat pole will have 1 05 inch area. Suppose the magnetising forces are such as to make $B_n = 90300$, then, by Table VI., the whole pull will be 118·75lb., and the actual number of lines through the contact surface will be $N = 948150$. Now suppose the pole be reduced by rounding off the edge till the effective contact area is reduced to 0·9 square inch. If all these lines were crowded through that area, that would give a rate of 105630 per square inch. Suppose, however, that the additional reluctance and the leakage reduced the number by 2 per cent., there would still be 103500 per square inch. Reference to Table VI. shows that this gives a pull of 147·71b. per square inch, which multiplied by the reduced area 0·9 gives a total pull of 132·91b., which is larger than the original pull.

(To be continued.)

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *September* 26, 1890.

The Edison Company.—This Company has settled down to business under its new organisation, and is just now very prosperous. It has been determined by its managers to abandon the manufacture of the Sprague type of stationary motor. A machine built on the pattern of the Edison dynamo will be substituted hereafter for the Sprague in all Edison work. Whether the change will be an improvement or not can only be told after a sufficient number of the new machines have been put out. How far the Sprague street car motor will be altered under the Edison management it is hard to say ; but Mr. Edison has been vigorously engaged in making changes, and some new features are anticipated, among other things a single motor probably will be used in place of the two heretofore employed on street cars. This will undoubtedly produce an improvement in the matter of general efficiency.

Subways.—The difficulty between the Subway Company and the electrical illuminating companies is still vigorously under way. Charges of every description are flying about, and where nothing further can be said the attorneys of both parties indulge in vituperation. Mayor Grant, as usual, is ready for anything to interfere with the electric service of the city, and can be depended upon to stand in the way of the illuminating companies every time there is an opportunity. There seems to be no good reason why the companies should be compelled to put their wires in conduits, for which a most exorbitant price is charged. It is an unquestionable fact that conduits sufficient for the necessary service can be laid at a very small fraction of the alleged cost of the present structure ; in fact, the annual rental demanded would almost pay for a proper conduit. The result of this obstruction policy on the part of the City Fathers is to hinder the operations of the electrical companies very seriously, and it is no easy matter to find a way out of the difficulty.

Westinghouse Traction Work.—Good reports still continue to come from the Westinghouse electric cars, started in operation in various portions of the country, but no further details of the machinery have been made public. The system is being vigorously pushed, however, and I presume the apparatus will be given the public prominence it deserves in a very short time.

The Life of Lamps on Arc Circuits.—There have recently appeared a number of interesting reports of long life in incandescent lamps, but very little has heretofore been reported concerning the type of incandescent lamps used on arc circuit in series. A recent account of some practical experiments gives results that are decidedly encouraging. 230 30-candle power, 10 ampere, series lamps of the Bernstein make were placed on the circuit of the Electric Light and Power Company, of Elizabeth City, N.C. At the present time there have been less than 30 renewals, in spite of the lamps being run up to the full amperage all the time. The time of burning has averaged something over 1,500 hours.

Electrical Execution.—The electrical execution matter is again before the public by reason of the desperate efforts that are being made on behalf of a Japanese murderer, sentenced under the new law.

CORRESPONDENCE.

MAGNETO-OPTIC E.M.F.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : About two years ago it occurred to me to try whether the rotation of the plane of polarisation of plane polarised light inside a coil would generate either a continuous or an oscillatory current in the coil ; and, with the aid of three friends, I tried the experiment in the Physical Laboratory of this College.

The light of an albocarbon lamp was passed through a Nicol prism which was fixed on a shaft connected with a small turbine. The ray which emerged from the Nicol was passed through a glass tube filled with turpentine, which was placed in the axis of a reel of fine wire, the extremities of which could be connected either with a galvanometer or a telephone. The rotation of the plane of polarisation was produced by rotating the Nicol by means of the turbine.

When the experiment was first performed, we came to the conclusion that no result was produced either in the galvanometer or in the telephone. Last May I thought that it was worth while to repeat the experiment with more care ; but again there was no result to "swear by."

Dr. Sheldon appears to have performed a very similar experiment on a much greater scale ; but most of my scientific friends doubt his success, and, indeed, deny that we have any reason to expect such a result at all.

One scientific authority said to me as I was about to try the experiment, "You expect the converse of the result produced by passing a ray of polarised light through turpentine in a magnetic field ; and as we know that when polarised light passes through a sugary liquid, its plane of polarisation is rotated, conversely, if you take a beaker of water, let polarised light fall on one side of the beaker, and rotate the plane of polarisation, I shall expect to see tons of sugar coming out at the other side."—Yours, &c., GEO. M. MINCHIN.

R.I.E. College, Cooper's Hill, October 4, 1890.

THE NEW MAGNETOMETER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of September 26th you notice a communication which I have recently made to the Royal Society on a new magnetometer. You will be good enough to let me correct you on one or two points. Your statement that H is measured by observing the deflection of the needle at the centre of the circular magnet, and by observing the angle through which the upper end of the bifilars has to be turned to make the plane of the "circular magnet" E. and W., is incorrect. It could, of course, so be measured, but not, I think, so conveniently as by measuring the deflections of both needle and magnet from the N.S. and E.W. directions respectively, before and after reversal of the magnet.

Then you say that the correction for torsion of the suspending fibres is *rather serious*. In the paper referred to, I style this correction *utterly negligible*. It can, of course, be made serious by using a cable of silk; but by making the circular magnet very light (and I hope to be able to reduce it much below 11 gms. in the more elaborate instrument I am designing), and suspending it bifilarly by an ordinary cocoon fibre, the correction for torsion with a 30cm. suspension is *utterly negligible* (*see* Gray, *Phil. Mag.*, January, 1887). The correction for torsion suspension of the little needle is much more serious, and with a coarse fibre may easily amount to 1 in 1,000. It can, however, readily be allowed for by turning the needle through 360°, and re-observing its position after the ordinary fashion.

In connection with the employment of a bifilar suspension to measure a horizontal couple absolutely, may I remark that while the measurements are necessarily somewhat rough with wire suspensions, unless these are of gigantic dimensions—dimensions tolerable only in German laboratories—the measurements can be made with the greatest ease and simplicity, certainly to 1 in 1,000, and I hope to be able to show, experimentally, to 1 in 10,000, provided the body is so light that a single cocoon fibre will support it bifilarly.

If any of your readers should be employing the method, may I just mention the one point to which slight attention must be devoted, viz.: the magnet must be so supported from the silk fibres that their tensions are roughly equal. A difference in tensions of 5 per cent. of the whole weight supported will make the observation of H too large by 1 in 800. A similar difference of 1 per cent. will affect H to the extent of 1 in 20,000, so that the adjustment of approximate equality of tensions need only be rough for one-tenth-per-cent. work. It should be mentioned that the observations referred to in the *Proc. Roy. Soc.* were made *without care being taken on this point*, because I relied upon the extensibility of the silk fibres to automatically adjust the tensions to sufficient equality. This is one of the points, I think, in favour of silk as a material for bifilar suspension. Of course, a smooth pulley, supported in frictionless bearings at the top of the instrument, and over which the silk fibre passes, perfectly satisfies the condition of equality of tension in theory. In preference to this, the arrangement which I should recommend is to attach a little hook at the middle of the wide hook under which the lower end of the bifilars pass, and to lower the weight on to the fibres by means of a loop of thread attached to this hook and afterwards removed.

One other point should be noticed, viz., that copper pieces should be attached to the vertical sides of the box to damp the oscillations of the magnet.

In conclusion, may I ask your readers to compare the formula for H in the case of the New and Kew instruments respectively? In the one case we have

$$H^2 = \frac{W\,d\,d'}{4\,l\,r^3}\,\frac{\tan\theta\cos(\phi-\theta)}{\sin\phi},$$

and there is no correction for anything except possibly a temperature correction for differential metallic expansion, which, as is well known, can be made exceedingly small in a bifilar arrangement. In the case of the Kew the formula is—but I forbear. Those of your readers who are interested in magnetometry will not have forgotten it, although they certainly will not remember all the minutiæ of its ramifications.—Yours, &c.,

WILLIAM STROUD.

The Yorkshire College, Leeds, October 4th.

THE SYPHON RECORDER AND THE D'ARSONVAL GALVANOMETER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The following Note appeared in *The Electrician* of July 18, 1890:—

"Whilst describing Sir William Thomson's syphon recorder, Dr. Walmsley made incidentally a remark which will be endorsed by all English electricians. He drew attention to the fact that the D'Arsonval galvanometer, about which we have heard so much during the last few years, is nothing else but a revival of the corresponding part in the syphon recorder, and that it therefore should properly be called the Thomson galvanometer. The wonder is that the similarity between the two instruments has not been pointed out before. The arrangement of a coil suspended between fixed poles and an inner soft iron fixed armature is, as Dr. Walmsley points out, to be found in Maxwell."

With regard to this interesting note, might it not be suggested that the similarity of the suspended coils of the D'Arsonval galvanometer and the Thomson syphon recorder has not been made a subject for special comment, for the reason that the likeness between the two is obvious? Is not Dr. Walmsley's stricture on the naming of M. D'Arsonval's galvanometer somewhat severe? If the latter gentleman has been the first to adapt the suspended coil to testing instruments, is it not but fair that the adaptation be named after the adapter? Sir William Thomson, in his syphon recorder, made use of the suspended coil—a contrivance already known. The "Mouse Mill" also was a modification, through a series of beautiful developments, of Varley's influence machine. In fact, the only novelty in the syphon recorder lay in the electrical spirting of the ink on to the paper band, a device now being superseded by the vibrator. Yet who will deny that the recorder—taken as a whole, an ideal of delicate adjustment and mathematical exactness in detail—was a genuine invention of the first order, and how grossly inaccurate it would be to speak of this combination of solved difficulties as anybody else's but Thomson's, even now that electrification is yielding the *pas* to the vibrator, and the mill to the simple motor, or to the still more prosaic clockwork.

Now, if a Thomson can utilise the suspended coil, why should not M. D'Arsonval be free to do the same when he constructs a galvanometer? And why should his instrument be named after Thomson, as Dr. Walmsley suggests. Sir William Thomson's great name is already associated with his own modification of and improvement on Weber's mirror galvanometer. Weber's instrument, with its heavy and sluggish magnetised steel mirror, could not well have benefited cable telegraphy, but was nevertheless the embryo which, under the treatment of a master mind, developed in one direction into the Thomson speaking mirror, and, in another, into the Thomson astatic mirror galvanometer, a familiar object in all electrical test-rooms.

A point worthy of the beginner's attention is that the movable coil between fixed magnetic poles, as an example of magnetic attraction and repulsion, is an exact opposite to Oersted's wire and needle, and to all the subsequent developments of this arrangement down to Thomson's galvanometer. Besides these two classes there are two others, in the first of which a movable coil is influenced by an inner fixed coil, whilst in the other an outer fixed coil influences an inner movable one. It happens that four well-known testing instruments exemplify all four classes, namely:—(1). Movable coil between poles, of fixed magnet: D'Arsonnal's galvanometer. (2). Movable magnets within fixed coil: Sir William Thomson's galvanometer. (3). Fixed coil within movable coil: Siemen's electro-dynamometer. (4.) Movable coil within fixed coil: Prof. Elihu Thomson's electric meter.

Owing to the complete analogy between a magnet and a current-traversed wire—so beautifully shown by Ampère—we can speak of current-traversed wires as wire magnets, and describe our four classes of instruments as follows:—(1) Movable wire magnet within fixed permanent magnet; (2) Movable permanent magnet within fixed wire magnet; (3) Fixed wire magnet within movable wire magnet; (4) Movable wire magnet within fixed wire magnet.

Explanations of electro-dynamical effects, such, for instance, as the above, are greatly simplified for beginners by treating current-traversed coils purely and simply as magnets, the two

Digitized by Google

faces of the coil being the poles, which vary in sign, with direction of traversing current. There are at least seven text-books, which describe the syphon recorder, but which, when treating of the suspended coil remain, one and all, content with the statement that a current through it causes it to be "impelled across the magnetic field in one direction or the other, according to the polarity and strength of the current passing throught it," or words to the same effect, as if this movement were some phenomenon too complicated for brief explanation. It may be that readers of these books are expected to know the elements of electro-dynamics before they study instruments in detail; but in practice, junior students—probationers at a submarine cable station, for instance, who have not much time for theoretical work—will want to understand their instruments without too close a study of Ganot or Deschanel, or without even patient perusal of earlier chapters in electrical text-books. Now, once the beginner realises that a current-traversed coil is practically a magnet, the *rationale* of all deflections becomes to him self-evident.

This suspended coil question is of special interest to the writer of this letter, who in 1887 successfully adopted this device in connection with a cable mirror, and a short account of which he hopes shortly to publish.—Yours, &c.,

Madeira, September, 1890. E. RAYMOND BARKER.

LEGAL INTELLIGENCE.

Watt v. Maxim-Weston Company (Limited)—Maxim-Weston Company (Limited) v. Watt.

On Wednesday morning, before Mr. Justice Vaughan Williams, sitting in the Chancery Division of the High Court of Justice, Mr. E. Morten applied *ex parte* in the above actions, which would shortly come before Mr. Justice North for trial, for an order for the examination of a witness before a special examiner. The actions involved a great many issues, one important thing being to unravel the dealings which had taken place in the shares of the Company at the instance of Mr. Watt, Chairman of the Company. For this purpose it would be necessary to have the evidence of the stockbroker who carried out the transactions on the Stock Exchange for Mr. Watt. Information had been just received that Mr. Barnard, the stockbroker in question, was about to depart for America in search of sport, which was likely to keep him there for the next six months. That being so, it was desired to take the examination early next week. In the case of Bidder *v.* Brydges, the Court had held that such an order would be made where necessary for the purposes of justice.

His Lordship said he was somewhat loth to make the order *ex parte*, but he would do so upon conditions. It was quite plain the examination could not be conducted effectively unless the other side had notice and the opportunity of being present. The order would go, but would contain upon its face the condition that notice should forthwith be given to the other side, and that they should be at liberty to apply to discharge the order.

Woodhouse and Rawson (Limited).

A motion for the removal of the liquidators of this Company, for the appointment of others in their place, and to restrain further dealing with the assets, was also in the list for hearing; but Mr. Baker stated that, by consent, it had been arranged that the motion should be withdrawn from the paper, no order being made upon it. His Lordship acceded to the application.

TRADE NOTES AND NOTICES.

[Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.]

TENDERS WANTED.—The Controller of Stores of the General Post Office invites tenders for the supply of red fir telegraph poles, and also for creosoting the same. Particulars of the conditions of the contract, &c., will be found in our advertisement columns, and forms of tender and all particulars may be obtained of Mr. Chas. E. Stuart, the Controller of Stores, Telegraph-street, E.C. Tenders must be in by noon on Friday, October 31st.

———Tenders are invited by October 15, 1890, for the supply of 5,000 kilogrammes of phosphor or silicium-bronze telegraph wire for the Telegraph Administration of Stockholm and Gothenburg. The diameter of the wire is to be 1·25 mm.; conductivity 30 per cent. of that of pure copper, and the tensile strength 80 kilogrammes per square millimetre. Offers, with price and conditions, are to be marked "Aubud á leverans af fosforeller silicium bronstrad."

TENDERS.—The Corporation of Dublin give notice that the time for receiving tenders for the electric lighting of the Dublin streets, &c., has been extended from the 13th October to 5 p.m. on the 30th October.

———An official intimation reaches us from Stockholm notifying that an error was made in the advertisement referred to in our editorial note of September 19, as to the time when tenders would be received for the erection of the central station at Stockholm.

SALES BY AUCTION.—On Tuesday, October 21st, Messrs. Wheatley Kirk, Price, and Goulty will sell by public auction, at the Drogheda Engineering Works, Drogheda, Ireland, at 10 for 11 o'clock prompt, the extensive premises, plant, fixtures, &c., of the business lately carried on by Messrs. Thomas Grendon and Co. The works are very extensive, and the buildings include substantial and extensive general drawing and private offices; heavy and light iron foundries; boiler and girder shops; turnery, erecting, pattern-making, and other shops; stores, brass foundry, &c. The contents of the Works include numerous overhead, travelling, portable iron and timber jib cranes; timber shear legs; sliding, surfacing, brake, screw-cutting, hand and other lathes; boring, planing, drilling, slotting, shaping, screwing, plate and and angle-bending, punching, shearing and other machines; steam rivetter; new stores; steam hammers; tools and utensils for several hundred hands; office furniture, fittings, and other effects. Included in the sale is also the schooner-rigged iron sailing vessel "Mouse," length 69·6 feet, breadth 16·1 feet, depth of hold 7·05 feet, with a cargo capacity of 75 tons. Further particulars are given in our advertisement columns, and full particulars and plans can be obtained gratis of the Auctioneers, 52, Queen Victoria-street, London, E.C.; and Albert-square, Manchester; or at the Works.

PRICE LIST.—The Electric Construction Corporation have issued a very handsome catalogue of their manufactures, with complete lists of their different types of accumulators, dynamos, transformers, instruments, switches, switchboards, &c. The tables showing the output, number of revolutions, and price of the dynamos are very conveniently arranged, facilitating the selection by offering for any particular output several sizes of dynamos at different speeds.

THE JOHNSON STORAGE BATTERY.—This battery, we are informed, has the active material suspended in a net-work of lead, and is said to have a capacity of 10 ampere hours per pound of element. These batteries are used on the Union Electric Car Company's tramways. A 21-lb. cell is reported to have been tested for two hours and ten minutes' continuous work, including twenty-three minutes' discharge at 100 amperes, the volts dropping from 2·05 to 1·67. A number of these cells were charged in Boston, and have been sent to this country, but it is difficult to see what interest attaches to their discharge in Westminster.

A NEW CUT-OUT.—As a rule we do not care to notice a cut-out of which we have not seen a sample; but the illustration and description of the Champion Cut-out is sufficient to condemn it in our opinion, since it is intended to be hidden away in ordinary wood casing, a most improper position, and makes use of vulcanised fibre, a most unsuitable material.

KOMMANDITGESELLSCHAFT W. LAHMEYER AND CO.—Under this title a company has been formed in Frankfort-on-the-Main, with a capital of 1,200,000 marks, to carry on the business of electrical engineers. The new firm will manufacture the larger dynamos of Messrs. Garbe, Lahmeyer, and Co., of Aachen, with which Company it will act on friendly terms.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

September 17, 1890.

14,666. J. CHARTERS. Glasgow. Improvements in electric switches.

14,679. W. WILKINSON and W. A. SYKES. Halifax. Improvements in electrical alarm apparatus for shops, stores, and other purposes.

14,686. W. R. LAKE. London. Improvements relating to the preparation or treatment of carbons for electric lamps or lighting apparatus (Lacombe and Co., France).

14,693. J. P. BAYLY. London. Galvanic battery (José Siliceo, Mexico).

14,696. J. P. BAYLY. London. Improved telegraphic relay (J. M. Treber, United States).

14,698. R. E. B. CROMPTON and W. A. CHAMEN. London. Improvements in conductors for the distribution of electrical energy, and in apparatus connected therewith.

COMPANIES' MEETINGS & REPORTS.

Woodhouse and Rawson (Limited).

An extraordinary general meeting of the shareholders of this Company was held yesterday afternoon at Worcester House, Walbrook, E.C., and not at 11, Queen Victoria-street, as stated on the notice. The Press were refused admission; but we understand that Sir John Stokes presided, and apologised for the change of the place of meeting, and spoke generally of the labours and troubles and energy of the liquidators. The assets were more favourable than was thought. Liquidation had been delayed by (1) founders (2) by arbitration, and had lasted more than one year instead of three months. No time or labour spared. The liquidation had been pushed on so as to secure the dividend shortly to be announced by the United Company, and it was hoped that the shareholders would now obtain this dividend, which was in respect of working up to June, 1890. Further details he would not go into.

A dissentient shareholder asked what his position was, and wished for more detailed information. He was told that he would get his capital back in cash, and nothing else—no dividend and no interest.

The shareholders are to receive scrip of Woodhouse and Rawson United at par, with 15 per cent. bonus, in the proportion of three ordinary and two Preference shares.

In reply to the demand of a Shareholder, it was promised that a copy of the accountss hould be furnished at the close of the liquidation.

The remuneration for the services to the old Company by Mr. Hoster and Mr. F. L. Rawson were discussed. The latter asked for £12,000, but, after discussion, it was decided to award £10,000.

It will be remembered that in July, 1889, the Woodhouse and Rawson Company, in conjunction with several sub-companies, were consolidated into a new Company, called the Woodhouse and Rawson United (Limited). The profits, which at that time were said to belong to and have been earned by the old Company, amounted to £75,000; and, in spite of this, no dividend whatever was paid for the year 1388-9. The profits having been pledged to the new Company to guarantee a dividend of 15 per cent. on their ordinary shares, the shareholders were promised shares in the new Company equivalent to the shares which they held in the old Company. But since the United Company was formed in July, 1889, the shareholders in the old Company have received no scrip and no dividend of any sort. Dividends at the rate of 15 per cent. have been half-yearly declared in favour of the United Company (possibly out of the guarantee fund belonging to the old Company), but in spite of this not one penny has been paid to the shareholders in the old Company.

The International Okonite Company (Limited).

The statutory general meeting of the members of this Company was held yesterday, at the Cannon-street Hotel, Cannon-street, "for the transaction of the general business of the Company." The chair was taken by Mr. Samuel Pope, Q.C.

The SECRETARY (Mr. P. J. Bordessa) having read the notice convening the meeting,

The CHAIRMAN said: Gentlemen, in the absence of our chairman, Lord Greville, who is in Ireland, it becomes my duty as deputy-chairman to take the chair at this the statutory meeting. You are aware, of course, that the law compels a company to hold a meeting of this sort at all events within four months of the date of its registration. Business at such statutory meetings is generally of the most formal character, because, of course, no report and no balance-sheet is possible in the limited period in which the Directors have had control of the undertaking. But our articles also fix that our first general meeting shall be held within the statutory period of four months; and my colleagues have, therefore, thought it desirable that we should not treat this meeting as of the purely formal character which a statutory meeting ordinarily is; but that we should meet the desire of many of our shareholders, and state exactly what has been done since we came into office, and the prospects which we think the undertaking affords for future development. Now, gentlemen, you know that our capital was originally fixed at the sum of £440,000. It was divided into £170,000 worth of £10 Preference shares, £170,000 worth of £10 Ordinary shares, and £100,000 of £100 Debentures, making a total of £440,000. Of this amount £113,330 was paid to the vendors as vendors' shares and £33,300 of Debentures. That left, as you will see if you work it out, £226,670 of Preference and Ordinary shares as the balance to be allotted to the various applicants. Of that amount of £226,670 the whole has been fully subscribed without a single share having been underwritten. Now of the Debentures, out of £66,700—the balance of the £100,000, deducting the £33,300 to be allotted to the vendors—there has been taken up £51,700, leaving a balance of £15,000, the only balance unallotted of the entire capital, which it is our intention not to allot until we require the money. You may therefore take it that our capital account is summed up in the description that the whole capital has been subscribed for and allotted with the exception of £15,000 of Debentures, which we do not require to allot, and which, it seems to us, it would be folly to allot until we want the money. Our Managing

Digitized by Google

Director and Mr. Connolly, our works manager, have visited the United States since the incorporation of the Company for the purpose of examining into the business, and technical working of the factory at Passaic, New Jersey, and to learn the special processes carried on there for the purpose of erecting similar plant at our Manchester works. The Managing Director has returned, and Mr. Connolly is on his way home. The Managing Director reports—and I believe Mr. Connolly agrees with him—that the works are in first-class order, well organised, admirably arranged, and fully occupied. If the turn-out from the factory for the year 1887 be assumed at the unit 100, then the turn-out in 1888 represented 164, in 1889 244, and for 1890, so far, at the rate of 450, a satisfactory figure. In other words, our investigation has shown that the output at our American works has become four and a-half times what it was in 1887. Now, in addition to the vendors' shares named in the prospectus, the Directors who form the American Committee have subscribed for considerably over £60,000 in shares, paying for them in the ordinary and usual way. The title to the American factory has been fully examined and approved by our solicitors, Messrs. Davies, Short, and Townsend, of New York. The whole of the purchase-money has been paid, and the property in America has been vested in the Central Trust Company of New York as trustees for the Debenture holders. From personal inspection, our managers report that they are satisfied that the business is a sound and lucrative one, with every prospect of a large and continual increase, and that there is an immense advantage in having a factory both in New York and at Manchester. With regard to our Manchester works, the business has been taken over and paid for, and we have since acquired a plot of vacant ground of about one acre, bounded on one side by our own factory, on another by the Rochdale Canal, and on the other two sides by good roads. On this we are at present erecting, and are actively pushing on, an important fireproof factory for the manufacture of our speciality of high-class okonite wires and cables, and the necessary machinery is well in hand. The works are in full swing, manufacturing various classes of insulated wires, and orders are coming in most satisfactorily. Messrs. Shaw and Connolly have agreed to serve the Company for a term of years; and as both these gentlemen have great technical and business knowledge—second to none, I may say—in the manufacture of insulated wire, we have every reason to anticipate that, with the capital at our command, our English business will soon rival, if it does not exceed, our American. Certain statements as to the profits of the year were made in the prospectus which was issued to the shareholders, and some shareholders have questioned the profits for 1889 and 1890 of Messrs. Shaw and Connolly, which were taken as estimated and not ascertained, of the old Okonite Company, these profits not having been ascertained by a competent accountant at the date of the prospectus. We are, however, now in possession of Messrs. Price, Waterhouse, and Company's report; and the statements made of estimated profits in the prospectus are well under the actually ascertained amount. I should, however, say, with respect to the profits of 1890 of the old Company in America, that we have not yet got Messrs. Price and Waterhouse's certificate. We cabled to New York in order that we might have the most recent information as to the progress of the audit, for, of course, we thought it desirable, as soon as we came into possession of the property, that we should ascertain, as far as we could, the actual facts with respect to it. We have received from the New York office, under date of September 26th, a letter in which they say:—"We have not got our books quite closed yet. Approximately, I think the profits will be considerably larger than we claimed they would be on the prospectus." But, as I say, we were anxious to put before you, if we could, not merely a confirmatory statement by the vendors, but the actual result of investigations, and we cabled yesterday for such results. I do not think we have yet received the certificate, but from what our general manager tells us he ascertained there, I think there can be no doubt that both these statements will be abundantly justified by the facts when we come to make them out. I have very little more to say, because, of course, we can have had no great experience in the management of the concern during the short period we have been in office. I think I may say, however, that the view which my colleagues, and which, I am sure, I myself, would desire to see carried out, would be to manage this concern with an eye to make it a substantial commercial undertaking—not with a view merely to create a temporary fictitious value in the shares of the Company, but with the view, if possible, of developing a commercial enterprise in a legitimate and commercial way. Now, during the last three years of the Okonite Company's working they never had returned to them a single yard of okonite wire as being defective in insulation. The whole of the wires are guaranteed to a standard far in excess of working requirements, and are tested fully 100 per cent. over our guarantee before they leave the works. We shall adopt the same system in England, as, although it tends slightly to increase the cost of production, it is so important to have electrical insulated conductors of high-class which can be relied upon with absolute confidence that we feel we cannot make our Okonite wire too good. The scrip certificates have been issued, and application has been made to the Stock Exchange for a special settlement and quotation in their official list; and for this purpose the whole of the necessary papers have been sent into the Committee. Your Directors do not entertain any doubt that in a very short time their request will be complied with, and the shares of the Okonite Company will appear in the official list of the Stock Exchange. That is all I think I can say at this meeting, unless any shareholder desires further information; and if anything occurs to him upon which he would like to put a question, it shall be answered with as much frankness as I hope I have laid this statement before you. He added: As a commencement—or hardly a commencement—but as showing that we are active in our English business, the Managing-Director has put into my hand an order which we have just received for 135,000ft. of Okonite wire from an English firm.

Mr. J. B. FERRIER (Cardiff) expressed his satisfaction with the statement which the Chairman had made. There had been some criticisms in a financial organ, but he did not know that it was of much standing. He had been induced to take his shares in the Company through the connection with it of Lord Aberdare and Mr. Pope.

Mr. W. JOHNSON (York) said that a friend of his had thought it very curious that the six or seven gentlemen whose names appeared to the Memorandum of Association only held one share each.

The CHAIRMAN: I am afraid if your friends had been accustomed to dealing with joint-stock Companies they would know that in every case the Memorandum of Association is signed for one share each, whatever the gentlemen concerned may ultimately take. That is the usual thing.

Mr. JOHNSON asked whether it was legitimate or usual for the remuneration of the Directors to be fixed before the meeting of the shareholders.

The CHAIRMAN: The Directors' remuneration is frequently—generally, in fact—fixed in the Articles of Association.

Mr. JOHNSON said he had been told that it was generally fixed by the shareholders attending the ordinary meeting.

The CHAIRMAN said he did not think that that was the usual course.

A SHAREHOLDER: It is a great deal more often the other way.

The CHAIRMAN: No doubt it is sometimes arranged by a vote of the shareholders, but, generally speaking, especially in Companies like this, which involve a great deal of personal labour, the remuneration is fixed. Otherwise you would not get gentlemen of experience to sacrifice their time. I do not intend to say a word about the financial paper that has been mentioned. I am sure our friends in the country will understand that criticisms are frequently made for the purpose of acquiring notoriety; and I do not intend to contribute to that notoriety in this case. At this particular meeting there can be no resolution submitted, and, therefore, I am anxious, if possible, to encourage shareholders to disburden their minds of anything they may have upon them. If, however, no other gentleman has anything to say, that will necessarily close the proceedings of the statutory meeting; and with your permission we will now resolve ourselves into an extraordinary general meeting.

The SECRETARY read the notice convening this meeting, which was to consider the confirmation of the subjoined resolution, which was passed at the meeting on the 10th ult.:—

"*That the Articles of Association of the Company be altered in manner following:—*

"*(a.) In Clause 35, that the portion of the clause following the words 'provided that' be struck out and the following inserted: 'The funds of the Company shall not be expended in the purchase of or lent upon the security of its own shares.'*

"*(b.) In Clause 72, that the following words be added at the end of the clause: 'And unless he shall do so, he shall be deemed to have agreed to take the said shares from the Company, and the same shall be forthwith allotted to him accordingly.'*

"*(c.) In Clause 116, that the following words be added at the end of the clause: 'And a copy of such balance-sheet shall be posted to each member at his registered address at least eight days before such ordinary general meeting.'*"

The CHAIRMAN: The object of the special resolution is to make certain minor changes in the Articles of Association, which are called for by the Committee of the Stock Exchange; and, of course, it is necessary that we should make our articles conform with their rules and wishes, seeing that we are applicants to them for a quotation in their official list. I will now move the confirmation by this meeting of the resolution which was passed by the extraordinary general meeting referred to in the notice.

Mr. H. H. DOBREE seconded the resolution, which was carried unanimously.

A vote of thanks to the Chairman brought the meeting to a close.

Woodhouse and Rawson United (Limited).

The following is the annual report of the Directors of Woodhouse and Rawson United (Limited), for the year ended 30th June last, to be presented at the general meeting to be held at Winchester House, E.C., to-day (Friday), the 10th instant, at 12 o'clock:—

Of the original capital all the ordinary and Preference shares have now been issued. Of the ordinary shares one-half of their value remains uncalled. The premiums from the second issue, amounting to £4,050. 5s., have been placed to a reserve fund. From the balance-sheet which accompanies the report, it will be seen that after payment of all expenses and writing off £7,421. 16s. 9d. in reduction of the sum standing to patent account, the balance to the credit of the Company amounts to £61,085. 1s. 9d. Out of this sum the Directors propose to pay a dividend at the rate of 15 per cent. per annum on the ordinary shares and of 8 per cent. per annum on the Preference shares, which, together with the interim dividend for the half-year already paid at these rates, amounts to £18,749. 6s. 6d. Of the balance, amounting to £42,335 15s. 3d., the Directors propose to place to reserve £25,000, of which £10,000 will be set aside to a goodwill reserve fund and £15,000 to a general reserve fund, and to apply £1,000 to the formation of an Employés' Pension Fund, leaving £16,335 15s. 3d. to be carried forward to next year's account. The Directors do not propose to increase the dividend anticipated in the prospectus, as the prudence of building up reserve funds ot a considerable amount will be evident to the shareholders.

The Directors think it well on this occasion to give more information than is usually contained in an annual report, in order to enable the shareholders to realise the scope and extent of the operations in which the Company is engaged. Their efforts during the past year have been directed to consolidating and extending the several branches of business which have

Digitized by Google

been taken over by the Company. These are of a very comprehensive character, and include—

1. The manufacture of all articles connected with electricity and engineering, so far as they can come reasonably within the technical and financial resources of the Company.

2. The supply of all articles connected with electricity and electrical engineering.

3. The execution of all works of installation coming within the province of electrical engineers and contractors.

4. The testing and proving of new patents and inventions connected with electrical and engineering science, and their introduction to the public, either by arrangements for working such inventions by this Company, or by assisting the owners in forming separate companies for working them.

The experience of the past year leaves no doubt that great services may be rendered to the shareholders and to the public by developing this latter branch of the business, with prudence and energy; and the knowledge acquired from an extensive range of manufactures, and a thorough acquaintance with the demand and channels of supply of electrical plant and apparatus, place this Company in an exceptional position to invite and secure the confidence of inventors, and to assist them in bringing their inventions before the public. With this object it is necessary to command the ready means of practically testing every kind of electrical and mechanical invention which may be offered, and to maintain an extensive business and correspondence in all parts of the world.

The following are the factories owned by the Company and the character of the work done:—

(*a*) West Kensington Hall Works, Hammersmith-road, W.—These works, over an acre in extent, are the Company's freehold. Here are manufactured light goods, such as switches, lamps, measuring and other electrical instruments, primary and secondary batteries, and every class of small automatic machinery. Here also is carried on the electro-plating business and manufacture of plating plant. At these works most processes offered to the Company are tested, and only when they have thoroughly passed the examination of the Company's experts is the purchase or introduction to the public entertained. At the present moment four important electrical inventions of exceptional merit are undergoing the process of final testing.

(*b*) Union Foundry, Kidsgrove, near Crewe.—These works, which are also freehold, have been recently acquired on advantageous terms, and are well situated in the heart of the coal and iron district, having both a railway sliding and a canal adjoining. They are fitted up with every class of heavy machinery to enable the Company to construct engines and boilers of almost any size or power, water and gasworks, plant, steam and hydraulic cranes, tanks, pumps, large dynamos and other heavy machinery, whilst further special plant is now being erected to keep abreast of recent improvements.

(*c*) Cornbrook Telegraph Works, Manchester.—These works are leasehold, and are fully engaged in the manufacture of telegraphic instruments; there are also manufactured small dynamos and motors, as well as light lathes and drilling, shaping, milling and screwing machines, specially designed for electrical work. Practically the whole of the contracts for telegraphic instruments, &c., for the London and North Western Railway for a period of two years, together with contracts for the Caledonian and Great Eastern Railway Companies, have been placed with the Company at these works.

(*d*) The supply department is rapidly increasing its turnover. Its catalogue of electrical goods and appliances connected therewith is recognised as the most complete and comprehensive of its kind, and forms a standard text-book in the trade. The acquisition of the new warehouse, with entrance at 30, Cannon-street, and more recently of the lease of the neighbouring premises at 34, Cannon-street, and 84, Queen Victoria-street, enables the Company to keep in hand and exhibit an extensive stock of nearly every kind of electrical apparatus and fittings.

(*e*) The Installation Department has carried out a large number of important contracts. Among others, the lighting of the Palace at Mysore, India, by electricity has been satisfactorily and profitably finished; and the Sociedad Española del Electricidad, in Barcelona, has placed the whole of their arrangements for improving and extending the lighting of that city by electricity in the hands of this Company.

(*f*) At Bradford the Company have a branch establishment with showroom and warehouse, which provides for installatiens and the supply of electrical goods in the North of England. The Company has been specially appointed contractors to the local authorities in that town in connection with their central electric lighting station.

(*g*) An electric bell and signalling business is conducted at 2, Gray's Inn-road, under the management of the Messrs. Jensen, whose well-known patents this Company has acquired.

(*h*) The Company has also acquired the electric and steam launch business of Mr. Sargeant, carried on at Chiswick.

Branch offices have been opened during the year in Sydney, Melbourne, Johannesburg, and Valparaiso, besides additional agencies in various other foreign countries.

In the early part of the present year the Directors disposed of a portion of their premises at West Kensington to the Kensington Co-operative Stores, Limited, a new Company, which obtained the support of this Company because it afforded an opportunity of disposing, upon advantageous terms, of a portion of its buildings unsuitable for manufacturing purposes, and increased the value of the remainder of the property. A second issue of shares of the Kensington Stores has lately been made at a large premium, and was applied for two and a-half times over.

The Directors have, in addition, been instrumental in forming the International Okonite Company, for the working throughout the world of the patents for that valuable insulating material. The Company, whose shares have been entirely allotted, has an established business in America of a profitable and rapidly increasing character; and owns works also at Manchester, from which it will supply the Okonite wire required in Great Britain. The yield of both the American and English works during the current year has largely increased, and a profitable return may be looked for.

This report would not be complete without an allusion to the success that has attended the introduction by Woodhouse and Rawson, Limited, of the now well-known Elmore process for manufacturing copper articles by electro-deposition at a great saving of cost, and of unique quality. Since the expiration of the financial year ending on June 30, 1890, this Company has introduced Elmore's French Patent Copper Depositing Company with very marked success; 66,750 shares were offered for subscription, and over 250,000 shares were applied for.

The official quotation of the shares of this Company in the Stock Exchange list is now before the committee. Owing to the delay in the winding-up of the Vendor Companies, mainly caused by the protracted arbitration in which one of them was engaged at the time of purchase, a final settlement with them had not been effected before the close of the first financial year of this Company. These difficulties have since been removed, and the Directors daily expect to have the quotation granted.

The sum of £75,000 which, as stated in the prospectus, Woodhouse & Rawson, Limited, was to lodge with this Company as a guarantee fund for the payment of a minimum dividend of 15 per cent. per annum for the first three years, has been duly received.

The shareholders will doubtless approve of the formation of an Employés' Pension Fund, which will tend to the retention of those employed by the Company, by requiting faithful services when age, failing health, or other causes necessitate their temporary or permanent withdrawal from the Company's employ. The amount proposed to be placed to the credit of this fund, though comparatively small for the purpose intended, will form a nucleus to which, in future, as the Company's success is con-

solidated, larger sums may be allocated. A resolution to give effect to this proposal will be submitted to the meeting.

The Directors feel that the shareholders owe a great deal to the various members of the staff for devoted services rendered, regardless of personal comfort and hours of labour, and especially to the Managing Director, Mr. F. L. Rawson, to whose zeal, enterprise, and judgment the results obtained in this the first year of the Company's operations are mainly due.

By the Articles of Association two Directors retire. The two who retire are Lord Aberdare and Sir Rawson W. Rawson; the latter, being eligible, offers himself for re-election; the former from impaired health and enforced absence from London, does not offer himself for re-election. In his place the Directors propose, with the approval of the shareholders, to elect the Right Hon. Sir Edward Thornton, G.C.B.

The auditors, Messrs. Pixley and Co., retire according to the articles, and offer themselves for re-election.

In conclusion the Directors congratulate the shareholders on the position and prospects of the Company.

NEW COMPANIES REGISTERED.

LEEDS AND LONDON ELECTRICAL ENGINEERING COMPANY (LIMITED).—Registered by Wilson, Bristows, and Carpmael, 1, Copthall-buildings, E.C., with a capital of £100,000 in £5 shares. Object, to form centres in any towns and districts in the United Kingdom or elsewhere, at which electrical energy may be generated and accumulated, and from which the same may be distributed. There shall not be less than three nor more than seven Directors; the first to be appointed by the subscribers to the memorandum of association. Qualification, £500. Remuneration, one-tenth of net profits after 7 per cent. dividend, with the proviso that the same shall not exceed £1,500 divisible.

ELECTRO-METALLURGICAL COMPANY (LIMITED).—Registered by T. H. Philpots, Rolls Chambers, 89, Chancery-lane, with a capital of £2,500 in £5 shares. Object, to acquire the business of the Electro-Metallurgical Company, now carried on at 23, Newhall-hill, Birmingham, and the Victoria Plating Company, carried on at 9 and 10, Sherbourne-road, Balsall-heath, Birmingham. The regulations of Table A mainly apply.

NEW COMPANIES REGISTERED DURING SEPTEMBER.—The following electrical and engineering companies were registered during the month of September:—

	Capital.
Combination Telephone and Electrical Engineering Company (£1 shares)	£20,000
Electrical Inventions (£1 shares)	35,000
Elmore's Austro-Hungarian Patent Copper Depositing Company (£2 shares)	200,000
Elmore's French Patent Copper Depositing Company (£2 shares).	200,000
Freedman Battery Company (£1 shares)	2,000
J. E. H. Gordon (£10 shares)	50,000
Railway Construction and Maintenance Company (£10 shares)	100,000

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY (LIMITED).—The accounts of this Company, subject to audit, show a profit sufficient to enable the Directors to recommend a final dividend of 3s. per share, making, with previous distributions, a total dividend of 6 per cent. for the year ending June 30, 1890; and also admits of the payment of a bonus of 3s. per share, both free of income-tax, which, together, will amount to £39,000, being a distribution in the aggregate of 7½ per cent. for the past year, leaving a balance of £42,416. 18s. 1d., of which amount £40,000 has been placed to the Reserve Fund, increasing that fund to £352,626. 2s. 11d. and £2,416. 18s. 1d. carried forward. For the purpose of paying the above dividend and bonus on the 23rd inst., the register of transfers will be closed from the 14th to the 22nd inst., both days inclusive. The receipts of this Company for the week ended October 3 amounted to £5,323.

CUBA SUBMARINE TELEGRAPH COMPANY.—The estimated traffic receipts of this Company for the month of September were £3,000, as compared with £2,372 in the corresponding month of last year. The receipts for the month of June, estimated at £3,300, realised £3,324.

DIRECT SPANISH TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of September were £2,526, as compared with £2,139 in the corresponding period last year, an increase of £387.

EASTERN TELEGRAPH COMPANY, LIMITED.—This Company announce the payment by warrants on 1st November next of interest for the half-year ending 31st October on their 4 per cent. mortgage debenture stock. The transfer books will be closed from the 28th October to the 1st November, both days inclusive. The traffic receipts of the Company for the month of September, 1890, amounted to £55,346, as against £51,881 for the corresponding period of 1889, or an increase of £3,465.

EASTERN EXTENSION TELEGRAPH COMPANY.—The receipts of this Company for September amounted to £43,938, as against £40,418 in the corresponding period, showing an increase of £3,520.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic returns of this Company are as follows:—Receipts in September, 1890, £25,800; 1st January to 30th September, 1890, £206,800; corresponding months, 1889, £205,200; corresponding months, 1888, £202,600.

REUTER'S TELEGRAM COMPANY.—The Directors of this Company have declared an interim dividend at the rate of 5 per cent. per annum, free of income-tax, for the half-year ended June 30th last, payable on the 11th inst.

STOCK EXCHANGE.—Application has been made to the Committee to allow 4,000 additional shares of Bell's Asbestos Company (Limited) to be quoted in the official list.

TELEPHONE COMPANY OF AUSTRIA.—This Company has declared the usual half yearly dividend to the 30th ult. on the Preference shares at the rate of 6 per cent. per annum, payable, tax free, at an early date.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this Company for the month ending 30th September, 1890, amounted to £5,050.

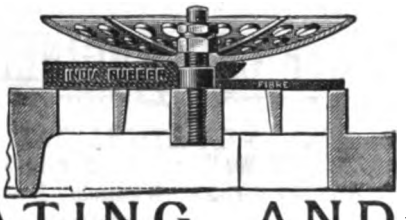
WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The receipts of this Company for the half-month ended September 30th amounted to £2,405, as compared with £2,218 in the corresponding period, an increase of £187.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ending October 3, 1890, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £4,163.

WOODHOUSE AND RAWSON (LIMITED).—An extraordinary general meeting of the shareholders of this Company was held yesterday, at Worcester House, Walbrook, E.C., for the purpose of receiving the liquidators' statement of assets and liabilities of the Company and as to the position of the liquidation, and for the purpose of considering, and, if thought fit, sanctioning certain compromises or arrangements by the liquidators with (1) Woodhouse and Rawson United (Limited), (2) Albert Hoster, one of the liquidators, (3) Frederick Lawrence Rawson, one of the liquidators, and (4) the Schulke Gas Lamp Company (Limited), the particulars of which compromises or arrangements were laid before the meeting; and for the purpose of considering, and, if thought fit, sanctioning the compromise or arrangement by the liquidators with Woodhouse and Rawson United (Limited), on such terms as the liquidators shall consider desirable, of further questions pending between the liquidators and Woodhouse and Rawson United (Limited) with reference to the payment of the sum of £75,000, payable in certain events by the said Woodhouse and Rawson United (Limited), to this Company in the month of July, 1892; and for the purpose of considering, and if thought fit, sanctioning the immediate payment and distribution to and amongst the holders of the ordinary shares of the Company, of the amounts in cash and shares as provided by the arrangement made by the liquidators with the holders of the founders' shares, persuant to the extraordinary resolution passed at the general meeting of the Company held on June 23, 1890, and also for the purpose of reconsidering the question of the remuneration of the liquidators, and, if thought fit, amending the resolution of the extraordinary general meeting of the Company held on September 26, 1889, with reference thereto. Particulars of the meeting will be found in another column.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 26th Sept. 1888.

"DEAR SIRS,—In reply to your letter of the 26th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 648.—Vol. XXV. FRIDAY, OCTOBER 17, 1890. Price Fourpence.

NOTES.

At the Corporation enquiry into the water supply of the Metropolis last Monday it transpired that the number of Acts of Parliament passed, transferring the water supply to local authorities, now numbered over seventy. As illustrating the extent to which these bodies have applied themselves of late years to the superseding of private Corporations, this fact is worth noting.

The laying of mains in the streets of London is a new art. The more serious excavations of the Gas and Water Companies were far more simple to arrange, as there was nobody there before them. For more than one reason the conductors are being put, when possible, under the foot-pavement; but, besides the numerous occasions on which he has to cross the streets, the crowns of the cellars or the structure of the houses frequently compel the engineer to turn into the road, and to explore the labyrinth of pipes below its surface. Being obliged to go to a considerable depth, he comes against the water and other pipes, and rarely does he care to use his powers to divert them. But according to an abstract in the last volume of the *Proceedings* of the Institution of Civil Engineers, it was found necessary to alter the position of the main conduit of the water supply of the town of Hague, and the superintendent of the waterworks resolved to try the bold plan of slewing a length of 273 yards, weighing 65 tons, sideways bodily, without stopping the supply. "No leaks of importance occurred in the lead joints," which speaks highly for the quality of the original work, but will hardly encourage electrical contractors to repeat the operation when they find the proposed route of their conduits impeded by a water-main.

In the September number of the *Philosophical Magazine* will be found a remarkable Paper by Prof. Langley, entitled "The Cheapest Form of Light." The important question whether it is possible to produce illumination with less waste of energy in mere heat than is now the case by electrical or any other means, is discussed with especial reference to phenomena of phosphorescence; since it is by the study of the latter that economy in future lighting will most likely be brought about. The light produced by the glow-worm does not appear to be indissolubly connected with the life of the organism. It persists after death, is stimulated by oxygen, and is extinguished in a vacuum or in an atmosphere such as carbonic acid gas. It is apparently the result of slow combustion; and there is nothing to forbid the hope that it may be ultimately possible to reproduce this kind of light on a large scale by purely material means. The result of photometric measurements is to show that the radiation of the glow-worm is much more confined to the luminous part of the spectrum than is the case with solar radiation or any other known source of light; and hence it has always been assumed that much less heat is needed for its production than in any other case. The truth of this assumption has never been established by actual thermal measurements, owing to the extreme delicacy of the apparatus required. Prof. Langley has, however, with the aid of the bolometer, been enabled to establish the fact beyond a doubt, and has shown that the insect's light is accompanied by less than one four-hundredth part of the heat given out by an equal amount of gas light.

Some idea of the smallness of the quantities measured is conveyed by the statement that the heat given off from the glow-worm per second, exclusive of mere animal heat, was less than one millionth part of a gramme degree, and the portion of this falling on the bolometer in one second was not enough to raise an ordinary mercurial thermometer one millionth part of a degree centigrade. The most important measurements made are shown graphically in certain curves, which we are able to reproduce in this issue; and practically the investigation shows that the light of the fire-fly is produced at the expense of one four-hundredth part of the energy of an equal amount of gas light, and at the cost of a small fraction of the energy of an electric light of similar power.

It is somewhat surprising to find that the Edison General Electric Company of the United States are putting forward as a new invention a mode of winding drum armatures under the name of the Edison-Eickmeyer system. The paragraph announcing it in the American papers says that all the tramway companies are using Siemens armatures with the old winding, in which the wires cross at the ends and become heaped up in a cone. The "half round and under" method was well known in this country before the Siemens patent ran out, and a system ascribed to Crompton and Swinburne is clearly shown in the second edition of Prof. S. P. Thompson's "Dynamo-Electric Machinery." There are several different ways of preventing the heaping-up, which is never to be found in a good modern drum armature; and there are several arrangements for avoiding the crossing which constantly led to short-circuits, and which was always troublesome to repair.

THE somewhat lengthy Paper which has been presented to the Royal Scottish Society of Arts, "On the Telpher and Electric Railways of the Edinburgh Exhibition," is not calculated to assist the development of electric traction to the extent that its authors desire. Not long ago we were informed that the series system was far and away the best and most economical. The Northfleet line was to be the first specimen, and the tramway companies would find that it was what they had all been waiting for. But in this Paper the Northfleet line is dismissed in six and a-half lines, without even a word to say that it is working well. A long account is given of the Telpher system at Eastpool, Cornwall, and of the ingenious devices which are necessary in the construction of both line and locomotive. The originator, unfortunately, did not live to see it beyond the toy stage, and it is difficult to say what advances have since been made. The centrifugal governor of Prof. FLEEMING JENKIN, which cuts off the current when the train goes too fast, is still retained; but why it should survive in this application, when the knowledge of governing motors has advanced so much, we are not told.

THE great feature of the flexible line is still prominent, but it appears that a good many special arrangements are needed to make it efficient. The end over which the loaded train runs is strained with a weight of six tons, and the side which carries the light one is kept taut by four tons hung on to the end. The sags per span are four feet and five feet on the light and loaded lines respectively; and "the locomotives are so spaced that one locomotive is always descending a sag, whilst the other locomotive is ascending a sag." The advantages of this system, hampered as it is by so many subsidiary details, are not so apparent as one might wish; but we hope that in practice it will work well, and permit of some simplification.

WITH no less than three distinct systems of traction in hand, the Electrical Engineering Corporation appear to be very sanguine of the rapid advance of that branch of electrical engineering in this country. But it does not seem that their arguments will help the cause when they inform us that "the large mileage thus being worked in America enables us to form a judgment beyond question as to the cost of operating electrical tramways from fixed conductors either overhead or underground, and we may take the figure of 3d. per car mile as the total amount for traction." Now, we do not doubt that this 3d. per mile will be shown before long on the balance-sheet of some carefully planned and well engineered undertaking; but to take American prices as an argument for this purpose is as rash as to propose to start a Shoe-blacking Company, on the strength of the fact that half-a-dollar is commonly charged in New York for this service.

THE authors of this paper do not hesitate to describe a fourth system in addition to those they have taken under their protection; but in stating that "the method with conductors suspended overhead is the method adopted by an overwhelming large percentage of the electrical tramways in existence," they will not convince our countrymen that such conductors are not objectionable, even when "the City of Boston, supposed to be one of the finest, architecturally, in the United States, is being fitted up with overhead conductors." As a matter of fact objections have been raised there; but why use arguments based on practice in America, when in that country railways run through and across the streets of crowded cities, and neither bells nor cow-catchers prevent numberless accidents? It is certain that most of the present tramway companies and many investors who will some day equip new lines, are only waiting to see electric traction in a satisfactory form and at a fair cost. If the Electric Engineering Company would work towards this end, instead of expending its energies in providing attractions for an unnecessary and unappreciated Exhibition, the result would be more speedily attained.

THE number of different sets of rules for wiring is almost as great as the number of different sources from which they have emanated. We have in this country the fire insurance offices, the Institution of Electrical Engineers, the supply companies, the Board of Trade, and the inventor. Those of the first are too vague; the second too academical; the third relate to the tests that will be applied, rather than the manner in which the work is to be done; the fourth is not much concerned with anything short of an earth on the consumer's side of the terminals; the last merely describes his own system. The municipal authorities of Hanover have issued a very elaborate set of rules in connection with the extensive supply system with which they are providing that City. We have a similar case, on a much smaller scale, at Bradford, whose Corporation have issued a brief set of regulations. The abstract, which will be found in another column, of the Hanover rules, exhibits a paternal interest on the part of the authorities, and they will probably fail to meet Mr. Wilson Hartnell's approval in the matter of current density; but several of the points are worth the consideration of those who desire one standard set of rules.

WE learn that the contract for the erection of the municipal central lighting station at Copenhagen, for which several English firms were tendering, has been obtained by Siemens and Halske, of Berlin. Prof. Jurgensen is connected with the undertaking.

Paisley.—The Town Council have agreed to apply for an electric lighting Provisional Order.

Telegrams for Guatemala.—We are informed that telegraphic communication with Guatemala has been restored.

Newcastle.—At the last meeting of the Town Council it was resolved to introduce the electric light into the Public Free Library at a cost of £600.

Monmouth.—At the last meeting of the Town Council it was decided, after hearing the report of a deputation who had visited Fareham, to light the borough with electricity.

University College of North Wales.—The bequest to the University College of North Wales, under the will of Dr. Evan Thomas, of Manchester, is officially announced to be £39,500.

The Spanish-African Cables.—*The Gaceta Oficial* will publish this week the new conditions in connection with the tenders for the laying of cables between Spain and her African possessions.

Birmingham.—The driver of one of the accumulator cars on the Bristol-road line last week, lost control of it while descending an incline, but the car was ultimately pulled up before any mishap occurred.

Digitized by Google

The Channel Telephone Cable.—We understand that Messrs. Siemens Bros. and Co. have secured the contract for manufacturing the 4-cored cable to be used for telephoning across the Channel.

Lyric Theatre.—We understand that Mr. Horace Ledger has contracted with the St. James and Pall Mall Electric Light Company (Limited) for the supply of all the current required for lighting the Lyric Theatre.

Lewes.—At the adjourned public meeting of the Lewes ratepayers, held to consider the lighting question, it was resolved to ask the Corporation to make inquiries with regard to electric lighting and to take a poll of the town.

Nelson.—The Local Board have decided to lay down an electric light installation for 600 lights. Already shopkeepers have applied for 200 lights, and no difficulty is expected in obtaining applications for the remainder.

Copenhagen.—A new College of Engineering was opened at Copenhagen on 1st September with much ceremony. The old College, erected some sixty years ago, had for its first Director Hans Christian Orsted. The Director of the new College is Prof. Julius Thomsen.

Newington Vestry.—At the last meeting of this Vestry a letter was received from the London Electric Supply Corporation, stating their intention to commence the laying of electrical mains in Blackman-street, Newington-causeway, Newington-butts, and the Walworth-road.

Board of Trade Rules.—We are indebted to the Electric Department of the Board of Trade for a copy of the Regulations for supply under the Order of the Metropolitan Electric Supply Company (West London). These rules are verbally identical with those made under the Notting-hill Order, which we published on August 29th (p. 466).

Fiume.—The Town Council has granted a concession to the international Elektricitäts Gesellschaft of Vienna, to erect a central light and power station. In addition to the lighting of the harbour and railway station, electric power will be used for the working of elevators, and perhaps also for a railway one mile long, uniting the two ends of the town.

Action against a Labour Union.—Some employers in the Connellsville (U.S.A.) coke region have brought an action against their ex-employés and the officials of the local branch of the Knights of Labour for an alleged breach of agreement. Damages to the amount of £20,000 are demanded. It will be interesting to see what the Law Courts will make of this matter.

New Books.—Amongst the new books announced by Messrs. Crosby Lockwood and Sons are "The Mechanical Engineers' Office Book for Machine and Boiler Construction," by Nelson Foley; "The Analysis and Valuation of Fuel," by H. J. Phillips; "Asbestos, its Properties, Occurrence, and Uses," by R. H. Jones; "Electric Light: its Production and Use," by J. W. Urquhart. Fourth edition. Revised and extended.

SS. "Silvertown."—Some members of the technical Press and a small party of friends were entertained at luncheon on board the India-Rubber, Gutta-Percha and Telegraph Works Company's cable ship "Silvertown" on Friday last. The ship lay off Greenhithe, and was about to start for South America to lay the Lima-Valparaiso cable of the Central and South American Telegraph Company. The "Silvertown" is expected to be away on this expedition for about six months.

The Electric Light in the Meuse Forts.—A committee, appointed by the Belgian Ministry of War, has been making trials at the works of the "Société de la Meuse," with the new armoured electric light towers, designed for the forts along the Meuse. These are steel turrets, intended as a protection to the projectors and the men in charge of them. The light is furnished by a very powerful self-focussing arc lamp, the current for which is obtained from a dynamo driven by a gas engine.

Cable Extensions in the West Indies.—The Compagnie Française des Télégraphes Sous-Marins are pushing forward the completion of the network of cables connecting French Guiana with Brazil on the one hand, and with the West Indies and North America on the other. The Martinique-Paramaribo section, 660 miles in length, is about to be shipped, and will be laid before the end of the year. This cable has been manufactured by the Société Générale des Téléphones at their Bezons works.

Institution of Mechanical Engineers.—The ordinary general meeting of this Institution will be held on Wednesday evening, 29th October, and Thursday evening, 30th October, at 25, Great George-street, Westminster. The following Papers will be read and discussed, as far as time permits:—"On Tube-Frame Goods-Waggons of Light Weight and Large Capacity, and their Effect upon the Working Expenses of Railways," by Mr. M. R. Jefferds; "On Milling Cutters," by Mr. George Addy; "On the Mechanical Treatment of Moulding Sand," by Mr. Walter Bagshaw.

The London Electric Supply Corporation Mains.—Major C. B. Waller, the manager and secretary of the London Electric Supply Corporation, was summoned by the Vestry of St. George the Martyr, Southwark, for cutting away and taking out part of a sewer in Union-street, Borough, for the purpose of laying electric lighting mains without first having obtained the permission of the Vestry. For the defendants it was urged that the Vestry had no power to interfere; and in the end the summons was adjourned, to give both parties an opportunity of referring the matter to the Board of Trade.

Edinburgh Exhibition.—The Royal Scottish Society of Arts held a Special Session at the Exhibition on October 13th, under the presidency of Lord Kingsburgh. Five Papers were read, three of which were electrical, viz., "On the Telegraphic Exhibits," by Prof. Grant-Ogilvie; "Telepherage and Electric Railways," by Mr. E. Manville; and "Electrical Navigation," by Mr. A. R. Bennett. There was a large attendance of members. The members afterwards took trips on the telpherway and electric tramway and in the electric launches; and a special vote of thanks was accorded to Mr. Bennett, to whose invitation the meeting had been due.

Personal.—Mr. Oddie, of Ballarat (Australia), who was recently in this country, before leaving England commissioned Mr. Goodwyn Lewis to paint a portrait of Mr. Thomas Parker, with whom he had become acquainted. This picture is intended to be fixed in the Ballarat Art Gallery as a present from Mr. Oddie to the town of Ballarat. It will be exhibited in Wolverhampton shortly.——Mr. Oswald Haes, who is an old student of the Finsbury Technical College, and has been on the engineering staff of the Brush Electrical Engineering Company and its predecessor for three years, has been appointed to the management of the engineering department of the Company's branch in Australia, and is about to proceed to Sydney, New South Wales, to take up his position.

Alloys for Fuses.—The following proportions for fusible alloys may be of interest—they are due to Weisbach, and have been used in actual practice:—

Lead.	Tin.	Bismuth.	Melting points in degrees Centigrade.
1	1	4	93·8
5	3	8	94·4
2	3	5	94·4
1	4	5	118·8
1	4	1	125·0
1	1	1	241·1
1	2	1	167·7
1	3	1	167·7
1	3	1	200·0

Leamington.—At a meeting of the Town Council on Monday the report of the Watch and Lighting Committee was read, showing that tests had been made from time to time of the electric light; and of the lamps tested the registered illuminating power ranged from 10·2 candles to 14·5, the illuminating power specified in the contract being 16 candles. A discussion ensued, in the course of which it was stated that the light was most unsatisfactory. Mr. C. Davies proposed that the Town Clerk should be requested to consider whether the Electric

Digitized by Google

Light and Power Company could be required to recoup the Corporation in respect of the past payments to the Company having been made on the basis of the supply of a 16-candle power light, which had not been supplied. The motion was adopted.

Ninove (Belgium).—The township of Ninove has entered into a thirty years' contract with a Brussels electric lighting company, and its streets were lit up for the first time by electricity on October 1st. The plant consists of two 16·8 kilowatt Siemens dynamos and a battery of Tudor accumulators. The wires, which are of bronze, are run overhead, and the radius of supply is more than 800 metres on either side of the central station. The public lighting is carried out with 120 25 candle-power lamps. A portion of the street lamps are automatically switched off at midnight, and during the winter automatically switched on again at six in the morning to light the streets for the factory hands. The charge for private consumers is nine centimes per 100 watts-hours (9d. per Board of Trade unit). The price of gas at Ninove is at present 18 centimes per cubic metre (4s. 6d. per thousand cubic feet).

Radial Axles for Tram-Cars.—The additional power required to propel a tram-car round a curve was not appreciated until electric traction became common. It has been found on the Boston lines that the current will go up five or ten amperes when the car rounds a curve. To avoid this loss, cars have been built with three axles and six wheels, two of the axles carrying motors and four of the wheels being drivers. The driving axles are on bogies turning on pivots; the third axle is on a bogie which can slide sideways under the car. The same principle has been tried on the Indian railways, but without very good results. The dimensions of the car are as follows:—Length over all, 36ft. 4in.; length of body, 28ft.; wheel base, 15ft.; seating capacity, 42 passengers; carrying capacity, including standing room, 150. These cars have been running satisfactorily for several months.

Localisation of a Fault in an Electric Light Circuit.—In a recent number of *La Lumière Electrique* M. Henri Wilbrant states that he was lately able to localise a fault in an underground electric light circuit to within five metres (the total length of the circuit being 900 metres) by the following method. He looped together the lead and return at both ends, and connected a battery, one pole of which was to earth, to one junction. In each lead an ammeter was inserted. If C_1 = current flowing to the earth along one branch of the circuit, and C_2 = current flowing to the earth along the other branch x; and if L = the total length of the looped cable, we have $\frac{C_1}{C_2} = \frac{x}{L-x}$ or $x = \frac{C_1 L}{C_1 + C_2}$. The two cables must, of course, be identical and of the same resistance per unit length throughout, in order that their lengths may be taken as proportional to their resistances.

Obituary.—We regret to have to announce the death of Dr. Emil Stöhrer, whose name has been connected with several most important improvements in telegraphy. Dr. Stöhrer died at Dresden, after a prolonged illness, on the 25th of August. Born in 1812, he was the son of a surgeon in Delitzsch, and in 1842 set up a small mechanical workshop in Leipsic. In 1844 he first tried to use his improved magneto-electric machine for telegraphic purposes, and two years later he succeeded in getting a Government order for two of these machines for use with the double-needle instrument on the Bremen-Bremerhaven line, and in 1847 two of these instruments were installed in the Imperial telegraph office in Vienna. His magneto-electric dial telegraphs were adopted in 1846 for Bremen-Bremerhafen, in 1847 for the railway service between Leipsic and Altenburg, and in 1850 on the railways of the Bavarian Government. During his last years Dr. Stöhrer devoted himself chiefly to medical electricity.

Electric Traction in Canada.—From the number of applications for charters in Ontario and Canada generally for power to operate railroads in which electricity is mentioned as the motive power, it is very evident, says the *Electrical, Mechanical, and Milling News* of Toronto, that there is to be a boom in the electric motor business in this country. Considerable interest will attach to the starting of the electric road in North Toronto, which is expected to take place in a few weeks. The conditions under which it will operate will be about as difficult as are to be found anywhere—pretty stiff gradients, a road-bed, while good enough for single horse cars, scarcely of sufficient solidity for heavy traffic and considerable loads on special occasions. Negotiations are also all but completed for a complete system of electric street railway in the City of Ottawa, where it is expected the availability of water-power will make it a very satisfactory investment. Round Toronto also there are several roads talked of, such as between Mimico and the terminus in Parkdale, and West Toronto Junction to the City; so that, on the whole, considerable activity may be looked forward to in the near future in this field.

Electric Motors for Street Railway Purposes.—In a Paper read before the New York Street Railway Association at Rochester, the President of the Albany Street Railway was very emphatic in his remarks on the electric motor:—"Over four months' experience has taught us that the electric motor is efficient and reliable, though we have yet to learn, by experience, that it will ascend an 8 per cent. grade at the rate of five miles per hour in winter, as it has during the summer. How the motor is to be arranged with reference to the car body so as to admit of easy access to it for examination and repair must be left to mechanical and electrical engineers. That we will continue to drag them in the dust and mud very long I cannot believe. I think the opinion of all who are unprejudiced is that the overhead single trolley under contact systems are the most reliable and efficient. The question as to whether the electric motor is as economical as the horse car cannot yet be answered, and need not be answered. Just as certainly as the horse car supplanted the omnibus, the electric motor will supplant the horse car. The horse car, however economical, must go; and the electric motor, no matter how expensive, must come."

City and Guilds of London Central Institution.—More than 100 candidates entered at the end of September for the Matriculation examination at the City and Guilds Central Institution, and of these 60 passed, and 16 did sufficiently well to be allowed to enter the College as unmatriculated students. In addition to the regular students in their second and third years, and the 76 above referred to, who are admitted to attend courses in *all* the four departments of Mathematics and Mechanics, Engineering, Physics, and Chemistry, some 20 special students have entered for portions of the advanced courses in one or more of these departments. On the result of the entrance examination the Clothworkers' scholarship of £60 a year, with free education, tenable for two years and renewable for a third, was gained by C. E. Stamp from St. Paul's School, and the three Institutes' scholarships, each of sufficient value to cover the student's fees for three years at the Central Institution, were gained by G. H. Baillie from Winchester House School, C. V. Drysdale from the Finsbury Technical College, and A. A. Sonneborn from Tottenham College. At the end of last session the John Samuel scholarship, granted to a meritorious student of the Central Institution at the close of his second year's course, and consisting of £30 and free education for the third year, was awarded to C. W. Clinton; the Siemens medal, given to the student of greatest merit in the department of Electrical Engineering, was taken by R. Wightman.

The New Standard Edison Electrolytic Meter.—At the Minneapolis meeting of the Edison Illuminating Companies, Mr. A. E. Kennelly stated that since the last meeting of the Association the new and improved pattern of the Edison meter had been decided upon, and had already been introduced into two stations (Brooklyn and Winnipeg); and the reports upon its behaviour in each case were excellent. There are four standard sizes. They are numbered 1, 2, 4, and 8, respectively; designed to supply 40, 80, 160, and 320 lamps. In all sizes, the bottles, plates, and spools are alike, making the resistance of the bottle circuit the same in every meter. In the smallest meter each milligram of weight transferred represents one ampere hour of supply, and the transfer is 10 milligrammes per hour on full load. Similarly every meter transfers 10 milligrammes per hour at full load, so that each milligramme of transfer in a No. 8 meter represents eight ampere hours, and in a No. 4 meter

Digitized by Google

four ampere hours, the number of the meter being the index of the supply in each case. A cause of discrepancy in the electrolytic meter has always existed in a slight gain of the plates in weight independently of the current's action and due to their oxidation superficially. With the old meters it increased with the size of the meter, since a larger plate offered a larger surface of oxidization. In the new pattern it is a fixed amount in all sizes, and owing to the small area of plate is in any case very small. Another improvement is in the plates. These are castings of pure zinc alloyed with 2 per cent. by weight of pure mercury. The only other noteworthy change has been in the solution, which is about twice as dense as in the old bottles.

The Wheless System of Electric Traction.—The overhead system of electric traction, judging by recent statements in the American technical journals, is not altogether admired, even in the United States; and electric traction engineers in that country are beginning to encounter, though, of course, in a modified form, that strenuous opposition to trolley-wires, &c., which makes such a system out of the question for the majority of English towns. Thus, at Washington, D.C., by a recent enactment of the local legislature, it has been decided that there shall be no resort to the overhead system. If electricity is to be employed, it must be in some other way than that; and the legislation has been made absolutely prohibitive. This prohibition is the more noteworthy since, in the Eckington and Soldiers' Home line, Washington possesses an example of the overhead system, which is as close an approximation to the ornamental as could be expected. One result of this enactment has been a trial of the Wheless conduit system, which was briefly described in *The Electrician* of November 29, 1889. Mr. Wheless' system has, however, been completely transformed since that date. As then described it was a closed-conduit series system; as now described in *The Electrical Engineer* of New York, it is a combined open and closed conduit system. A well-insulated main cable is buried by the side of the track, and the current is automatically switched into successive sections of a bare conductor placed in the conduit. This switching is effected as the car moves along by means of electro-magnets energised by a couple of storage cells on the car.

The Elmira (N.Y.) Electric Railway.—On July 30th the Elmira and Horseheads Railway Company, says the *Electrical Engineer* of New York, placed a contract with the Edison Company for the equipment of about 1½ miles of track, six motor cars, and a full station equipment. At the same time, a contract was placed with the John Stephenson Car Company for six new cars. The contracts were made, in both cases, with the strong guarantee that the roads should go into operation on September 1st. On August 15th the Stephenson Company announced that its cars were ready for equipment, and at about the same time the motors were shipped from the Schenectady Works. The strike on the New York Central Railway at this time bid fair to cause serious delay, as the cars were to be equipped in New York. However, the motors were sent to the cars by a roundabout route, and on August 20th the completed cars began to go out from the Stephenson factory at the rate of two per day. At 12 a.m. on August 23rd the street construction work commenced. Provision for the dynamos and appliances had been made by engaging a part of the Westinghouse station. On August 31st notice was sent to the railway company that the road would begin operation on the following morning, and at 6 a.m. on September 1st the road carried its first passengers. For the first few days the strains on the new machinery were excessive, the cars frequently having to carry two loaded trailers, and to remain in service from early morning until late at night. The number of passengers carried by these electric cars, with their complement of trail cars, in a day, was over 25,000.

Institution of Civil Engineers.—We have received from the Secretary of this Institution a copy of the current list of subjects upon which, among others, original communications are invited. The following are the subjects likely to be of interest to our readers:—The lighting of railway carriages by oil, gas and electricity compared; electrical traction for roads and railways; the design and arrangement of electric supply stations, and of electric distributing apparatus, for domestic, trade and general service in towns, particularly as to economy and safety; the comparative advantages of gas and electricity for lighting purposes; the application of electricity to bleaching; recent researches into the molecular properties of steel; the production of aluminium and its alloys, and their use for engineering purposes; electric mining machinery for pumping, hauling, and coal cutting in mines and collieries; the application of electricity to smelting and metallurgical operations; the electro-deposition of copper; the laying out of engineering workshops; the comparative merits of triple and quadruple expansion engines; friction at different velocities, and the comparative value of different lubricants; the utilisation and distribution of water power; windmills for raising water for general power purposes; liquid fuel motors, and their applications; the cost of the production and distribution of electrical energy; the distribution and application of electric power in towns; electrical measuring instruments, such as ammeters, voltmeters, power-meters, and supply-meters. This list is to be taken merely as suggestive, and not in any sense as exhaustive. For approved Papers the Council of the Institution has the power to award premiums, arising out of special funds bequeathed for the purpose, the particulars of the more important of which are as follows:—The Telford fund, this bequest produces £260 annually; the Miller fund, bequeathed for the purpose of forming a fund for providing premiums or prizes for the students of the Institution, this fund realises £150 per annum.

Engineering Ignorance.—In a recent article in the *American Machinist* Mr. W. K. Stevens discourses on the ignorance of engineers. In the acquirement of learning, he remarks, one of the first and most important steps is to discover how vastly ignorant we are. In engineering the world is now taking that step. In quite recent years we were contented with certain engineering rules and formulæ, if they were laid down by high authorities. Now, however, we are beginning to doubt the accuracy of the old authorities, and our confidence is extremely limited in the newer ones. Concerning iron and steel, how little is really known! Why should cast iron vary all the way from 12,000lb. to 45,000lb. tensile strength per square inch? In wrought iron and steel constructions, how shall we determine the best factor of safety? Who knows whether high carbon or low carbon steel is best adapted to resist repeated strains without crystallisation? Is there really any such thing as crystallisation of iron or steel? In the steam engine, is a steam jacket of any value? What is the amount of cylinder condensation with different types of engine, and with different points of cut-off? What is the most economical ratio of expansion for different classes of engines? If large engines have developed a horse-power with 13lb. of steam per hour, why is it necessary to use from two to four times that amount in small engines? In the use of bituminous coal, who knows how to obtain the maximum economy from different qualities? To remove ignorance and contribute to the advancement of real knowledge, we require careful scientific experiments and prompt publication of results. But there is already too much publication of crude observations. It were better if publication could be deferred until at least a year after making the observations. In fact, the increasing bulk of engineering publications is becoming a burden rather than a benefit. Each of the technical societies publishes a yearly volume, which tends to grow larger; and the number of such societies is steadily increasing. The scientific colleges publish monthly or quarterly magazines, and the technical and trade journals and the book-makers are doing their share to swell the bulk of matter which engineers are expected to read. But, out of all this vast mass, how little is there which really is a contribution to knowledge! Even in the "Transactions" of our technical societies, how few papers appear which have any permanent value! The great reason why the engineering profession is still so ignorant of facts and data in its own science is, that these facts and data are not easily obtainable in a shape which renders them valuable for comparison and permanent record. The immediate need of the profession in this matter is not more schools, more books, more society papers, but more experiment.

MAGNETISM IN IRON AND OTHER METALS.*—XXXIII.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 636.*)

§ 120. **Effects of Stress: Introductory.**—No part of our subject is more interesting than that which deals with the effects of mechanical stress in altering the susceptibility, the retentiveness, and other qualities of the three magnetic metals. The matter is not, at least as yet, one of practical moment, for it has at present no direct bearing on any of the applications of magnetism; but its importance on the theoretical side is not easily overrated. The effects of stress form a fascinating subject of inquiry to the physical student, and are likely to play a considerable part in revealing the molecular structure which makes magnetisation possible. The subject is a large one, and the results that have been already obtained are too intricate to permit more than a very general account of them to be given here. It will be most convenient to state the salient facts, without much regard to the historical order of their discovery. The first inquirer in this field appears to have been Matteucci,† who noticed an increase of magnetism in a magnetised iron bar when the bar was pulled lengthwise. Villari ‡ made the important discovery that the character of this effect was liable to be reversed if the bar was sufficiently strongly magnetised: let the iron bar be weakly magnetised, and the effect of pull is to increase the magnetism; but let the bar be strongly magnetised, and the effect of pull is to reduce the magnetism. This "Villari reversal" (as it is now called) of the magnetic effects of stress in iron was rediscovered by Sir W. Thomson in the course of an inquiry which may be said to have laid the foundation of exact knowledge in this subject.‖ Thomson studied the effect of longitudinal stress by loading and unloading iron wire and steel wire in magnetic fields of various strengths; he extended the same method of investigation to nickel and cobalt. He found by experiment with a steel gun-barrel under hydraulic pressure that the effects of transverse stress were opposite in kind to those of longitudinal stress. Comparing the results of longitudinal and transverse pull, he pointed out that the effect of a simple pulling or pushing stress was to develop a difference of magnetic susceptibility in directions lying along and across the line of pull or push; and he applied this consideration to the case of torsional strain, deducing results which were verified by experiment, and discussing earlier experiments by Wiedemann, who, it may be added, has made the relations of torsion and magnetisation the subject of much detailed study.* The work of Thomson has been followed up and extended by others, particularly in the direction of investigating the forms which the magnetisation curve (the curve of I and H) assumes when the piece under test is subjected to various kinds and degrees of stress; and also of investigating, by continuous magnetometric observations, the manner in which a loaded piece gradually acquires or loses magnetism when the loads are varied, a constant magnetising force being kept in action. The effects of hysteresis, which present themselves at every turn in experiments on this subject, do much to complicate the results: and it is only by following both methods of inquiry—that is to say, by examining the consequences of changing the magnetic force while the state of stress is kept constant, and also those of changing the stress while the magnetic force is kept constant—that we can obtain a tolerably clear connected view of the phenomena.

§ 121. **Effects of Longitudinal Pull on the Susceptibility and Retentiveness of Nickel.**—It is most convenient to begin with nickel for the two reasons that the effects of stress are —for the most part—much greater in it than in the other metals, and are also simpler in one very material respect. There is nothing in nickel that corresponds to the Villari reversal in iron. If we apply pull to a magnetised rod or wire of nickel, we find—as Thomson first showed†—that pull diminishes the magnetism, and relaxation of pull increases the magnetism; and this effect is still observed, however strongly the piece be magnetised.

If we magnetise nickel while it is kept in a state of longitudinal tension by means of a constant load, we find an enormous reduction in its susceptibility. This is well shown by the curves of Fig. 95, which show the magnetisation of a long piece of annealed nickel wire under various amounts of longitudinal pull.‡ The wire was 0·068cm. in diameter, and 374 diameter long; its section was 0·363 sq. mm., so that each kilogramme of load produced a stress of 2·75 kilogrammes per sq. mm. The curves drawn in full lines show the relation of I to H when there was no load, and also when the load was

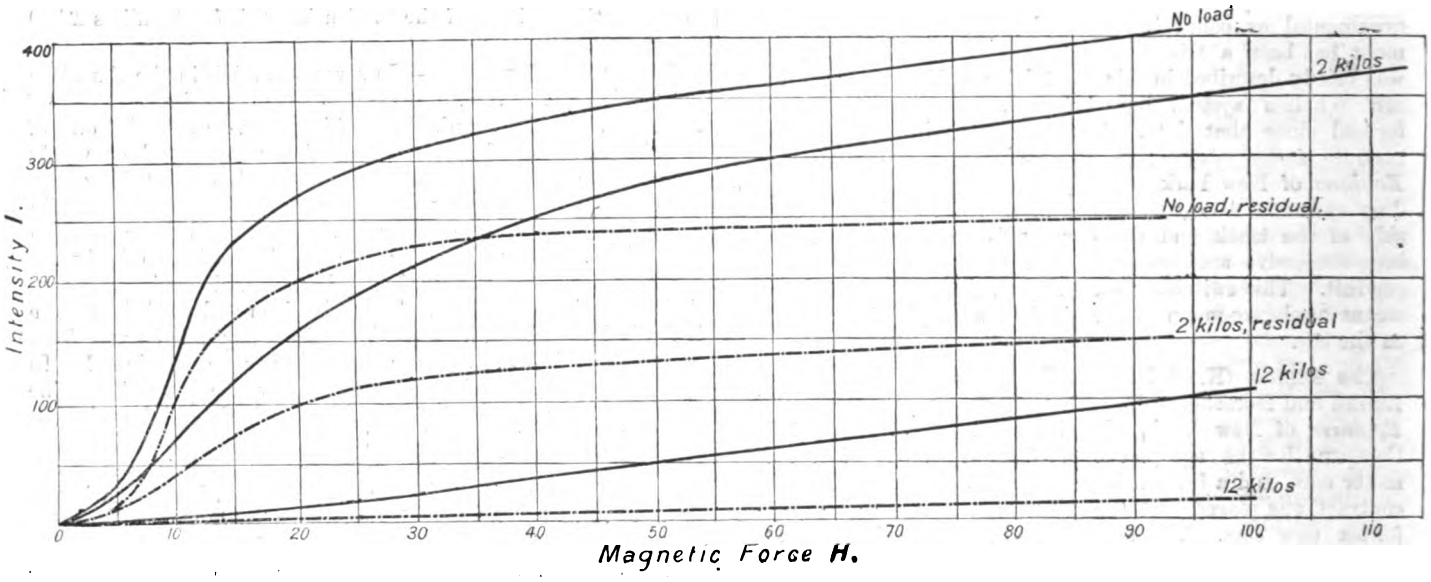

FIG. 95.—Magnetisation of annealed Nickel Wire under various amounts of longitudinal pull.

‡ This and a number of the succeeding figures are taken from the Paper on the "Magnetic Qualities of Nickel" (*Phil. Trans.*, 1888, pp. 325 and 333), in one of which the author had the collaboration of Mr. G. C. Cowan.

Digitized by Google

2 and 12 kilogrammes, corresponding to 5·5 and 33 kilos per sq. mm. respectively. The effect of tensile stress in depressing the magnetisation curve is very marked. With no load the maximum susceptibility is fully 15, with 2 kilos it is only about 8, and with 12 kilos the resistance to magnetisation has become so great that the maximum of susceptibility has not been reached even by raising H to 100 C.-G.-S.

Great as the effects of stress are upon the magnetic susceptibility, they are even greater on the retentiveness. In the same figure (95), three curves shown have been drawn in broken lines, thus: — - — - —, to show the residual magnetism that was found on withdrawing H at each of a series of stages during the process of magnetising under each load. The presence of load reduces the residual magnetism even more than it reduces the total induced magnetism. The residual value of I, after applying a force, H, of 100, is nearly 300 when there is no stress; under 2 kilos, it is only reduced to 150; and under 12 kilos it is only 16. The proportion of residual to total induced magnetism has a maximum of 0·76 under no load; but under 2 kilos it is reduced to 0·61, and under 12 kilos to 0·19. The amounts of magnetism which disappear when H is removed, under various loads, form a greater proportion of the whole the more the load is increased, although (owing to the reduction in the total magnetism) the absolute amount that disappears when a strong force is removed is greater for a small load than it is for no load, and then less again for a large load.*

The presence of a *small* amount of load may, therefore, be said to *increase* the susceptibility of nickel with respect to that part of the magnetism which comes and goes when H is alternately applied and renewed, provided H is strong; when H is weak the effect of any load is only to reduce this susceptibilty.

Fig. 96 gives the same results of a similar experiment in which the same piece of nickel wire, after being hardened, however, by a slight amount of stretching beyond its limit of elasticity, was magnetised under a succession of pulling loads, ranging up to 18 kilos., or about 50 kilos. per sq. mm. With no load the maximum susceptibility of this hardened wire was about 8. Under the highest load the susceptibility was practically constant within the range of H used (up to 100 C.G.S.), and its value was only about 0·5 (permeability about 6·3). In this condition of stress the residual magnetism is almost *nil*. The dotted lines in this figure show the effect of gradually removing the strongest value of H which had been reached in the process of magnetising; they illustrate well how the residual magnetism becomes smaller, not only absolutely, but as a fraction of the whole magnetism, as the load is increased.

(To be continued.)

* This fact has been noticed independently and commented on in a recent Paper by H. Tomlinson (*Phil. Mag.*, May, 1890).

ON THE ELECTRO-DYNAMICS OF STATIONARY BODIES.*

BY H. HERTZ.

(Continued from page 637.)

PART B.

Explanation of the Phenomena by means of the Fundamental Equations.

We shall divide the phenomena to which our equations refer into three distinct groups—static, stationary or steady, and dynamic. A phenomenon can only be considered static or steady when the electric and magnetic forces do not change with time; and it is thus necessary, in these two cases, for the first members of equations (10) and (11) to disappear. For static phenomena it is, in addition, necessary that no variation shall occur in any of the quantities defining the state, and thus no transformation of energy can arise. For this to be the case, the values of u, v, and w must be zero.

Static Phenomena.

On substituting zero for u, v, w, in (11), and also for the left-hand members of each of the equations (10) and (11), we notice that the equations divide themselves into two distinct groups; the first of which (10) refers to electro-statics, and the other (11) to magneto-statics.

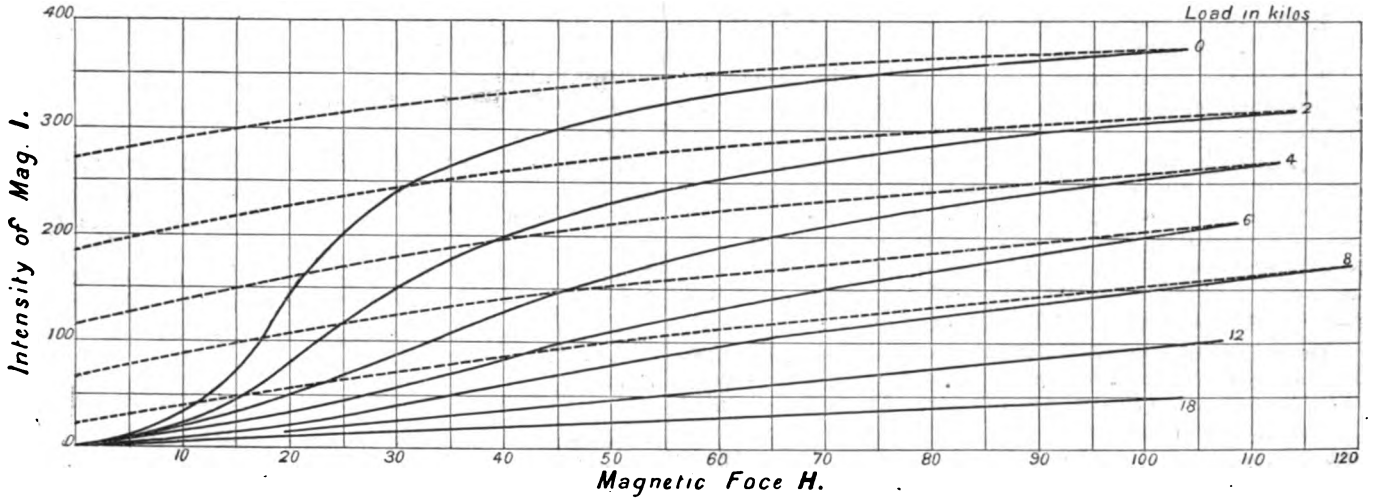

Fig. 96.—Nickel Wire hardened by stretching, magnetised under various amounts of longitudinal pull

Electrostatics.—For good conductors the forces X, Y, Z must be zero, since otherwise currents would be produced. For bad conductors equations (10) reduce to

$$\frac{dZ}{dy} - \frac{dY}{dz} = \frac{dX}{dz} - \frac{dZ}{dx} = \frac{dY}{dx} - \frac{dX}{dy} = 0,$$

and it follows that a potential ϕ exists, for which

$$X = -\frac{d\phi}{dx} \qquad Y = -\frac{d\phi}{dy} \qquad Z = -\frac{d\phi}{dz}. \quad (26)$$

The function ϕ is, in general continuous, since the forces are generally finite. It must be constant throughout a good conductor; and the tangential component of the force must be the same on the two sides of a surface separating two media.

If the quantity of "true" electricity in a unit volume be ρ_p, we see from (17) and (8), and the expressions for X, Y, and Z, given above, that

$$\frac{d}{dx}\left(\epsilon\frac{d\phi}{dx}\right) + \frac{d}{dy}\left(\epsilon\frac{d\phi}{dy}\right) + \frac{d}{dz}\left(\epsilon\frac{d\phi}{dz}\right) = -4\pi\rho_p;$$

since in (8) we may put $\epsilon_{11} = \epsilon_{22} = \epsilon_{33} = \epsilon$, and the other coefficients are zero.

* An abstract of a paper published in the "Nachrichten von der Kœniglichen Gesellschaft der Wissenschaften," for March, 1890; and reprinted in *La Lumière Électrique*, July, 1890.

Digitized by Google

For free ether we may put $\epsilon = 1$, and the volume density of "free" electricity being denoted by ρ we obtain

$$\Delta\phi = \frac{d^2\phi}{dx^2} + \frac{d^2\phi}{dy^2} + \frac{d^2\phi}{dz^2} = -4\pi\rho. \quad . \quad . \quad (27)$$

This equation reduces to $\Delta\phi = 0$ for all parts of space which are uncharged. The function ϕ, which satisfies these equations, is—

$$\phi = \int \frac{\rho}{r}\, d\tau \quad . \quad . \quad . \quad . \quad . \quad . \quad (28)$$

where r is the distance of the point considered from the volume element $d\tau$, which is charged to a density ρ; and this is the well-known expression for the potential at a point due to surrounding charged bodies. Coulomb's law of electric attraction and repulsion follows at once, since the force in the direction r is $-\frac{d\phi}{dr}$, and this by differentiation is seen to be inversely proportional to r^2.

The expression given in (12) for the electric energy—

$$\frac{1}{8\pi}\int (X\,X_p + Y\,Y_p + Z\,Z_p)\, d\tau$$

can by suitable transformations be reduced to—

$$\frac{1}{2}\int\int \frac{\rho_p \rho}{r}\, d\tau\, d\tau$$

Magneto-statics.—All the remarks made in the preceding section about the electric forces can be repeated with very slight modification with reference to the magnetic forces. There are, however, certain points of difference.

1. The distinction of bodies into conductors and non-conductors does not exist.

2. With the exception of bodies exhibiting the phenomena of permanent magnetism the "true" magnetic density is everywhere zero.

3. Although the dielectric constant ϵ of all known bodies is greater than 1, the magnetic constant μ of a great number of bodies is, on the contrary, less than 1. Bodies are called paramagnetic or diamagnetic according as the value of μ for them is greater or less than 1. The surface density of "free" magnetism on a bounding surface is proportional to $(1-\mu)$, and is thus of opposite sign for the two classes of bodies.

The science of magneto-statics acquires a special significance, because iron and steel, the most important substances dealt with, only obey the theory very roughly. The polarisation of the particles is in part independent of the acting forces, and is not determined by a single directed quantity. The relations are, moreover, no longer linear, and thus these substances must be regarded as outside the scope of the present theory. We may, however, for theoretical purposes, replace them by two imaginary bodies; perfectly soft iron, and perfectly hard steel. These are defined as bodies obeying the equations, and having a coefficient μ, which is very large indeed for soft iron, and equal to unity for hard steel.

Phenomena of the Steady State.

In bad conductors, as soon as the steady state is established, the same conditions hold as for static phenomena. For homogeneous conducting bodies, equations (10), (11) and (9) take the form

$$\frac{dZ}{dy} = \frac{dY}{dz}, \quad \frac{dX}{dz} = \frac{dZ}{dx}, \quad \frac{dY}{dx} = \frac{dX}{dy} \quad . \quad . \quad (29)$$

and

$$\left.\begin{aligned} \frac{dM}{dz} - \frac{dN}{dy} &= 4\pi A\, u \\ \frac{dN}{dx} - \frac{dL}{dz} &= 4\pi A\, v \\ \frac{dL}{dy} - \frac{dM}{dx} &= 4\pi A\, w \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (30)$$

$$u = \lambda (X - X'), \quad v = \lambda (Y - Y'), \quad w = \lambda (Z - Z'). \quad . \quad (31)$$

From (30) we obtain by differentiation

$$\frac{du}{dx} + \frac{dv}{dy} + \frac{dw}{dz} = 0 \quad . \quad . \quad . \quad . \quad . \quad (32)$$

And the modification of this at every separating surface can be shown to be

$$(u_2 - u_1)\cos(n,x) + (v_2 - v_1)\cos(n,y) + (w_2 - w_1)\cos(n,z) = 0 \quad . \quad . \quad . \quad . \quad . \quad . \quad (33)$$

The equations 29, 31, 32, and 33, determine a system without reference to the magnetic forces, which may therefore be left out of account. When the components u, v, w of the current are found, it is easy, by means of equations 30, to obtain the magnetic forces exerted by the current.

Distribution of Steady Currents.—From (29) we conclude that the forces X, Y, Z, are the differential coefficients, with the sign changed, of a potential function ϕ. This is true even within a good conductor, and it follows from this, and from 31 and 32, that at all points we have

$$\frac{d}{dx}\left(\lambda\frac{d\phi}{dx}\right) + \frac{d}{dy}\left(\lambda\frac{d\phi}{dy}\right) + \frac{d}{dz}\left(\lambda\frac{d\phi}{dz}\right) = -\left[\frac{d}{dx}(\lambda X') + \frac{d}{dy}(\lambda Y') + \frac{d}{dz}(\lambda Z')\right] \quad . \quad . \quad (34)$$

At the surface separating two media this equation takes the form

$$\lambda_2\left(\frac{d\phi}{dn}\right)_2 - \lambda_1\left(\frac{d\phi}{dn}\right)_1 = -\Big[(\lambda_2 X'_2 - \lambda_1 X'_1)\cos(n,x) + (\lambda_2 Y'_2 - \lambda_1 Y'_1)\cos(n,y) + (\lambda_2 Z'_2 - \lambda_1 Z'_1)\cos(n,z)\Big] \quad (35)$$

If one of the media is conducting, we have

$$\left(\frac{d\phi}{dn}\right)_1 = 0 \qquad X'_1 = Y'_1 = Z'_1 = 0$$

and if, under these circumstances, we integrate ϕ along the normal n, we have

$$\phi_1 - \phi_2 = \int [X'\cos(n,x) + Y'\cos(n,y) + Z'\cos(n,z)]\, dn. \quad (36)$$
$$= \phi_{12}$$

If the integral is taken across an infinitely thin bounding layer between two media, we may obtain a finite value for the integral, even though the forces X', Y', Z' are infinite throughout the layer, and in this case ϕ_{12} may be called the electromotive force of contact between the two media. Equations (34) and (35) show that $\Delta\phi = 0$ within a good conductor, $\lambda_1\left(\frac{d\phi}{dn}\right)_1 = \lambda_2\left(\frac{d\phi}{dn}\right)_2$ at a surface separating good conductors, $\frac{d\phi}{dn} = 0$ at a surface separating a good conductor from a bad one.

These equations refer to conductors in three dimensions. When linear conductors are considered the modified equations are very simple to use, and by employing them we may readily deduce the definition of resistance, the law of Ohm, and Kirchoff's laws.

(To be continued.)

THE SUSPENDED COIL IN CABLE WORK.

BY E. RAYMOND BARKER.

In 1887 I was engaged in experimenting at Madeira with a view to arrange a mirror suspension which, whilst sufficiently heavy and sluggish to be unaffected by jerky vibrations, due to gas bubbles from a troublesome cable fault, would be sensitive enough to give fair signals in response to firm manipulation of the distant station's key. I was endeavouring, in short, to evolve an instrument sympathetic to firmly transmitted signals, but the reverse to sudden vibrations arising from a fault. A brief account of the experiments and the results achieved may not be uninteresting or uninstructive.

Tiny Thomson mirrors, with short delicate suspensions, we found far too sensitive to vibratory influences, although they gave capital signals when the fault happened to be quiet, which was but seldom. It is interesting to watch the behaviour of a fault. There is, first of all, a slight but almost constant vibration of the "spot," which, however, scarcely interferes with

Digitized by Google

signalling. The same cannot be said of what follows. The slight vibration dies away, whilst the signals rapidly increase in size and clearness, when, suddenly, the emission of a gas bubble at the fault gives a violent jerk to the "spot," which again settles down with a shiver most bewildering to the mirror reader.

Unfortunately for the experiments (*pace* B. S. T. C. !) the fault was cut out before we could give a thorough trial to a new arrangement, which consisted of a long-range mirror on a 500ω coil, the latter hung between the poles of a strong permanent magnet, and kept in position by fibres and weights, as in Thomson's recorder. Experiments, however, show that :—

1. This instrument approaches very near to what is wanted, and has an action which tends greatly to smooth off jerky vibrations, while readily responding to battery impulses.

2. It is a capital "all-round" mirror, for one adjustment suffices for signals from cables of very unequal lengths. The Madeira—St. Vincent sections of the Brazilian Submarine Company's cables are roughly twice the electrical length of the Madeira—Lisbon ; yet the suspended-coil mirror answers equally well on all, without alteration of suspension.

3. Notwithstanding the great comparative weight of coil and mirror, and the general stiffness and rigidity imparted to the

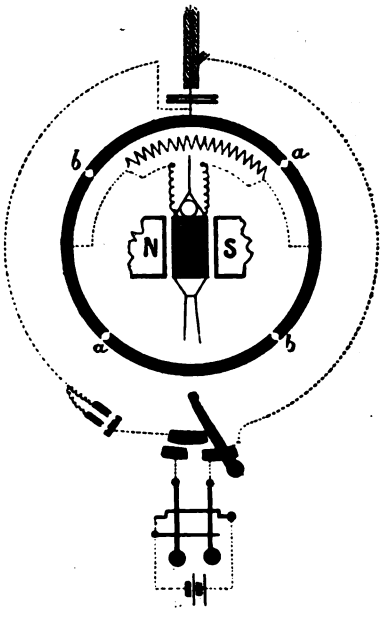

Fig. 1.—Diagrams of Connections of S. C. mirrors.

signals by the lower bifilar suspension and weights, the instrument, as a signalling mirror, is more sensitive than the Thomson.

4. In a test comparing a Thomson long-cable mirror of 3,000ω with a S.C. mirror of 500ω, range of mirrors being one metre, the current giving one division on test scale, for Thomson's mirror was ·0017 milliampere, and for S.C. mirror ·00089 milliampere. That is to say, the S.C. mirror is roughly twice as sensitive as Thomson's. The instruments were tested just as they stood, and both might have been more sensitive.

Such sensitiveness as that here shown is certainly not necessary. In fact, for mirror signalling, nothing could be superior to the Thomson, which simple, sensitive, and portable, is an ideal instrument. The writer only wishes to show what the S.C. mirror is capable of, and the advantages attaching to its use under certain conditions.

Fig. 1 shows connections of our S.C. mirror. They are made to give sending signals as a check on key and battery. There are two low-resistance shunts adjusting out-going signals to high and low battery powers. The poles and coil protrude upward through the table, a small glazed aperture in wooden cover permitting projection of the "spot" in a radius lengthways with the table. Reading can be carried on either from scale or from the wall opposite to the clerk, as he sits square with the table. In the latter case, the mirror throws the "spot" on to a looking-glass, where it is again projected at right angles on to the wall. Also a large convex lens may be used, which gives a "spot" 1ft. high, read with ease from the far end of the room. The signals on wall being reversed to what they are on scale, the coil and receiving-shunt are joined through a reverser which alters direction of current at will. There is also a sloping desk, supporting a message pad, on to which the "spot" can be thrown for self-writing, which is further facilitated by the "spot" being projected, at will, across entire pad. This instrument would be excellent for a "leak" station, which breaks in at intervals, and adjusts sending and receiving conditions to varying lengths of cable, and number of stations in circuit, and where one reliable permanent mirror is required, and nothing more.

In the Brazilian Submarine Company the mirror is now of the past, and the recorder is universal. Last year, however, occasion offered a new experience with the S.C. mirror. A

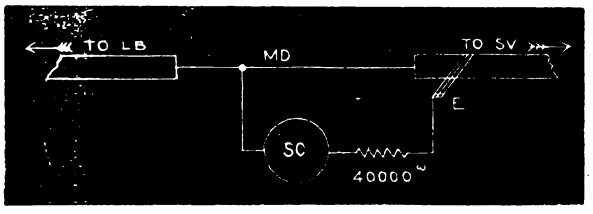

Fig. 2.

week's experiments were made for through working between St. Vincent and Lisbon (Carcavellos) with a leak of about 40,000 ohms at Madeira. In leak circuit, Madeira (M.D.) had an S.C. mirror as in Fig. 2.

With St. Vincent (S.V.) sending, a Thomson mirror with ordinary suspension showed the slightest perceptible movement, but no readable signals. The Lisbon (L.B.) signals were plain, with S.C. mirror substituted. Signals from S.V. were perfectly readable, whilst with L.B. sending, S.C. had to be heavily shunted with key pressed down or raised, according as S.V. or L.B. transmitted. Signals from L.B. being, of course, reversed to those from S.V., we arranged, as in Figure 3, signals, as seen on the reflection of scale in the looking-glass, were reversed to real signals on scale itself. So we read from scale or looking-glass, according as signals come from L.B. or S.V.

Ten years ago the writer designed a relay for submarine cables of medium length. It was merely the suspended coil in a magnetic field with a projecting tongue to close two local

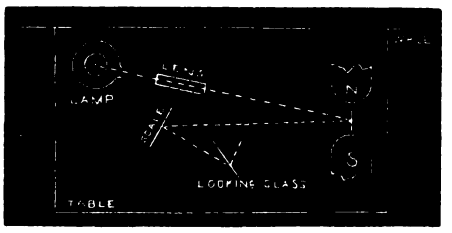

Fig. 3.

circuits after the manner of Bright's bells. Had this been practicable, automatic translation would have followed as a matter of course ; but the idea was abandoned by the writer on his hearing that Mr. De Sauty had already tried the suspended coil as a cable relay, but without success. Three years ago the writer again experimented with the S.C. as a cable relay. (*See* Fig 4.) P P are brass projections adjustable, by micrometer screws, at right angles to the aluminium tongue *t*, which carries a cross-piece *c*, the latter having needle-point ends. On P P are platinised depressions carrying globules of mercury *m m*, which act as contacts on both sides of *c*, and which, by capillary elevation, stand well above the surrounding brass, thus permitting *c* to swing against them free of P P. + and − impulse, through S C, cause corresponding contacts between *c* and *m m*-which bring into local circuits the sounders S^1 S^2, which, differing in tone, can be easily read.

Digitized by Google

Experiment showed that although with customary battery and condensers it was possible to receive distinct words through our Madeira—Lisbon sections, yet with anything approaching to fast working, make-and-break between *c* and *m m* could not be relied on, even with anti-speaking devices between *c* and *m m*.

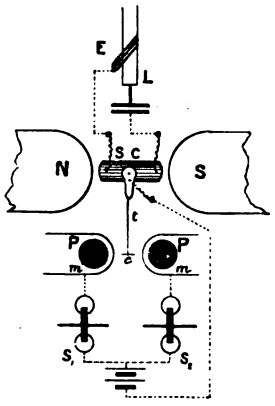

FIG. 4.—S. C. Relay

With St. Vincent sending at ordinary speed we obtained only confused beats on the sounders, without any perfect signals, it being impossible to adjust *m m* to the varying zero on this comparatively long cable. As an alarum relay, however, this instrument would work anything, from a bell to a mid-day gun or time-ball.

THE COMPENSATION OF ALTERNATING-CURRENT VOLTMETERS.*

BY J. SWINBURNE.

In 1887 I had the honour of bringing before this Section several methods of compensating voltmeters and resistance-bridges for variations of temperature. Wires with different temperature co-efficients were used, by which means errors from change of temperature can be avoided. Methods of compensating wattmeters for the errors inherent in them were also explained. The present communication relates to a somewhat analogous arrangement for compensating alternating voltmeters for changes of frequency.

It is much more easy to make a current indicator for alternating than direct currents, for troubles from hysteresis do not come in, and the slight tremble makes the moving part hang freely. If it is attempted, however, to use such an instrument as a voltmeter, the self-induction makes the reading far too low, and the error varies with the frequency.

To get over this trouble, a voltmeter may have a non-inductive, or nearly non-inductive, resistance put in shunt to its active coil. A coil with an adjustable iron core is then put in shunt to the active coil, this shunt coil having a very much larger time-constant. Though both coils have iron cores, they have open magnetic circuits, so they have practically constant co-efficients of self-induction. When the frequency increases, the current through the whole instrument under a given pressure falls; but the back pressure of the shunt coil increases more rapidly than that of the active coil, so that it takes less than its share, while the active coil gets a larger share of the reduced current; the actual current, and therefore the reading, in it remaining constant. The instrument is calibrated with a direct current. An alternating current is then put on, and the core of the shunt coil regulated till the readings agree with those of the direct current.

A similar effect might be obtained by putting a condenser in shunt to the non-inductive series resistance; but it does not look so promising, and I have not gone into the size of condenser needed in practice.

* Paper read before the British Association in Section A Leeds, September, 1890.

"SILVERTOWN" DYNAMO AND "GLOBE" COMPOUND ENGINE.

This dynamo, which is capable of giving a continuous output of 350 amperes, and 104 volts, at 300 revolutions, has been designed for coupling direct to a high-speed engine, and is so coupled to a Globe compound engine, having cylinders 8½in. and 15in. diameter, by 8in. stroke The magnets are of the single horse-shoe type, with pole pieces at the lower end, each vertical limb carrying a metal bobbin, on which is wound both series and shunt wire. The armature, which is of the ring type, has its core built up of thin annealed charcoal iron discs, insulated from one another, every alternate disc having a thin coating of special ebonite cured on to a thicknes of 3 mils. The discs themselves are 32 mils thick. This gives 91 per cent. of iron and 9 per cent of insulation, or, allowing for irregularities in the plates, 88 per cent. may be reckoned upon in practice. The discs are key-holed, and carried by a four-armed gun-metal spider, which in turn is securely keyed to the steel shaft. The armature winding consists of one layer of insulated strand cable, wound and connected on, in the ordinary method, to the commutator, which is built up of hard drawn copper segments, insulated with mica, and carried at each end by insulated gun-metal rings, fitting into grooves turned in the commutator. The insulation of these rings is obtained by the use of ebonite, which is cured on to a thickness of about one-eighth of an inch; and it has been found that this has given much more satisfactory results than the old method of having separate insulating pieces. The rings fit on to a gun-metal sleeve, bored to fit the shaft, and the whole commutator is screwed up tight by nuts on this sleeve, so that it is complete in itself. There are three brush-holders on each spindle, each fitted with separate adjustments for pressure, and with hold-off catches. The brushes and holders are made of ample section, and each brush-holder is connected by a separate flexible conductor to the terminal board of the machine, to avoid the necessity of collecting the current through the contact between the holder and the spindle on which it is carried. The dynamo has been designed for continuous running in an engine-room, the temperature of which is somewhat over 100° Fahr, and the rise of temperature has therefore been kept low; an actual test made by placing the thermometer on the armature directly the machine was stopped, and noting the highest temperature recorded by the thermometer, showing a rise of 25° Fahr.

ELECTRIC LIGHTING AND FIRE INSURANCE RULES.*

BY WILSON HARTNELL.

The early inexperience and ignorance of many who undertook electric lighting, and consequent accidents, rendered some guidance and restrictions absolutely necessary for protection against fire. Much is left to the conscience or ability of the contractor, which is unjust to those who abide by the best rules.

Such rules should contain the minimum that is necessary, and this should be strictly enforced.

In regard to conductors my first point is to show that any attempt on the part of the insurance companies to determine a fixed current density is useless, vexatious, and scientifically wrong. For any electric light installation it is necessary to limit the fall of potential in the more distant lights. This can only be done by so limiting the current density that there is not the remotest chance of fire from over-heating of the wires. If, however, an arbitrary rule, such as 1,000 amperes per square inch, be insisted upon, this rational principle of lighting cannot be adopted. It is, of course, necessary to adopt some limits of currents, but these depend upon the sizes of the wires, as it is easily shown by experiment and reasoning that the larger the cable the less must be the current density. *However small* the current, the smallness of the wires must be limited. For example, No. 20 S.W.G. is perhaps the smallest size that should be used for fear of mechanical injury. In mansions, &c., where the first cost of wiring is of less consideration, and also where the wires are placed out of sight, No. 16 S.W.G. may be the limit of smallness. That wires can be made

* Abstract of a Paper read in Section G, at the British Association, Leeds, September, 1890.

Digitized by Google

red hot by electricity, and give rise to fires, was one of the most obvious facts thrust upon the notice of the Insurance Companies, and apparently almost the only one they could imagine or comprehend. This danger has been greatly magnified. It is, moreover, the danger most easy to absolutely abolish by judiciously arranged cut-outs.

In order to prove my points experimentally, I have provided for a current of 250 amperes at 110 volts dynamos.

The smallest wire used in electric lighting is the twin flexible wire, equal in section to that of No. 22, S.W.G. It usually carries one lamp and consists of 23 strands, 6 mils diameter. My first experiment shows that one strand only taken out of 23/40s and 6 mils diameter will suffice to light one 110 volt 16 candle-power lamp requiring about ·58 amperes. The whole pendant of 23 such strands is therefore absolutely safe with one lamp. The current density in this small filament is 20,500 amperes per square inch. By further experiment I now show that this filament will carry three such lamps, say 60,000 amperes current density, without being hot enough to burn anything. It becomes dull red hot with five lamps and a current density of about 100,000 amperes per square inch.

Experimenting with the complete 23 strand twin wire, it will be seen that it easily carries eight or ten lamps. The 1,500 candle-power Sunbeam lamp at 35 amperes gradually destroys the insulation. It is equal to 60 16 candle-power lamps. It may, therefore, be pronounced absolutely safe with two or three 16 candle-power lamps. The smallest solid wire used iu electric lighting is No. 20 =36 mils, which at 2,000 amperes per square inch would carry one ampere, say two lamps, but would seldom be used for more than one lamp. No less than about 80 lamps or 46 amperes are necessary to destroy it. No. 16, at 2,000 amperes to the square inch, would carry six lamps, but is here shown to be comparatively cool with 33 lamps.

These experiments on the smaller wires have demonstrated that there is not the most remote danger of fire with the currents ordinarily used, and therefore for Insurance Companies to fix a current density is vexatious, and cannot secure safety.

Fusible cut-outs seem to be regarded with some mistrust. The second point I desire to establish is that by their means the mains and branches may be absolutely protected from danger by fire from excess of current. The highest current will be required to melt a cut-out when it is short, and itself and connection cold—when it is longer or covered up, and heated gradually, a lower temperature melts it. Wires are efficiently protected by fusible wires of the same diameter; and this is the only point that Insurance Companies need trouble about. Experience with cut-outs shows that if only a very small margin be allowed they are after a while liable to melt with the working current, apparently from deterioration of contacts and gradual accumulation of heat.

Cut-outs must be placed in conveniently accessible positions. The subject of the construction and position of cut-outs is most important, but would require a Paper to itself. Experience has led me to regard good cut-outs, properly fixed and wired, with almost implicit confidence as protecting the wire. Cut-outs are no protection against heating and sparking from imperfect or broken contacts.

The insulation required for telegraphic work and that for electric lighting work are not necessarily the same. In the former the wires extend for hundreds of miles, and the storage of energy in the batteries is both costly and very limited. In electric lighting the wires are short and power abundant. The chief object of electric light insulation is, therefore, safety; and this safety, like that of a steam boiler, should be not for one or two years, but for as many years as possibie. Durable insulation is, in my opinion, of far more consequence than high insulation. Naked wires on insulators (where practicable) are the best and most imperishably insulated. Vulcanised india-rubber gives the highest insulation for covered wires. Exposed to the air, vulcanised rubber often cracks, and more or less perishes in a few years. When held together and protected from the air, as it is in the cable, it may last much better. For damp places vulcanised rubber is indispensable, or some waterproof insulation.

A very important point, which experience alone can determine, is what insulating coverings will remain most trustworthy at the end of ten, twenty or thirty years.

The greatest protection, in my opinion, is to be obtained by using good material and good workmanship throughout, and not trust to merely insulation tests only. It is not fair to demand very high insulation tests for wire without also specifying the quality of insulation; because a single rubber wire, or possibly a wire innocent of india-rubber, may test as well as vulcanised wire in dry weather, so that the covering required is indeterminate. It must also be remembered that although the insulation of the bases of the switches and cut-outs is high, yet in the aggregate (if the switches, &c., be numerous) they will reduce considerably the total insulation. If the test be between the positive and negative wires the lamp fittings will greatly reduce this; so would also the twin wires for the pendants.

The casings are mechanically useful to protect and support the wires; they have the disadvantage, putting it from an insurance point of view, of concealing it. The space between the grooves has now been reduced to a reasonable width; at the same time it seems unreasonable to put all qualities of wire on the same footing. It seems to have been forgotten, curiously, that when switch wires, say positive, are laid on a positive wire and switched off, they become negative. The possible current through them is no doubt limited to that which would go through the lamps. The use of varnishing casing seems very doubtful; if the place be not damp it can be of no service; if it be damp, then a wire that will stand damp ought to be used. Non-inflammable paints to prevent the casing taking fire seem to me ridiculous. There can be no remote risk of fire in the casing if the work be properly done.

Of switches very little need be said. On the main sections double-pole switches are convenient; but on the branches double-pole switches and double-pole cut-outs, by the extra expense and complication they would entail, would more than defeat any imaginary advantage urged by their advocates.

The grievance of ill-framed and conflicting fire insurance rules is not only that they interfere with the carrying out of the work in the manner best suited to the circumstances, but there is difficulty in knowing what is required. By insisting, or appearing to insist, on a certain class of material, certain conditions, &c., in one case, and passing very different things in another, there is a further difficulty in not knowing what, by chance or caprice, they may accept. Meantime, those who require the electric light, and know nothing of the matter, are still further bewildered, and are apt to choose the work which is the least expensive, so that the insurance companies defeat the professed object. In conclusion, I would most strongly urge that the rules of the Institution of Electrical Engineers, with, perhaps, a few additions, be accepted by all the fire insurance companies.

DISCUSSION.

Mr. W. H. PREECE said that he did not go the whole way with Mr. Hartnell in attacking the fire insurance offices. They had taken infinite pains to secure accurate rules, and their sole object was not to throw obstacles in the way of users of electricity or difficulties in the way of contractors; but to secure their own purses from being drawn upon too much by accidents that were really remedial. One of the most frequent sources of danger in houses was the existence of a bad joint, which generated heat. A point not touched upon by Mr. Hartnell was the use of wood casing in damp places. He had seen two or three very nasty instances where a possible accident might have occurred through a leakage crossing the casing, which had become damp from moisture, falling over it. The wood had become carbonised; it had, in fact, become a conductor; heat had been generated, and the wood itself had been practically burnt.

Sir FREDERICK BRAMWELL said it appeared to him that the heat which was developed in a wire was simply due to the destruction of energy by the resistance of the wire to the passage of the current, and that the result would be cumulative, and that the temperature would continue to increase until the dissipation of heat from the surface of the wire either in contact with the air or in contact with some other material carries off the heat as fast as it is generated, and there is no further increase in temperature. If that be the right way of looking at it, then it seemed to him wrong to suggest that any particular size of wire could carry with safety any number of amperes, without knowing the incidents of the surroundings of that wire.

Major-General WEBBER said the rules drawn up by the committee formed by the Institute of Electrical Engineers were rather rules for guidance as to principles; and it had been left to the insurance companies themselves to draw up their own bye-laws, as they might be called. He believed that the use of casing, except in certain positions, would gradually die out.

Mr. KAPP said he was not prepared to go with Mr. Hartnell in his condemnation of a current density limit. The current density rule was a very unscientific one, but in practice it worked very well, as people were in the habit of employing the bellhanger or somebody else round the corner who would not understand a more scientific rule. He agreed with General Webber in regard to the casing.

Mr. TROTTER said the heating of very large conductors was perhaps a subject some times to be considered, but the heating of small wires hardly ever need be entertained. As for putting large currents through small wires, which Mr. Hartnell had done, he thought that the experiments were most misleading. He should be sorry to see a No. 20 wire used in a house; he was strongly opposed to using a No. 18 wire, and thought that a No. 16 wire the smallest that should be used in such work.

Mr. HARTNELL, in reply, said that he thought the rules of the Institution of Electrical Engineers were immensely superior to those adopted by the Fire Insurance Companies. He should like to see the British Association, as they did in the case of electric standards, introduce some national code of laws, founded on principles for protection from fire, giving the minimum that was required: and that that minimum should be enforced. In regard to Mr. Trotter's remarks, he had totally missed the point; he had shown by experiments that the wires could carry with perfect safety much larger currents than those permitted by the fire offices.

THE POSTMASTER-GENERAL'S ANNUAL REPORT.

Whatever may be the departmental reasons for treating the Telegraphs as a separate branch of the Post Office the fact that they continue to be so treated enables us to note from year to year the growth of that part of the business which has most interest for our readers. As usual, the POSTMASTER-GENERAL'S Report, just issued, for the twelve months ended 31st March last, furnishes, with much particularity, the details of all receipts and expenses connected with the Telegraph Service quite distinct from the Postal Service accounts. For several years past we have failed to see the object of continuing this practice, unless it were to convince certain unbelieving reformers that the Telegraphs have never yet been worked at a profit. But if that is the true explanation, we should like to know why the same plan is not adopted in respect to some other descriptions of Post Office undertakings—the Parcel Post, for example. The Parcel Post is described in this year's Report as growing steadily "in a satisfactory manner"; but even from the meagre details set forth on page 4 of the Report it is plain that with half the receipts paid over to the railway companies the profits, if any, do not go to swell the Post Office revenue. As, however, the expenditure on this popular, but financially questionable, experiment has never been separated from that of the main business, the public are not made aware of the extent to which parcels are transmitted through the post out of pure benevolence. Not so the Telegraphs; every item of expenditure is paraded with an exactness which provokes the wondering inquiry how two businesses so intermingled as manifestly the Telegraph and Postal businesses are can have their accounts so squarely apportioned. The cost of keeping separate balance-sheets must from beginning to end exhaust

Digitized by Google

a considerable sum of money; and unless there is some occult reason for keeping them asunder, the Postmaster-General might, one would think, usefully direct his attention to bringing about a real amalgamation of the accounts similar to that which has taken place between the respective services.

We have been led into making these observations partly through weariness of seeing repeated the oft-told story that the Telegraphs do not yet pay interest on the original outlay; and partly from a similar reiteration of complaints that certain portions of Telegraph business are conducted at a loss. The wording of the present Postmaster-General's Annual Report always leaves us in doubt whether his remarks on these points are intended as lamentation or as explanation. But in whatever way we take them they appear to us a waste of breath; for if Press telegrams and Railway telegrams are a grievous burden to the Telegraph Department, they ought either to be got rid of, or accepted in silence like many another burden which the Post Office has been saddled with, and has carried without a murmur. It naturally occurs to friends of the Telegraphs that the Post Office, which has a very broad back, could very well afford to carry some of the dead-weight under which its younger brother has so long been staggering. In other words, if the two services were united financially as they are administratively, there would be an end to these unavailing complaints, and the saving effected would probably go a great way towards removing all ground for them. Meanwhile it should never be forgotten that the annual profits of the Telegraphs have been spent on extending and perfecting the service, which is now the best-equipped and most efficient in the world—a result which the Department rightly considers of far more importance to the public than payment of interest on the purchase money.

Turning, however, to that portion of Mr. Raikes' Report which deals with the Telegraph statistics of the year 1889-90, it is noticeable that the increased prosperity of the country has had a marked effect on the revenue, the improvement amounting to £233,871, as against £137,016 for the year preceding. On the other hand, the expenditure is shown to have exceeded all previous years, and, indeed, nearly absorbs the increase in the receipts, the exact figures being £2,181,472, an increase of £212,148 over the expenditure in the previous year. Notwithstanding this additional outlay, the net revenue has exceeded by nearly £20,000 that of the year ended March, 1889, the deficit being reduced from £265,183 to £197,690. A sum of £27,370 has been this year expended in the conversion of the stock, representing capital expended in the purchase of the Telegraph system, thereby lessening the yearly interest by £27,000, which now stands, therefore, at £299,216, instead of £326,417 as heretofore. If this process be repeated, and the rate of present improvement in net revenue maintained, not many years ought to elapse before the Telegraph receipts will actually cover the current interest on its capital. When that time arrives, the one intelligible reason for keeping a separate set of accounts for the Telegraph Department will have disappeared, and the Post Office may then, perhaps, condescend to accept the Telegraph surplus as part of its own.

No material change appears to have taken place in the habits of the public, who continue to exhibit considerable smartness in curtailing their messages, the average payment for which is still a fraction below 8d. This is the standard which apparently it may be expected to maintain—rather less than more, however, as the economy of words will grow with practice even when economy of money is not sought after in such prosperous times as the present. Recent correspondence in *The Times* relating to short addresses, which are deemed insufficient by the Department, betray this tendency in a remarkable way. It is evident the writers of these indignant letters are often actuated as much by a desire to save themselves trouble as by any designs on the Telegraph revenue; and this being the case it would be idle to calculate on the average telegram ever exceeding its present limited dimensions. People will send more Telegrams, but they will not pay more for them; and the Postal Telegraph Department may as well recognise the fact by improving its methods of delivery.

In another direction a more conciliatory spirit has been shown, and has been appreciated to an extent probably not anticipated. Telegraph money orders, which were confined at first to less than a score of large towns, were extended early in the present year to all head and branch offices in the United Kingdom, with the result that in the first month of the larger experiment 1,769 orders were issued to the value of £6,262. When we remember that the cost of remitting money by wire is rather exorbitant, these figures show that the system is one which has met a real want, though nobody seems able to explain how it can arise so frequently. The acquisition of the continental cables has been rapidly followed by a large increase in the number of telegrams forwarded and received between this country and the continent, partly due to the reduction of rates, but largely, no doubt, to the improved working and extended facilities which are afforded under Governmental management. On this transaction the Postmaster-General has good reason to congratulate himself, and the public will not grudge him the credit that is certainly his due. As regards telephony the Report is singularly silent; but we can draw no conclusions from this circumstance, because probably none have as yet been arrived at by its author.

ELECTRICAL DISTRIBUTION BY TRANSFORMERS FROM CENTRAL AND ECCENTRIC STATIONS.*

BY DR. J. A. FLEMING, M.A.

(Continued from page 648.)

§ 14. **Switch-Boards and Regulators.**—The switch-board arrangements in this system are particularly well devised. A switch-board is generally set up for each dynamo and for five or six feeders. The usual American practice is not to work the dynamos in parallel, although this is quite practicable, but to permit each dynamo to supply two or more feeding or primary circuits at full load, and then, as the load goes off, to group or gather together the feeders on to one or two dynamos in order to keep the working dynamos as far as possible fully loaded up. Figure 40 shows a switch-board arrangement (not, however, the newest form) for two dynamos and four primary lines.

Commencing at the bottom of the switch-board we see four rheostats. The two small ones at the centre control the field circuits of the exciters. It is the usual practice to provide each station having more than one dynamo with duplicate exciters, each having a capacity sufficient to charge the fields of all the alternate dynamos. Only one exciter is in use at a time, the other standing idle as a reserve. It follows, therefore, that the governing of the electromotive force of all the alternators is effected by an introduction of resistance into the field circuit of this exciter.

The control of the electromotive force of each separate alternator is effected by the introduction of resistance into the field circuits of these machines by the rheostats on either side of the

* All rights are reserved.

Digitized by Google

middle ones. The small changing switches between the rheostats are for connecting either exciter with either dynamo at will, and for connecting the field circuits of both dynamos together. Over the rheostats are shown four sets of trunk wires, each consisting of two heavy parallel copper rods. Between each upper and lower set are three changing switches. The wires leading to the middle connection of the centre switch come from the No. 1 dynamo, whose current can be delivered to the upper or lower trunk wires at pleasure. The two outside switches of each triplet enable the primary wire attached to the centre connection of the switch to be put in connection with either trunk circuit at pleasure. Between the two sets of trunk wires are seen two multiple-arcing switches, which enable the dynamos to be run in parallel if desired, and a synchroniser or phase indicator is provided as described in connection with the Leghorn Central station (see § 9) to enable the dynamos to be put in parallel when in phase.

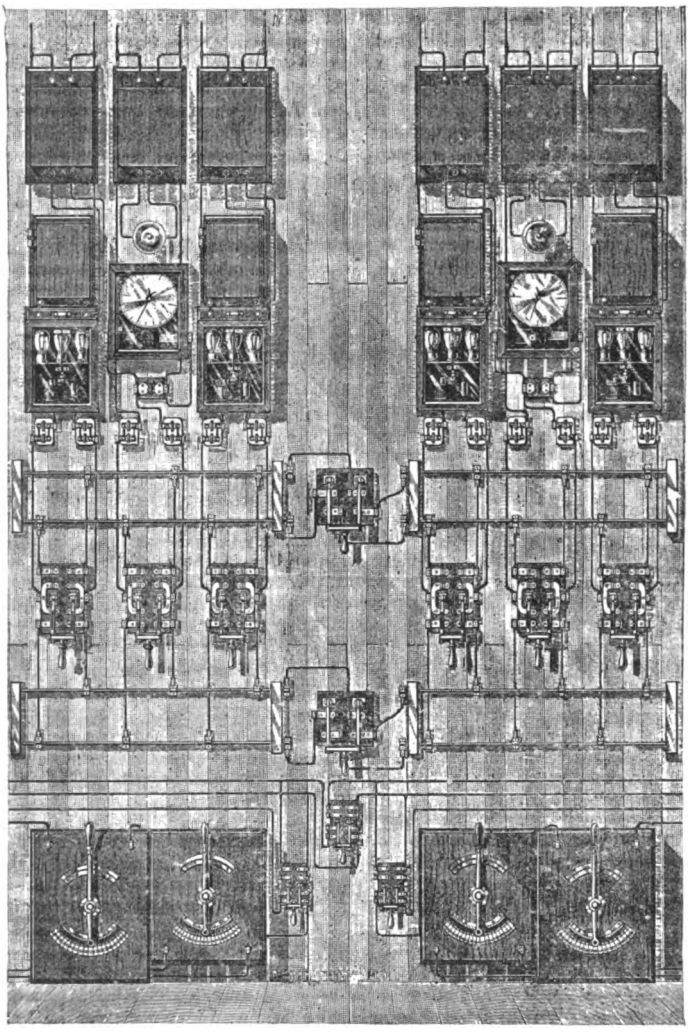

FIG. 40.—Westinghouse Switchboard for Two Dynamos and Four Circuits.

Over the trunk wires come a row of six safety catch-holders, each with double fuses and plug cut-outs. Over these safety fuses are four voltmeters, each with its attendant compensator above it. These voltmeters serve to measure the pressure at the far end of the line, and the compensator corrects the voltmeter reading for the fall in volts along the line. Between the voltmeters on the dynamo main comes the amperemeter. At the top of the switch-board is a row of small transformers, which serve to reduce the pressure for the voltmeter. It is easily seen that a large variety of possible changes are readily effected with a switch-board of this kind, and that it enables one attendant to regulate a number of feeding or primary circuits. In larger central-station switch-boards the arrangement is somewhat different. For each feeding or primary main there is a separate panel, and, by an arrangement of plug switches, any one of the whole battery of dynamos can be worked on to this feeder. Also, by a throw-over switch in the centre of this board, this feeder can be instantly thrown over on to any other selected dynamo. Hence it becomes the easiest operation to group, or collect, or change over the feeders from one machine to the other; and American practice has seemed to indicate that this arrangement is, on the whole, easier to operate than working the dynamos in parallel.

When several feeders proceed from one dynamo, and on these supply lines different consumption exists than in each of the primaries, the fall in volts may require adjustment from time to time. To introduce resistance into the feeder would be a

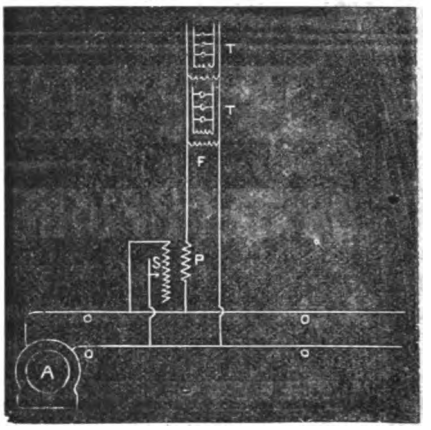

FIG. 41.—G. Kapp's Method of Regulating Electromotive Force at the termination of a feeder F. P is a primary coil in series with the feeder F, and S is a secondary coil in shunt off the omnibus mains O O. More or less of the turns of S are thrown into circuit as required.

very crude device; the necessary independent adjustment of the volts at the far end of the feeder can be better obtained by a method due to Mr. G. Kapp.* Let O, O, Fig. 41, be the omnibus bars from which the feeders start. The feeder F has in series with it one coil, P, of a transformer, the other coils of which is a shunt across the omnibus bars; by inserting more or less of

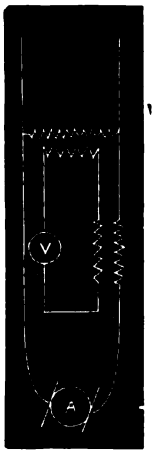

FIG. 42.

the turns of the coil S into circuit by a shifting contact, a little auxiliary volts are put into the feeder by the inductive action of the coil, which is in shunt across the omnibus bars. This regulating device may be so designed as to add, or be capable of adding, 50 to 100 volts to the 1,000 or 2,000 volts already on the feeder; hence, a movement of a lever enables the station engineer to adjust with great accuracy the volts at the far end of the feeder, and to do this for each feeder independently, even though all may be working off one dynamo. The arrangement employed for determining the volts at the far end of the feeder is essentially the same as the method already described in connection with the Ganz system. The voltmeter is in series with the secondary circuits of two transformers, one of which has its primary in series with the feeder circuit, and the other of which has its primary as a shunt across the feeder (*see* Fig. 42).

* See *Proc. Inst. Elect. Eng.* London, Vol. XVIII., p. 215, 1889.

Digitized by Google

The electromotive forces of these two transformers are opposed to one another. Since the secondary electromotive force of the transformer in shunt is proportional to the primary electro-

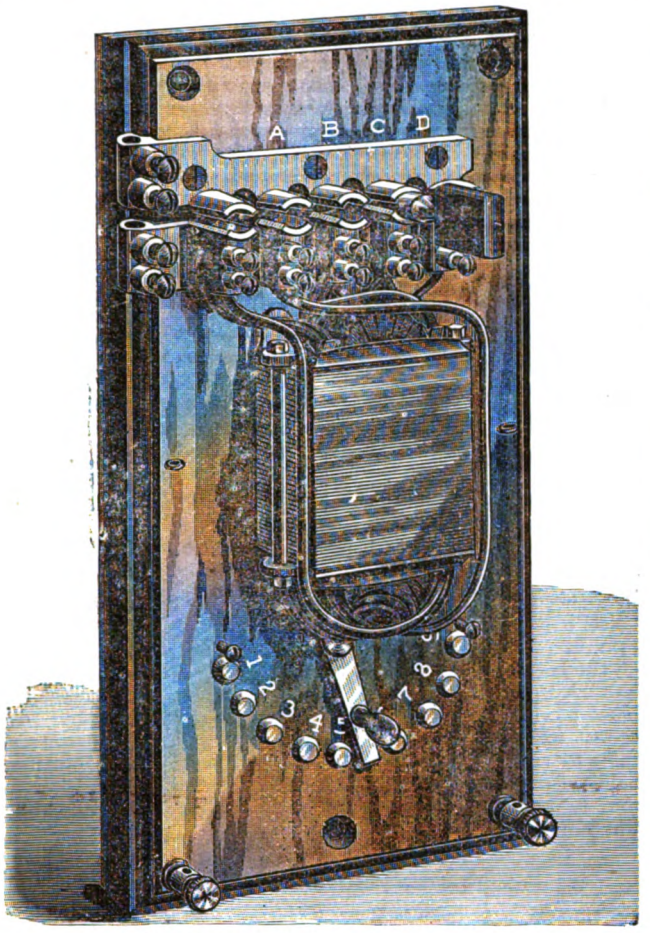

Fig. 43.—Westinghouse Compensator.

motive force, and since the secondary electromotive force of the transformer in series is proportional to the primary current strength, the difference between the two is proportional to V – R C, where V is the primary volt and C the primary current strength. As already explained, this difference is proportional to the pressure at the far end of the feeder, and by

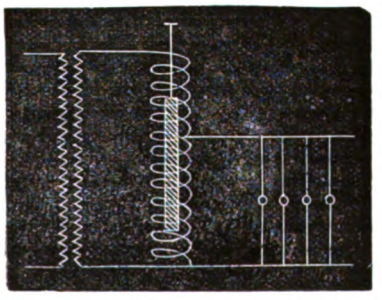

Fig. 45.

proper adjustment the voltmeter can be made to indicate this pressure, without any need for pressure wires run back to the station. In the Westinghouse system, the necessary transformers for this purpose are put together into a box and called a compensator (*see* Fig. 43); all that has to be done is to connect the voltmeter to the compensator.

In addition to the regulation of pressure which is carried on at the station, it is necessary at theatres and in houses to be able to adjust the working electromotive force on the lamp circuits. There are two neat devices used by the Westinghouse Company for this purpose, called stage and house regulators. The stage regulator, intended chiefly for the regulation of stage lights, is shown in Fig. 44. It consists of two connected coils of wire, with an iron core not quite so long as one bobbin sliding through both. One coil may be called the series and the other the shunt coil. The diagram below (Fig. 45) shows the mode

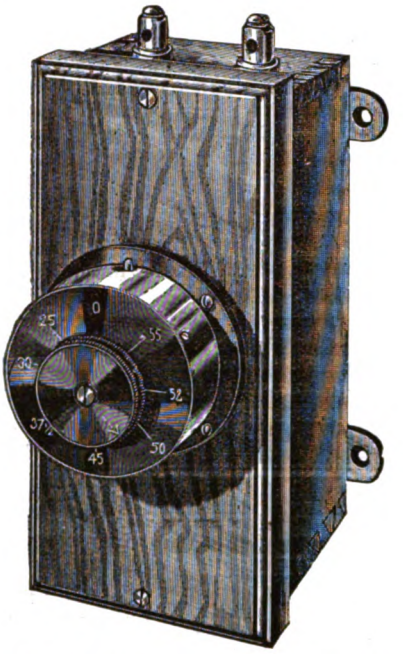

Fig. 46.—Westinghouse House Lamp Regulator.

of connection to the lamp circuit and transformer. When the iron core is pushed wholly within the shunt coil it bestows upon it such inductance that it blocks out all current through the

Fig. 44.—Westinghouse Stage Regulator.

shunt, and the lamps will be at their full brilliancy. On gradually drawing the iron core out of the shunt coil and into the series coil the inductance of the series coil is increased, and that of the other is diminished. Hence the current through the lamps is diminished by both actions, and the lamps become less bright.

A somewhat similar arrangement is provided for a house regulator. Across the secondary circuit of the house transformer is a single coil (*see* Fig. 46), and the several sections of this coil are brought up to a revolving contact. By turning a handle more or less impedance can be inserted in the lamp circuit. The coil also acts as an auto-converter, and can be made to raise the lamp volts slightly above the volts at the terminals of the transformer. The coils of the regulator which project as it were beyond the points *a b*, at which the transformer secondary circuit is joined in, have inductive electromotive force set up in them by the neighbouring coils, which, being added to the actual secondary or impressed electromotive force, between *a b*, make it possible to have the volts on the lamps actually higher than the secondary terminal volts at the transformer.

(To be continued.)

ELECTRIC MOTORS IN WORKSHOPS.*

BY C. FREWEN JENKIN, B.A.

The author describes various applications of electric motors to drills, tube cutters, and cranes. He has used cast-steel in the construction of the field-magnets, and gives the results of tests of the magnetic properties of this material. Tests of two different qualities of castings show that cast-steel lies in an intermediate position between cast-iron and wrought-iron in its suitability for magnets. From the cheapness with which castings may be obtained in any complex shape, in order to simplify the framework of the motor, the advantages of cast-steel are important.

Among the factors which determine the design of small motors it is pointed out that a small armature can be easily wound for running with 50 volts, but becomes troublesome to wind for 150 volts; thus the size of the armature must be kept sufficiently large to make the winding fairly easy. As to whether the motor is to be shunt or series-wound; in a series-wound motor the magnets may be of any form desired, since the winding consisting of comparatively few turns of thick wire can be put on by hand. But in a shunt-wound motor it is almost essential, especially in high voltage machines, to make the magnet cores straight, so that the winding can be put on in a lathe. This difference in the shape of the magnets causes small shunt-wound motors to be heavier than series ones, since it is impossible to arrange them so compactly. Where the load varies much, the difficulty of governing series motors becomes very serious. This difficulty does not arise in shunt or compound-wound motors.

In a rough preliminary experiment on a common drilling machine, it was found that to drill a ⅜in. hole through Bessemer steel, at the rate of about a ¼in. a minute, took about one-fifth horse-power. The speed chosen for the electric drill was 60 revolutions per minute, running light, or about 45 loaded. The motor was designed to run at 3,000 revolutions, and a steel worm on the shaft was arranged to gear into a brass wheel on the drilling spindle. The armature was a gramme ring 4in. in diameter; it was wound with 480 turns of No. 18 for 50 volts, and 1,600 turns of No. 24 for 150 volts. There were 40 sections on the commutator. The magnets were wound with 9,800 turns of No. 27, the resistance being 332 ohms for working at 150 volts. Under a brake test, with the 50 volt armature, the results were:—2,950 revolutions, 26·6 amperes, 47·7 volts, B.HP. 1·05; efficiency, 59·2 per cent. Lightness was considered of greater importance than very high efficiency. The weight of the motor alone without the drilling spindle cannot be given quite fairly, since the magnets have been used to form part of the framing for carrying the drilling tackle. The weights of the different parts, so far as they could be taken to pieces, are as follows:—Magnets, bearings, and brushes, 32lb. 12oz.; armature, 8lb. 8oz.; boring tackle, 15lb. 4oz.; total, 56lb. 8oz. These figures bear out the claim made by the author for the advantages of cast steel over cast iron; and the general design of the drill shows how much more cheaply the parts can be cast than forged. This was a shunt machine. A ⅜in. hole could be drilled through a ⅜in. iron plate in 45 seconds, the electric power required being 0·732 horse-power.

The next motor that the author designed was for driving a small saw for cutting tubes out of boilers. The copper tubes in locomotive boilers have to be renewed from time to time, and the machine was designed to saw them off just inside the tube plate. A plug is fitted with two eccentrics. The saw spindle runs in a bearing in an inner eccentric, and is either central or eccentric in the plug, according to the relative position of the two eccentrics. The saw is brought into its central position while the plug is introduced into a tube end, and is then thrown out of centre, so that it cuts into one side of the tube. By turning both eccentrics together the saw is made to cut all round the tube. The magnets of the motor were curved, and were series wound. They were made from a single wrought-iron forging, on which were bolted two phosphor bronze brackets forming the bearings. The tests were not carried out at full load; they gave:—watts absorbed 2,600, B.H.P. 2 8, efficiency 71·7 per cent. The weight of the motor alone is 60lb. The armature is 5in. in diameter, and of the Pacinotti-Gramme type, with only $\frac{1}{32}$in. air space. It has 40 slots ½in. deep, and is wound with 840 turns of No. 19. Each magnet has 190 turns of No. 14. There are three times the number of turns on the magnet which are required for running at full load, 63 turns being then sufficient. The extra turns were put on to keep the speed moderate on light loads.

A 10 horse-power motor of the Manchester type was constructed for driving a travelling crane. In order to avoid sparking, a pair of small series-wound magnets were placed on opposite sides of the armature, so that their poles were on a horizontal diameter, and were over the section being short-circuited by the brushes. This method is described in Swinburne's patent, No. 6,754, 1887 (*The Electrician*, Vol. XXIV., p. 400). It was found to answer admirably and entirely prevented sparking, no matter how quickly the load was applied. The power required to drive the four belts on the crane was 2·85 horse-power. To lift eight tons at about 4ft. per minute, 6·5 horse-power additional were required, and to lift 4 tons at about 9ft. per minute, 7·0 horse-power. Traversing at 47ft. per minute took less than 1 horse-power. By arranging the motor to drive the rope by which the crane was formerly worked, it was found that there was a saving of 8·4 horse-power, or 43 per cent.

After the failure of several forms of friction gear a magnetic clutch was made in the form shown in Fig. 1. The flanges are used

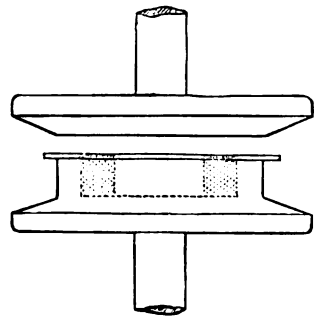

Fig. 1.—Magnetic Clutch.

in connection with the lowering gear. The diameter of the cylindrical portion is 6½in. A coil of 240 turns of No. 20 wire was put into the recess shown, and connection made to it by two brass rings on the back, against which two small brushes pressed. This clutch was tried, running at about 1,000 revolutions, and transmitted 8 horse-power satisfactorily, stopping and starting perfectly. In order to test what couple it could transmit with varying magnetising currents two levers were fixed to the two parts, and while one was held weights were hung to the other; but the coefficient of friction between the surfaces not being sufficiently constant the test was not satisfactory.

ON THE PROTECTION OF BUILDINGS FROM LIGHTNING.*

BY A. R. BENNETT.

Considerable uncertainty is reputed to exist amongst architects and others who are occasionally called upon to erect lightning conductors. I have had quite recently two cases illustrative of this suspected uncertainty brought forcibly to my notice.

The first case occurred in connection with this present Exhibition. The Electrical and Lighting Committee decided that both the old and new systems of protection should be illustrated practically; so the chimney of the boiler-house was ordered to be protected by a stranded copper rope of the ordinary type, and the minarets of the main building by iron wire, according to a design kindly furnished by Dr. Oliver Lodge. The erection of the chimney proceeded with unexpected celerity, and when the Committee went to specify the precautions they wished to have observed in earthing the conductor they were informed that the conductor was up, earthed, and finished. The builder assured them that it was "all right;" but appreciating the ridiculous figure that would be cut by an Electrical Committee were a chimney under their special care struck and injured, it was resolved to do violence to the builder's feelings and dig up his earth. It was found that the end of the conductor was only a few inches below the surface, and was loosely embedded in builder's *débris*. This was the first case, and was detected and remedied in time. The second was only revealed by an actual visitation of lightning.

Last month, during a severe thunderstorm, and while it was raining very heavily, the inmates of a house were startled by a tremendous report. The house is peculiarly situated, being erected on the slope of a rocky hill, about 600ft. above the base and some 1,000ft. below the summit. It is fitted with the electric light, all the leads being within the building. A telephonic connection exists with the stables in the valley below, some 1,000 yards distant; it consists of two copper wires thickly insulated with gutta-percha, which are used as a metallic circuit. They are underground the whole way, being laid in a wooden box buried in a trench, except at one point, where they cross a stream in an iron pipe laid in its bed. When the flash occurred light

* Abstract of a Paper read at the Edinburgh International Exhibition on September 5, 1890, before the East of Scotland Engineering Association.

Digitized by Google

was seen in almost every room of the house. A flame appeared around the kitchen grate. The housekeeper heard a faint rustling sound in the direction of one of the electric lamps, and was immediately conscious of a blaze of light, which seemed to dart from the lamp to the grate. A ball of fire, of a deep red colour, was seen, and a dazzling light of no defined shape appeared to play for an instant over the wall paper, which is embossed with metal. At the stables a ball of fire, of a white colour, about the size of a cricket ball, appeared in the middle of the room, and instantly exploded with a report. An examination showed that the safety fuses of the electric light system were melted. The hinged door of the box containing them, which was situated about 4ft. from the telephone on the same wall, was knocked off and thrown to a distance. It was much scorched inside. The telephone wires were fused in three different places, once in the iron pipe in the bed of the stream, once midway between the stream and the stables, and once a few yards on the house side of the stream. At the second place the wooden boxing was completely destroyed for about 6in.; at the third its bottom only was knocked out. In the stables the boxing was blown off the wall, but the wires escaped injury, as did the telephones at both ends. Where fused, the wires presented a sharpened or pointed appearance on the sections furthest from the house, and a rounded shape on those nearest it. At the moment of the discharge two bullocks grazing in the fields two or three miles off were struck dead. This tends to substantiate what has often been asserted, that lightning discharges frequently, if not invariably, are double; that at the moment a flash takes place from clouds to earth at one place, another ascends from earth to clouds at another, a phenomenon to which the name of back or return stroke has been given.

The house is largely roofed with lead, and has several iron spires which are in contact with the lead. The highest spire was found to be bulged and blackened at the junction of the iron with the lead. There are numerous metal drainpipes down the walls for carrying off the rain-water. These are in contact with the leadwork of the roof above; but no provision is made for earthing them below. When I add that there is no lightning-conductor, and that the house is built on a thin layer of soil covering rock, it will be seen that all the elements necessary for a first-class catastrophe were present. The absence of a conductor was accounted for by saying that when the house was built the architect stated that one was unnecessary. When telephone wires, and especially metallic circuits, are taken into a building they should be fitted as near the point of entry as possible with a good lightning discharge. This necessity I recognised several years ago as a consequence of more than one accident, since when all metallic circuits constructed by the National Telephone Company have been so fitted. Such a discharger, costing only a few pence, would in all probability have shunted the lightning to earth, and the inmates of the house might not have even been aware that a discharge had taken place. Telephones working with an earth return do not require such care as metallic circuits.

I recommend iron wire because, for the theoretical reasons adduced by Prof. Hughes and Dr. Oliver Lodge, iron is now widely admitted to be as effective as copper for currents appertaining to the character of lightning. When the greatest use has to be made of a certain sum I consider, theoretical reasons apart, that it is beyond comparison wiser to invest that sum in six or eight iron conductors than in one or two copper ones. Copper would be preferable on account of its greater durability when buried; but, still, galvanised iron will endure for years when so treated.

To secure immunity from lightning, certain invariable precautions have to be taken in all cases. These are specially, firstly, having at least one metal point—multiple points are much better—in as perfect connection with the earth as possible, preferably by several paths, raised above all stone, wood, and other non-conducting portions of the building. These points should be preferably over or quite close to the chimneys, unless wire cages are provided specially for them. Secondly, connecting all pipes, grates, bell-wires, and other masses of metal in the house to the conductors, preferably by means of soldered connections; when this cannot be managed, as with light and telephone leads, then by providing a small air space across which the discharge may jump harmlessly. Thirdly, by securing a good earth. When a house is built on rock, or on a thin stratum of soil over rock, or on chalk, this point requires special attention and study. Where gas and water pipes exist they should be joined to the conductors both above and below the ground, and gas and water meters should be bridged by soldered No. 5 wire. Even when water pipes exist Dr. Lodge considers it better to provide a separate earth for the conductor, also attaching it to the pipes; but this is a refinement I have not myself adopted when good water mains, always full, and jointed with lead, have been at hand.

In conclusion, I am able to show you some effects of a recent lightning storm, which emphasizes the necessity of having the highest point of any structure earthed. Last month a telephone wire erected on the tops of poles between Murtle and Cults in Aberdeenshire was struck. The wire was out of use, and was insulated at both ends, so that the lightning found no vent at the extremities. It accordingly struck through the solid porcelain insulators to the iron bolts supporting them, and jumped thence to the earth-wire, which was stapled up the poles to within an inch or two of the bolts. It shattered the insulators on the 1st, 2nd, 7th, 15th, and 35th poles, counting from Murtle. At three of the poles the wire, No. 18, B.W.G. silicium bronze, was fused, and at the foot of one pole the earth was disturbed and the grass burnt. Three of the insulators with fragments are on the table before you; the others were reduced entirely to small pieces, many of which could not be found. On one of those before you a metallic deposit from the fused wire is distinctly visible. Had each pole carried an earthed point raised above the topmost wire, the discharge would, almost to a certainty, have neglected the path of far higher resistance through the wire and porcelain, and all damage would have been avoided. This is a weak point in our telegraphic practice, common to Post Office, railway, and telephone companies, and one which I have raised my voice against for a good many years past. It is a curious question what the precise nature of the force is that splits porcelain in the manner shown. The destruction of trees and telegraph poles by lightning has been attributed to the sudden generation of steam in the pores of the wood due to the heat of the discharge or expansion by the heat of the air which the wood contains; but in porcelain there is neither moisture nor air, yet as you see, when it chances to intervene in the path of the least resistance, that does not prevent it from being split up and utterly destroyed.

THE LIGHT OF THE FIRE-FLY.

BY S. P. LANGLEY AND F. W. VERY.

In the *Philosophical Magazine* for September, the authors describe a research on "The Cheapest Form of Light," undertaken with the view of proving by actual measurement that the radiant energy emitted by the fire-fly is practically all utilised in producing luminous effect; and that the invisible heat rays which form so large and wasteful a proportion of the radiation emitted by all ordinary sources of light are, in this case, quite insignificant.

The chief results of the investigation are exhibited in the accompanying curves. In Fig. 1 a photometric comparison between

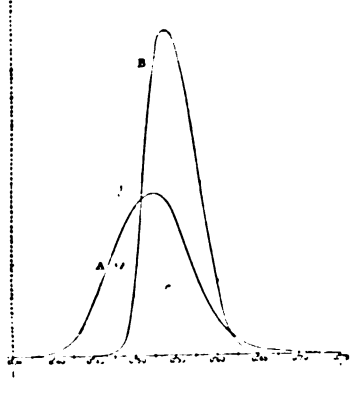

FIG. 1.

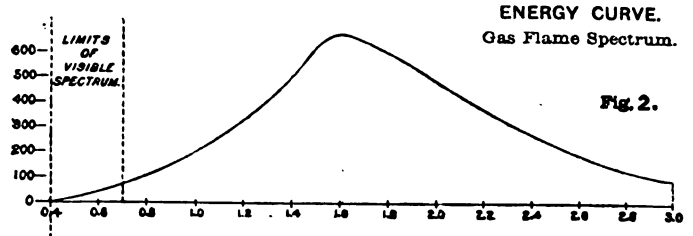
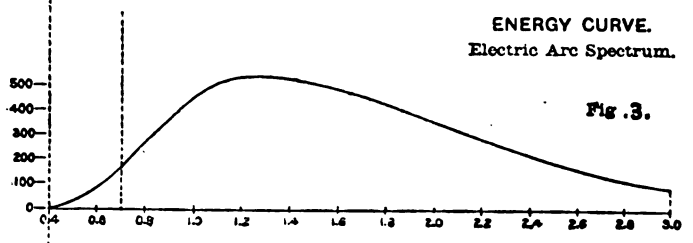
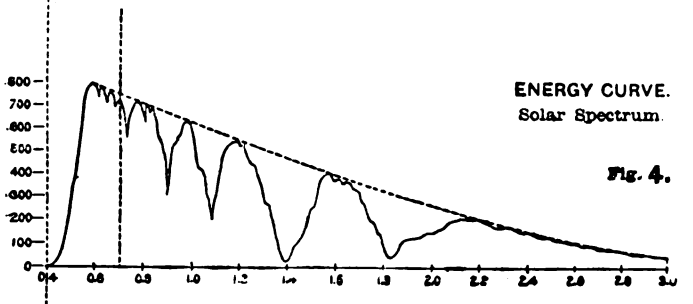
ordinary sunlight and the light of the fire-fly is exhibited by means of two curves, in each of which horizontal distances represent wave lengths, while ordinates denote luminous intensity as measured by a photometer. In the actual experiments the light of the sun was reduced until the total intensity of the rays tested was equal to that of the light given out by the fire-fly, before analysing either; and the curves have been so drawn as to have equal areas. It will be noted that while the maximum luminous intensity occurs in each curve in the neighbourhood of the yellow green rays the curve A for sunlight has a much broader base, and shows that the radiation of the sun is less confined to the rays, having the most intense luminous effect than is the case with the curve B, which represents fire-fly light. The four curves shown in Figs 2, 3, 4, and 5 are energy curves representing respectively the light emitted by the gas flame, the electric arc, the sun, and the fire-fly. In all these curves the abscissæ, or horizontal distances, represent wave lengths, as in Fig. 1; but the ordinates, instead of representing luminous intensity, denote the energy of the radiation of the particular kind represented by the corresponding abscissæ. The curves are drawn so that the area of each is the same. The

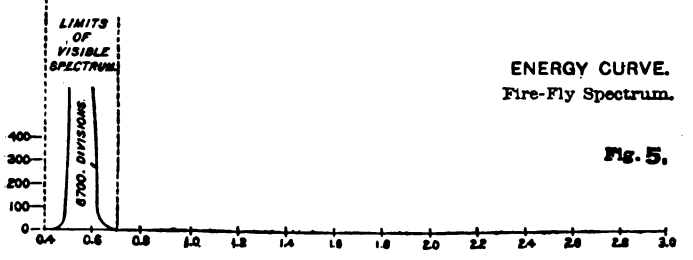
Digitized by Google

limits of the luminous spectrum are denoted by the dotted ordinates, and it is the area of the curve between these limits which represents the proportion of the energy actually used in producing luminous effect. The curve for the fire-fly is seen to lie entirely between these limits, and cannot be represented on the same scale owing to the magnitude of the ordinates; while the curve for the candle flame is such that only about one four-hundredth part of its area lies within the limits of the visible spectrum. If the light of the fire-fly could be manufactured on a large scale it would be far









cheaper than any other known form of light; and this does not appear impossible, since vital processes do not seem an essential feature in its production.

THE ELECTRO-MAGNET.*

BY PROF. SILVANUS P. THOMPSON.

(Continued from page 657.)

Let me show you yet another experiment. This is the same electro-magnet (Fig. 24) which has one flat pole and one rounded pole. Here is an armature, also bent, having one flat and one rounded pole. If I put flat to flat, and round to round, and pull at the middle, the flat to flat detaches first; but if we take round to flat, and flat to round, we shall probably find they are about equally good—it is hard to say which holds the stronger.

The law of traction can again be applied to test the so-called distribution of free magnetism on the surface: This is a subject on which I shall have to say a good deal. We must therefore carefully consider what is meant by the phrase. Let Fig. 26 be a rough drawing of an ordinary bar magnet. Every one knows that if we dip such a magnet into iron filings the small bits of iron stick on more especially at the ends, but not exclusively, and if you hold it under a piece of paper or cardboard, and sprinkle iron filings on the paper, you obtain curves like those shown on the diagram. They attest the distribution of the magnetic forces in the external space. The magnetism running internally through the body of the iron begins to leak out sideways, and finally all the rest leaks out in a great tuft at the end. These magnetic lines pass round to the other end, and there go in again, and the place where the steel is internally most highly magnetised is this place across the middle, where externally no iron filings at all stick to it. Now, we have to think of magnetism from the inside and not the outside. This magnetism extends in lines, coming up to the surface somewhere near the ends of the bar, and the filings stick on wherever the magnetism comes up to the surface. They do not stick on at the middle part of the bar, where the metal is really most completely permeated through and through

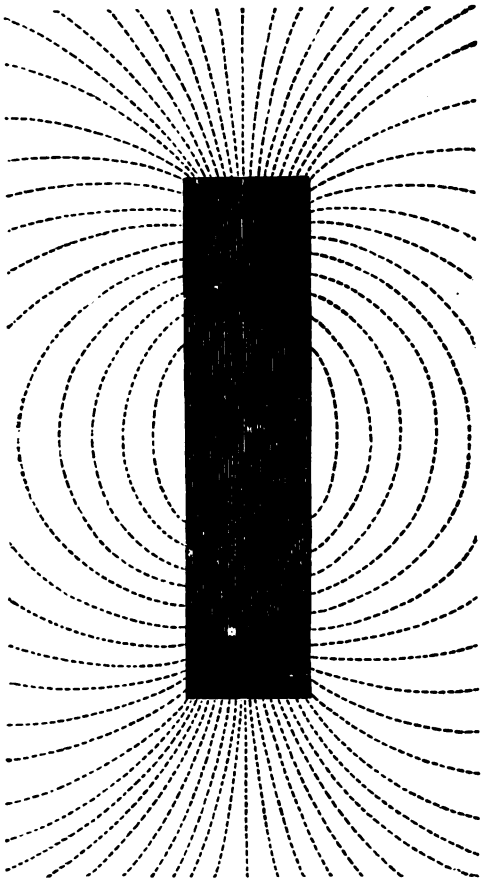


FIG. 26.—Lines of Force running through Bar Magnets.

by the magnetism; there are a larger number of lines per square centimetre of cross section in the middle region where none come up to the surface, and no filings stick on. Now, we may explore the leakage of magnetic lines at various points of the surface of the magnet by the method of traction. We can thereby arrive at a kind of measure of the amount of magnetism that is leaking, or, if you like to call it so, of the intensity of the "free magnetism" at the surface. I do not like to have to use these ancient terms, because they suggest the ancient notion that magnetism was a fluid or, rather, two fluids, one of which was plastered on at one end of the magnet, and the other at the other, just as you might put red paint or blue paint over the ends. I only use that term because it is already more or less familiar. Here is one of the ways of experimentally exploring the so-called distribution of free magnetism. The method was, I believe, originally due to Plücker; at any rate, it was much used by him. This little piece of apparatus was arranged by my friend and predecessor, Prof. Ayrton, for the purpose of teaching his students at the Finsbury College*. Here is a bar magnet of steel, marked in centimetres from end to end; over the top of it there is a little steel-yard, consisting of a weight sliding along an arm. At the end of that steel-yard there is suspended a small bullet of iron. If we bring that bullet into contact with the bar magnet anywhere near the end, and equilibrate the pull by sliding the counterpoise along the steel-yard arm, we shall obtain the definite pull required to detach that piece of iron. The pull will be proportional, by Maxwell's rule, to the square of the number of magnetic lines

* A series of four Cantor Lectures delivered before the Society of Arts, January—February, 1890.

* See Ayrton's *Practical Electricity*, Fig. 5a, p. 24.

Digitized by Google

coming up from the bar into it. Shift the magnet on a whole centimetre, and attach the bullet a little further on; now equilibrate it, and we shall find it will require a rather smaller force to detach it. Try it again, at points along from the end to the middle. The greatest force required to detach it will be found at the extreme corner, and a little less a little way on, and so on, until we find at the middle the bullet does not stick on at all, simply because there are here no magnetic lines leaking. The method is not perfect, because it obviously depends on the magnetic properties of the little bullet, and whether much or little saturated with magnetism. Moreover, the presence of the bullet perturbs the very thing that is to be measured. Leakage into air is one thing; leakage into air perturbed by the presence of the little bullet of iron, which invites leakage into itself, is another thing. It is an imperfect experiment at the best, but a very instructive one. This method has been used again and again in various cases for exploring the apparent magnetism on the surface. I shall use it hereafter, reserving the right to interpret the result by the light of the law of traction.

I now pass to the consideration of the attraction of a magnet on a piece of iron at a distance. And here I come to a very delicate and complicated question. What is the law of force of a magnet—or electro-magnets—acting at a point some distance away from it? I have a very great controversy to wage against the common way of regarding this. The usual thing that is proper to say is that it all depends on the law of inverse squares. Now, the law of inverse squares is one of those detestable things needing to be abolished, which, although it may be true in abstract mathematics, is absolutely inapplicable with respect to electro-magnets. The only use, in fact, of the law of inverse squares, with respect to electro-magnetism, is to enable you to write an answer when you want to pass an academical examination, set by some fossil examiner, who learned it years ago at the University, and never tried an experiment in his life to see if it was applicable to an electro-magnet. In academical examinations they always expect you to give the law of inverse squares. What is the law of inverse squares? We had better understand what it is before we condemn it. It is a statement to the following effect—that the action of the magnet (or of the pole some people say), at a point at a distance away from it, varies inversely as the square of the distance from the pole. There is a certain action at one inch away. Double the distance; the square of that will be four, and, inversely, the action will be $\frac{1}{4}$; at double the distance the action is $\frac{1}{4}$; at three times the distance the action is $\frac{1}{9}$, and so on. You just try it with any electro-magnets; nay, take any magnet you like, and unless you hit upon the particular case, I believe you will find it to be universally untrue. Experiment does not prove it. Coulomb, who was supposed to establish the law of inverse squares by means of the torsion balance, was working with long thin needles of specially hard steel, carefully magnetised so that the only leakage of magnetism from the magnet might be as nearly as possible leakage in radiating tufts at the very ends. He practically had point-poles. When the only surface magnetism is at the end faces, the magnetic lines leak out like rays from a centre, in radial lines. Now the law of inverse squares is never true except for the action of points; it is a "point" law. If you could get an electro-magnet or a magnet, with poles so small in proportion to its length that you can consider the end face of it as the only place through which magnetic lines leak up into the air, and the ends themselves so small as to be relatively mere points; if, also, you can regard those end faces as something so far away from whatever they are going to act upon that the distance between them shall be large compared with their size, and the end itself so small as to be a point, then, and then only, is the law of inverse squares true. It is a law of the action of points. What do we find with electro-magnets? We are dealing with pieces of iron which are not infinitely long with respect to their cross section, and generally possessing round or square end faces of definite magnitude, which are quite close to the armature; and which are not so infinitely far away that you can consider the polar face a point as compared with its distance away from the object upon which it is to act. Moreover, with real electro-magnets there is always lateral leakage; the magnetic lines do not all emerge from the iron through the end face. Therefore, the law of inverse squares is not applicable to that case. What do we mean by a pole, in the first place? We must settle that before we can even begin to apply any law of inverse squares. When leakage occurs all over a great region, as shown in this diagram, every portion of the region is polar; the word polar simply means that you have a place somewhere on the surface of the magnet where filings will stick on; and if filings will stick on to a considerable way down toward the middle, all that region must be considered polar, though more strongly at some parts than at others. There are some cases where you can say that the polar distribution is such that the magnetism leaking through the surface acts as if there were a magnetic centre of gravity a little way down, not actually at the end; but cases where you can say there is such a distribution as to have a magnetic centre of gravity are strictly few. When Gauss had to make up his magnetic measurements of the earth, to describe the earth's magnetism, he found it absolutely impossible to assign any definite centre of gravity to the observed distribution of magnetism over the northern regions of the earth; that, indeed, there was not in this sense any definite magnetic pole to the earth at all. Nor is there to our magnets. There is a polar region, but not a pole; and if there is no centre of gravity of the surface magnetism that you can call a pole from which to measure distance, how about the law of inverse squares? Allow me to show you an apparatus (Fig. 27), the only one I ever heard of in which the law of inverse squares is true. Here is a very long thin magnet of steel, about 3ft. long, very carefully magnetised, so as to have no leakage until quite close up to the end. The consequence is that for practical purposes you may treat this as a magnet having point poles about an inch away from the ends. The south pole is upwards, and the north pole is below, resting in a groove in a base-board which is graduated with a scale, and is set in a direction east and west. I use a long magnet, and keep the south pole well away, so that it shall not perturb the action of the north pole, which being small, I ask to be allowed to consider as a point. I am going to consider this point as acting on a small compass needle suspended over a card under this glass case constituting a little magnetometer. If this were properly arranged in a room free from all other magnets, and set so that that needle shall point north, what will be the effect of having the north pole of the long magnet at some distance eastwards? It will repel the north end and attract the south, producing a certain deflection which we can read off; reckoning the force which causes it by calculating the tangent of the angle of the deflection. Now, let us move the north pole (regarded as a point) nearer or farther, and study the effect. Suppose we halve the distance from the pole to the indicating needle, the deflecting force at half the distance is four times as great; the force at double the distance is one quarter as great. Wherefore? Because, firstly, we have taken a case where the distance apart is very

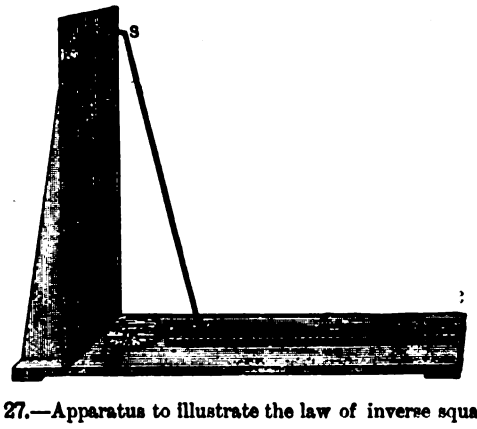

FIG. 27.—Apparatus to illustrate the law of inverse squares.

great, compared with the size of the pole; secondly, the pole is practically concentrated at a point; thirdly, there is only one pole acting; and, fourthly, this magnet is of hard steel, and its magnetism in no way depends on the thing it is acting on, but is constant. I have carefully made such arrangements that the other pole shall be in the axis of rotation, so that its action on the needle shall have no horizontal component. The apparatus is so arranged that whatever the position of that north pole, the south pole, which merely slides perpendicularly up and down on a guide, is vertically over the needle, and therefore does not tend to turn it round in any direction whatever. With this apparatus one can approximately verify the law of inverse squares. But this is not like any electro-magnet ever used for any useful purpose. You do not make electro-magnets long and thin, with point-poles a very large distance away from the place where they are to act; no, you use them with large surfaces close up to their armature.

There is yet another case which follows a law that is not a law of inverse squares. Suppose you take a bar magnet, not too long, and approach it broadside-on towards a small compass needle (Fig. 28). Of course, you know as soon as you get anywhere near the compass needle it turns round. Did you ever try whether the effect is inversely proportional to the square of the distance reckoned from the middle of the compass needle to the middle of the magnet? Do you think that the deflections will vary inversely with the squares of the distances? You will find they do not. When you place the bar-magnet like that, broadside-on to the needle, the deflections vary as the cube of the distance, not the square.

Now, in the case of an electro-magnet pulling at its armature at a distance, it is utterly impossible to state the law in that misleading way. The pull of the electro-magnet on its armature is not proportional to the distance, nor to the square of the distance, nor to the cube, nor to the fourth power, nor to the square-root, nor to

Digitized by Google

the three-half root, nor to any other power of the distance whatever, direct or inverse, because you find, as a matter of fact, that as the distance alters, something else alters too. If your poles were always of the same strength, if they did not act on one another, if they were not affected by the distance in between, then some such law might be stated. If we could always say, as we used to say in the old language, "at that pole," or "at that point," there are to be considered so many "units of magnetism," and at that other place so many units, and those are going to act on one another; then you could, if you wished, calculate the force by the law of inverse squares. But that does not correspond to anything in fact, because the poles are not points, and further, the quantity of magnetism on them is not a fixed quantity. As soon as the iron armature is brought near the pole of the electro-magnet there is a mutual interaction; more magnetic lines flow out from the pole

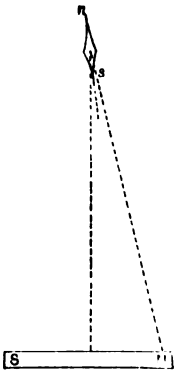

FIG. 28.—Deflection of needle caused by bar magnet broadside-on.

than before, because it is easier for magnetic lines to flow through iron than through air. Let us consider a little more narrowly that which happens when a layer of air is introduced into the magnetic circuit of an electro-magnet. Here we have (Fig. 29) a closed magnetic circuit, a ring of iron, uncut, such as that on which we experimented last week. The only reluctance in the path of the magnetic lines is that of the iron, and this reluctance we know to be small. Compare Fig. 29 with Fig. 30, which represents a divided ring with air gaps in between the severed ends. Now air is a less permeable medium for magnetic lines than iron is, or, in other words, it offers a greater magnetic reluctance. The magnetic permeability of iron varies, as we know, both with its quality and with a degree of magnetic saturation. Reference to Table III. shows that if the iron has

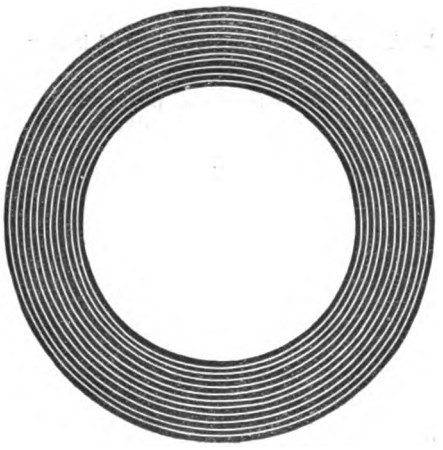

FIG. 29.—Closed magnetic circuit.

been magnetised up so as to carry 16,000 magnetic lines per square centimetre, the permeability at that stage is about 320. Iron at that stage conducts magnetic lines 320 times better than air does; or air offers 320 times as much reluctance to magnetic lines as iron (at that stage) does. So then the reluctance in the gaps to magnetisation is 320 times as great as it would have been if the gaps had been filled up with iron. Therefore, if you have the same magnetising coil with the same battery at work, the introduction of air-gaps into the magnetic circuit will, as a first effect, have the result of decreasing the number of magnetic lines that flow round the circuit. But, this first effect itself produces a second effect. There are fewer magnetic lines going through the iron. Consequently, if there were 16,000 lines per square centimetre before there will now be fewer—say only 12,000 or so. Now refer back to Table III., and you will find that when B is 12,000 the permeability of the iron is not 320 but 1,400 or so. That is to say, at this stage, when the magnetisation of the iron has been pushed only so far, the magnetic reluctance of air is 1,400 times greater than that of iron, so that there is a still greater relative throttling of the magnetic circuit by the reluctance so offered by the air-gaps.

Apply that to the case of an actual electro-magnet. Here is a diagram, Fig. 31, representing a horse shoe electro-magnet with an armature of equal section in contact with it. The actual electro-magnet for the experiment is here on the table. You can calculate

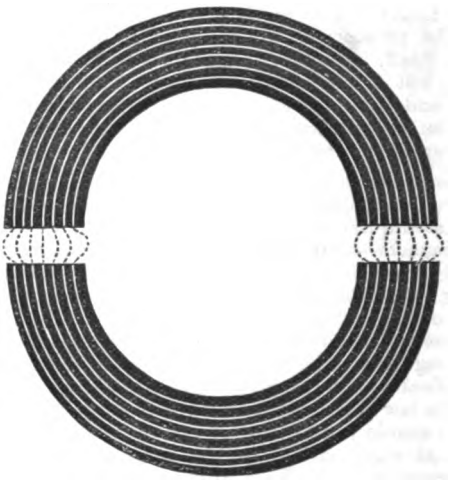

FIG. 30.—Divided magnetic circuit.

out from the section, the length of iron, and the table of permeability, how many ampere-turns of excitation will produce any required pull. But now consider that same electro-magnet, as in Fig. 32, with a small air-gap between the armature and the polar faces. The same circulation of current will not now give you as much magnetism as before, because you have interposed air gaps; and by the very fact of putting in reluctance there, the number of magnetic lines is reduced.

Try, if you like, to interpret this in the old way by the old notion of poles. The electro-magnet has two poles, and these excite in-

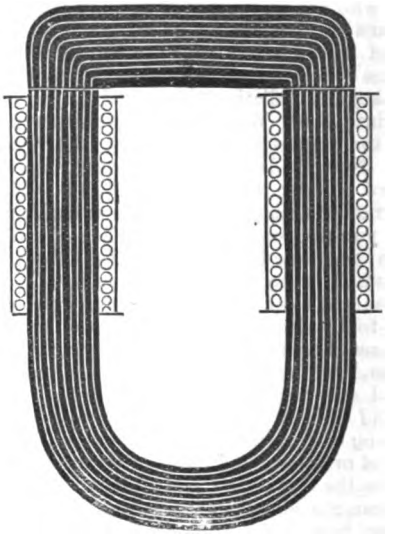

FIG. 31.—Electro-magnet with armature in contact.

duced poles in the opposite surface of the armature, resulting in attraction. If you double the distance from the pole to the iron, the magnetic force (always supposing the poles are mere points) will be one quarter, hence the induced pole on the armature will only be one quarter as strong. But the pole of the electro-magnet is itself weaker. How much weaker? The law of inverse squares does not give you the slightest clue to this all-important fact. If you cannot say how much weaker the primary pole is, neither can you say how much weaker the induced pole will be, for the latter depends upon the former. The law of inverse squares in a case like this is absolutely misleading.

Moreover, a third effect comes in. Not only do you cut down the magnetism by making an air-gap, but you have a new consideration to take into account. Because the magnetic lines, as they

Digitized by Google

pass up through one of the air-gaps along the armature, down the air-gap, at the other end, encounter a considerable reluctance, the whole of the magnetic lines will not go that way ; a lot of them will take some shorter cut, although it may be all through air, and you will have some leakage across from limb to limb. I do not say you never have leakage under other circumstances ; even with an armature in apparent contact there is always a certain amount of sideway leakage. It depends on the goodness of the contact. And if you widen the air-gaps still further, you will have

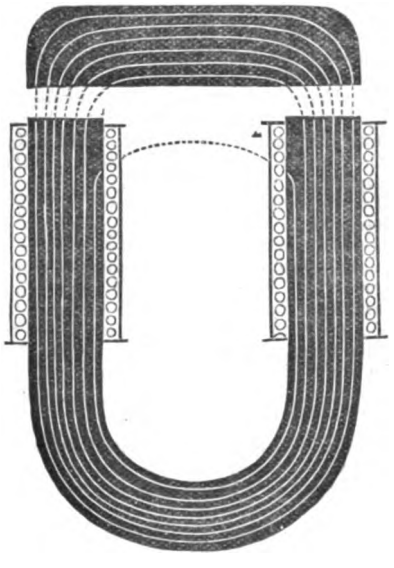

Fig. 32.—Electro-magnet with air-gaps one millimetre wide.

still more reluctance in the path, and still less magnetism, and still more leakage. Fig. 33 roughly indicates this further stage, The armature will be far less strongly pulled, because, in the first place, the increased reluctance strangles the flow of magnetic lines, so that there are fewer of them in the magnetic circuit ; and, in the second place, of this lesser number only a fraction reach the armature because of the increased leakage. When you take the armature entirely away the only magnetic lines that go through the

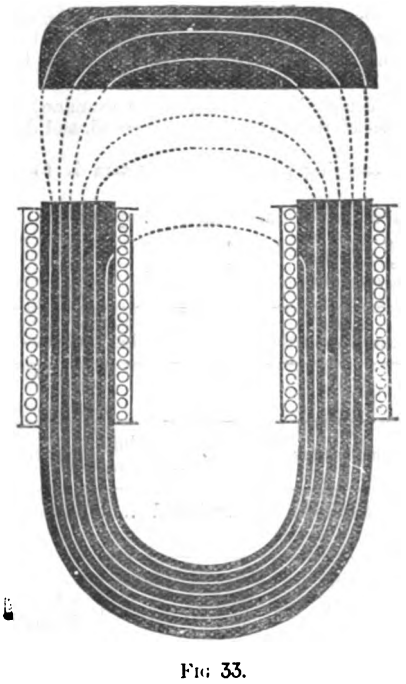

Fig 33.

iron are those that flow by leakage across the air from the one limb to the other. This is roughly illustrated by Fig. 34 the last of this set.

Leakage across from limb to limb is always a waste of the magnetic lines, so far as useful purposes are concerned. Therefore it is clear that, in order to study the effect of introducing the distance between the armature and the magnet, we have to take into account the leakage ; and to calculate the leakage is no easy matter. There are so many considerations that occur as to that which one has to take into account, that it is not easy to choose the right ones and leave the wrong ones. Calculations we must make by-and-by—they will be added as an appendix to this lecture—but for the moment experiment seems to be the best guide.

I will, therefore, refer, by way of illustrating this question of leakage, to some experiments made by Sturgeon. Sturgeon had a long tubular electro-magnet made of a piece of old musket barrel of iron wound with a coil ; he put a compass needle about a foot away, and observed the effect. He found the compass needle deflected about 23deg. ; then he got a rod of iron of equal length and put it in at the end, and found that putting it in so that only the end was introduced—in the manner I am now illustrating to you on the table—the deflection increased from 23deg. to 37deg. ; but when he pushed the iron right home into the gun barrel it went back to nearly 23deg. How do you account for that ? He had unconsciously increased its facility for leakage when he lengthened out the iron core. And when he pushed the rod right home into the barrel, the extra leakage which was due to the added surface could not and did not occur. There was additional cross-section ; but what of that ? The additional cross-section is practically of no account. You want to force the magnetism across some 20in. of air, which resists from 300 to 1,000 times as much as iron. What is the use of doubling the section of the iron ? You want to reduce the air reluctance, and you have not reduced the air by putting a core into the tube.

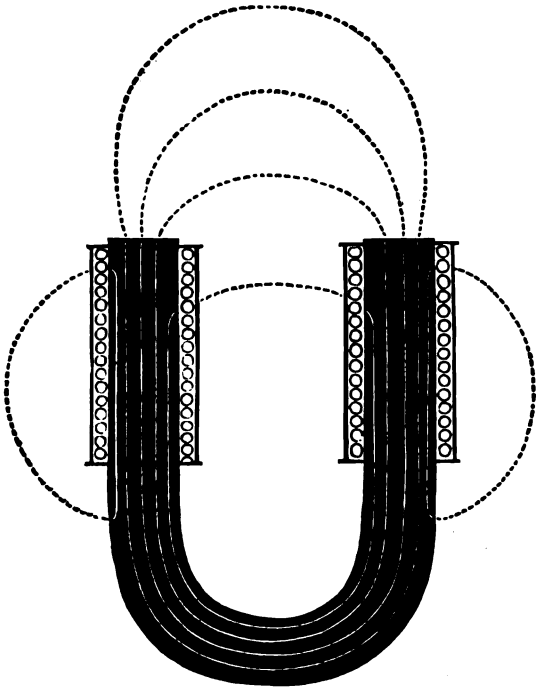

Fig. 34

There is a paradoxical experiment which we will try next week, that illustrates an important principle. If you take a tubular electro-magnet and put little pieces of iron into the ends of the iron tube that serves as core, and then magnetise it, the little pieces of iron will try to push themselves out. There is always a tendency to try and increase the completeness of the magnetic circuit ; the circuit tends to re-arrange itself so as to make it easier for the magnetic lines to go round.

Here is another paradoxical experiment. I have here a bar electro-magnet, which we will connect to the wires that bring the exciting current. In front of it, and at a distance from one end of the iron core, is a small compass needle with a feather attached to it as a visible indicator, so that when we turn on the current the electro-magnet will act on the needle, and you will see the feather turn round. It is acting there at a certain distance. The magnetising force is mainly spent not to drive magnetism round a circuit of iron, but to force it through the air, flowing from one end of the iron core out into the air, passing by the compass needle, and streaming round again, invisible, into the other end of the iron core. It ought to increase the flow if we can in any way aid the magnetic lines to flow through the air. How can I aid this flow ? By putting on something at the other end to help the magnetic lines to get back home. Here is a flat piece of iron. Putting it on here at the hinder end of the core ought to help the flow of magnetic lines. You see that the feather makes a rather larger excursion. Taking away the piece of iron diminishes the effect. So also in experiments on tractive power, it can be proved that the adding of a mass of iron at the far end

Digitized by Google

of a straight electro-magnet greatly increases the pulling power at the end that you are working with; while, on the other hand, putting the same piece of iron on the front end as a pole-piece greatly diminishes the pull. Here, clamped to the table, is a bar electro-magnet excited by the current; and here is a small piece of iron attached to a spring balance, by means of which I can measure the pull required to detach it. With the current which I am employing the pull is about 2½lb. I now place upon the front end of the core this block of wrought iron; it is itself strongly held on; but the pull which it itself exerts on the small piece of iron is small. Less than half a pound suffices to detach it. I now remove the iron block from the front end of the core, and place it upon the hinder end. And now I find that the force required to detach the small piece of iron from the front end is about 3½lb., instead of 2½lb. The front end exerts a bigger pull when there is a mass of iron attached to the hinder end. Why? The whole iron core, including its front end, becomes more highly magnetised, because there is now a better way for the magnetic lines to emerge at the other end and come round to this. In short, we have diminished the magnetic reluctance of the air part of the magnetic circuit, and the flow of magnetic lines in the whole magnetic circuit is thereby improved. So it was also when the mass of iron was placed across the front end of the core; but the magnetic lines streamed away backwards from its edges; and few were left in front to act upon the small bit of iron. So the law of magnetic circuit action explains this anomalous behaviour. Facts like these have been well known for a long time to those who have studied electro-magnets. In Sturgeon's book there is a remark that bar-magnets pull better if they are armed with a mass of iron at the distant end, though Sturgeon did not see what we now know to be the explanation of it. The device of fastening a mass of iron to one end of an electro-magnet in order to increase the magnetic power of the other end was patented by Siemens in 1862.

(To be continued.)

REGULATIONS FOR THE ERECTION OF ELECTRIC WORK IN HANOVER.

A very elaborate set of regulations have been drawn up by the municipal authorities of the town of Hanover. On the recommendation of Prof. F. W. Kohlrausch, the Town Council voted 1,500,000 marks at the end of last year, for the erection of a 15,000 light central station. The Municipality are undertaking the laying of the mains on the three-wire system, the work being carried out by Messrs. Schuckert and Co. Contractors for wiring have to obtain a certificate from the Town Council, and these certificates, it appears, can only be obtained by those firms who have previously carried out electric light work in a satisfactory manner. These certificates are liable to be withdrawn, and the holders are liable for compensation to the town for any damage arising from work carried out in a faulty manner. Plans and samples have to be submitted before the work is commenced, and it has to be passed by a municipal inspector before connection may be made to the town mains.

After some general rules, which we have epitomised above, the following regulations are given:—

14. The general arrangement of conductors and all apparatus pertaining thereto is to be such that all parts of the installation are capable of easy inspection and access, and that in the event of any breakdown in working occurring it can be easily and quickly put right. The main conductors, with the switches requisite for the branch leads, and the safety cut-outs are to be in easily accessible places, and as far as possible grouped at chosen spots by the use of switchboards.

15. The system of interior wiring may be carried out on the simple two-wire system where the expected consumption does not exceed 1,500 watts (about 30 16 candle-power glow-lamps, or their equivalent).

Installations for an expected consumption of 1,500 to 3,000 watts (30 to 60 16 candle-power glow-lamps or their equivalent) are to be first divided into two as nearly equal as possible groups and equal sets of glow-lamps, not exceeding 10 in number (*see* § 21), are to be taken alternately from each group and connected on either side of a three-wire system, each half of which will always supply an approximately equal number of lights.

Installations for a consumption expected to exceed 3,000 watts are to be so arranged that the three-wire system is carried out in the house itself for all leads which supply more than 1,500 watts.

For each 3,000 watts such a system of leads is to be provided. The further distribution is to be so arranged that as nearly as possible equal numbers of lamps are supplied on each side of the system. In such three-wire systems the middle wire is to be of the same section as the two outside ones, except when this section exceeds 35 square millimetres, when the middle wire may be of the nearest smaller section. (*See* § 19).

When groups of more than ten glow lamps are placed together, and are all operated by the same switch (big crown lights, theatres, &c.,) the middle wire in the three-wire system may be omitted, so that two lamps are in series.

As to the necessary safety cut-outs *see* § 21.

16. The maximum allowable fall of potential in the leads from the meters to the place where any branch takes off is not to exceed 1·5 volts. No variation from this rule will be allowed except by express permission of the Municipal Electric Works.

In the case of arc lamps this test can be made at the lead fuse belonging to the lamp, from which point through the lamps, two or four in series, a fall of from 15 to 30 volts may occur. In arc lamps in the open this fall may occur in the conductor, which may be of galvanized iron.

17. The section of conductor necessary is to be calculated from the following:—

(*a*) For each incandescent lamp (mean voltage 107 volts) is to be laid a branch calculated on the basis of ·8 ampere. For incandescent lamps of over 32 normal candles the exact current strength necessary is to be considered.

(*b*) For each arc lamp a current of at least 10 amperes is to be taken; arc lamps requiring a larger current, however, have this taken into consideration.

(*c*) For electromotors and other applications of the current, the conductors are calculated on the basis of a current one and a half times its normal value. The capacity of fuses, switches, &c., is to be chosen accordingly.

The sections as calculated are always to be examined, to see that the allowable capabilities of the wires are not exceeded, and dangerous heating is avoided.

The maximum carrying power of conductors is to be reckoned as follows:—

For a section up to	4	square mm.	3	amperes per square mm.
,, ,,	6	,,	2·5	,, ,,
,, ,,	100	,,	2	,, ,,
,, ,,	over 100	,,	1·5	,, ,,

§ 18. The choice of conductors, insulation, and mode of fixing, is to be determined according to the following table:—

Description of Conductor.	Positions.					
	Under floors or cornices.	Open air.	Dry rooms.	Damp rooms.	Rooms containing gases or vapours.	Lighting apparatus.
Bare wire	Not allowed	Porcelain insulators.	Not allowed	Not allowed ..	Not allowed ...	Not allowed.
Insulated wire (flexible cords, I.-R. or G.P. covered wire.)	In ceilings or dry cornices, on porcelain insulators with wood casing, or in metal tubes (with free access for air).	Porcelain insulators.	Porcelain insulators or cleats, wood casing or cleats.	Porcelain insulators.	Porcelain insulators.	Loose inside tubes, which are secured by insulating bands or metal strips.
Plain lead cable ...	Not allowed	Porcelain cleats, wood cleats, metal cleats (with soft packing).	Wood casing, wood or metal cleats (with soft packing).	Not allowed ..	Not allowed ...	Not allowed.
Asphalted lead cable.	As for insulated wire ...	Wood or metal cleats.	Wood casing, wood or metal cleats.	Tinned metal cleats.	Not allowed ...	If necessary, as for insulated wires.
Iron-sheathed lead cable.	Without further precautions.	Wood or metal cleats.	Wood casing, wood or metal cleats.	Tinned metal cleats.	Not allowed ...	If necessary, as for insulated wires.

Digitized by Google

Arrangement of Switches.

20. All switches, &c., employed must be so arranged that the conducting parts are surrounded by uninflammable materials well insulated from each other and from external objects. In particular all switchbases, &c., are to be uninflammable and of good insulating properties, especially in damp situations.

The switches shall be as far as possible brought together and fixed at suitable places on switchboards at such an elevation that they can be easily reached and attended to without the help of special appliances. In order to prevent their being meddled with, they are to be provided with covers.

In rooms in which combustible gases and vapours exist, or solid bodies in the shape of dust which form with air an explosive mixture, all switches are to be enclosed in perfectly air-tight casing; similarly also for rooms where corrosive fumes or gases arise. In such cases it is advisable to place all switches outside.

21. *Safety fuses.*—In the branch conductors, no more than 10 incandescent lamps may ever depend upon the same fuse.

The disposal of the lamps on the several branches must always be so effected that when more than five lamps are employed in one room, they are not all dependent on one and the same fuse. Fuses are to be so placed as to prevent every lamp, perhaps in more than one room, being extinguished through the melting of any one fuse.

The use of single pole cut-outs is not allowed. With two conductors, two pole cut-outs, and with three conductors three pole cut-outs are to be put up.

The two wire conductors branching from three wire systems (*see* § 15) are to be provided at the junction with movable cut-outs, so as to allow the branch to be connected on to either side of the three-wire system. These movable lead cut-outs are to be obtained from the Municipal Electric Works.

All fuse boxes are to be constructed so as to fit the lead fuses to be supplied by the Municipal Electric Works, and to be clearly marked with numbers corresponding with the numbers of the lead fuses.

The bases must be of fire-proof material of good insulating properties, even in damp rooms. The requisite cases are also to be made of fire-proof material. The construction of the cut-outs is to be such as to wholly obviate the possibility of their operating erroneously or in a dangerous manner. They shall operate as soon as a current twice as great as that allowed according to the capacity of the wire (*see* § 17) shall pass through the fuse.

The above rules hold good also for automatic mechanical safety cut-outs.

Mercury contacts will only be allowed by special permission of the Municipal Electric Works.

The design (which will be uniform) for the cut-outs to be used will be decided upon by the Municipal Electric Works, so that it shall be easily possible for their officials to inspect or otherwise attend to them.

22. Switches are to be placed on fireproof insulating bases, and to be covered with a fireproof casing, enclosing all parts through which the current passes. The making and breaking must always be the result of a springing action at both poles, and in all cases must be so constructed that the spring can only be at rest when it is at one end or the other of its play, *i.e.*—when the circuit is either closed or open. Where the three-wire system is in use, making and breaking is to be simultaneously effected at both external conductors.

Single-pole switches are only allowable in lamp fittings, and for single branches up to 10 incandescent lamps, and for arc light wires up to 10 amperes, which are connected to the leads by double-pole switches. It is to be noted that these single-pole switches are only to be used on one of the two external conductors, and never on the middle conductor of a three-wire system.

Rubbing contacts only may be used in which there is at least one square millimetre of contact surface for every tenth of an ampere.

In the case of switches with lever handle, the turning of the handle to the left or downwards is to open the circuit; turning it to the right or upwards is to close it, unless the switch is marked with special indications such as "closed," "open," or their equivalents.

Switches without handles are to be so arranged that it is possible to tell whether the circuit is open or closed without removing the cover.

Switches are to be conspicuously marked with the maximum current in amperes that they are allowed to carry.

In every installation a main switch for cutting off from the mains is to be provided close to the meter, and in an accessible position. If the conductors are divided into several branches behind the spot where they enter, each branch may be provided with a switch, and the main switch above referred to may be dispensed with.

In other respects the fixing of switches will depend upon circumstances. It is to be observed that it is only possible to extinguish all the lights by opening the main switch.

23. All resistances (rheostats) for arc lamps, &c., shall be so calculated that they shall reach at the highest a temperature of 50° C. Heating to a higher temperature, and especially to a red heat, is to be prevented. They must be well insulated and fastened to, and surrounded by fire-proof material. For such resistances iron, nickel, German silver, wire, &c., may be used, as well as copper.

24. Switchboards may best be placed at those spots on each floor of any installation where a large number of fuses, switches, resistances, &c., can readily be brought together in a place where they can be easily seen.

Switchboards, as well as the protecting cases belonging to them, are to be made of a non-combustible material, or of hard wood. All bright metal parts are to be covered, and interference on the part of incompetent persons is to be impossible.

The terminal strips on the switchboards, if of copper, must not carry more than 2 amperes; if of brass, not more than ½ ampere per square millimetre of section. Terminal strips lying next to one another must have a space of at least 3 centimetres between them. All crossing of the wires at the switchboards is to be avoided.

25. Meters are to be arranged and fixed exclusively by the Municipal Electric Works, and are to be hired by the consumers.

The sizes of the meters and the places where they are to be put are to be determined by the Municipal Electric Works.

The choice of a position will be made with due regard to its proximity to the street mains, and to the ease and convenience with which it may be got at without using stools, ladders, &c. Care will also be taken that bringing in the connecting cable shall present no particular difficulties, and that separate installations in the same house can be readily branched off when necessary.

If desired separate meters can be fitted to different parts of any installation.

Consumption of Current.

26. The choice of incandescent lamps is left to the consumers. It will, however, be to their advantage to obtain the lamps exclusively from the Municipal Electric Works.

For new installations only incandescent lamps with Edison filament, and for a normal mean tension of 107 volts will be allowed. For the connection of already existing installations further conditions are to be complied with.

The conductors of the lampholders must be insulated and fixed on to the lamp, and covered with a fireproof casing.

Suspending the lamp-holders directly on to the conductors is not allowed.

The use of glow lamps is permitted in all rooms; but where gases, vapours, or dust, that are inflammable, explosive or deleterious to metals, are produced (*see* § 20), the lamps must be enclosed in air-tight glass shades which also cover the connections between the lamps and the conductors.

27. The choice of arc lamps and the necessary carbons is also left to the consumers, but the Municipal Electric Works may express a decision on them and their applicability. It will, however, be advisable to obtain the lamps and the carbons from the Municipal Electric Works.

Arc lamps are to be supplied with wired globes provided with ash-holders to catch the droppings from the carbons. The globes must be securely attached to the lamp frames by means of clamps, and during the setting of the carbons must be suspended by chains, &c.

The lamps themselves are to be insulated as well as possible from their supports.

The use of the electric conductors for supporting the lamps is not allowable.

The lamps are to be brought into position by means of wire cords; letting down the lamps by incompetent persons is to be prevented.

The lamp attendants are to be particularly enjoined that the lamps are to be switched off before they are let down for the purpose of setting the carbons, regulating, &c.

The use of arc lamps in rooms in which explosive or easily inflammable gases and the like exist is absolutely forbidden.

28. The supply and erection of electro-motors* and their appurtenances is to be undertaken by the Municipal Electric Works or their agents.

29. The use of heating and cooking apparatus* is allowable, subject to the express permission of the Municipal Electric Works having been obtained.

With regard to laying, fixing, and insulating the conductors, &c., instructions are given that protecting casings are to be provided wherever the wires are liable to be meddled with or damaged, as, for instance, when they are placed within 2½ metres from the floor. Protecting tubes of vulcanite, china, or glass are to be used where wires are carried through walls, a separate tube being used for each wire, and no two tubes being placed within one centimetre of each other. In carrying conductors through flooring the protecting tubes are recommended to be placed inside gas-pipes, reaching at least 20 centimetres above the level of the floor. If for special reasons it is necessary to place wires inside walls or flooring, they have to be laid in channels of sheet iron at least two millimetres thick, and covered with slate or the like. For conveying wires through walls into the open air porcelain tubes with their mouths curved downwards are to be used. Soldered joints inside metal tubes are not allowed. In all cases it is to be observed that the air must have free access to the wires. Naked wires are only allowed in the open air at a height of not under 4 metres and not under 40 centimetres apart. They are to be supported on china insulators, and if long, to be protected by lightning conductors. They must not be brought within 1 metre of any telegraph or telephone wires. Where two wires cross they must either be held by a special fastening, so that they cannot approach within 2 centimetres of each

* Conductors for applying the current to commercial purposes must throughout their length be so marked that they cannot be mistaken for lighting conductors. Branching conductors for commercial purposes off the light leads, and *vice versâ*, is only allowable when special permission is granted.

Digitized by Google

other, or one of the wires must be provided with an insulating sleeve of vulcanite, porcelain, or glass, or kept away from the other wire by an insulating collar. Similar regulations apply wherever a conductor crosses any metal-work. Conductors are to be connected together only by soldered joints, but they may be connected to apparatus also by binding screws. In the latter case it is recommended to make a loop at the end of the wire. The best way of removing the insulation of a wire—that is, by scraping and not by a circular cut at right angles to the wire—is also pointed out. Instructions are given that all soldering is to be done with resin, and that the joints are to be cleaned and insulated when cold. The methods to be adopted for securing the ends of stranded conductors are also pointed out.

When wood casing is used it is directed that the breadth of the bridge between the two grooves must not be under 1 centimetre. The wires are to be laid in the casing without the use of staples, and free access is to be allowed to the air. Paperhangings must not be laid over the wood-casing except in perfectly dry rooms. Cylindrical porcelain insulators also may only be used in dry or slightly damp rooms. They are to be so placed that the wires are not within 4 centimetres of each other, and the distance between the insulators must not exceed 75 centimetres. The wires must be at least 1 centimetre from the wall. In damp rooms and where steam exists, as well as in the open air, porcelain insulators of the telegraph pattern are to be employed. They are to be so placed that the wires if bare are 40 centimetres apart, and if covered 20 centimetres apart. Porcelain lamps are subject to regulations similar to those for cylindrical insulators. Metal clamps and staples must be tinned. They are to be used principally for lead-covered cables, and in special cases for fastening insulated wires to wooden walls in dry rooms. They must not be more than 40 centimetres apart, and must hold the wires at a distance of 2 centimetres from each other. All wood casings, insulators, &c., are to be fixed to the walls by means of wood screws. Where conductors are attached to any apparatus, the nearest point at which the conductors are fixed must not be more than 10 centimetres distant.

Various regulations follow, giving the Municipal Works the right to test the installations, and for that purpose to run all the lamps, &c., on any installation for two hours, at the cost of the undertakers.

The insulation resistance between a complete installation, including wires, apparatus, lamps, &c., and the earth must be for 1,000 m. length of conductors at least 60,000 ohms; the total insulation resistance of any installation, whatever its magnitude, must not fall below 30,000 ohms. The following table is to apply both for complete installations and for individual branches thereof:

Total length of wires laid.	Necessary insulation resistance to earth.
Under 200 m.	300,000 ohms.
200 to 300 m.	200,000 ,,
300 to 500 m.	100,000 ,,
500 to 750 m.	80,000 ,,
750 to 1,000 m.	60,000 ,,
1,000 to 1,500 m.	40,000 ,,
1,500 and over	30,000 ,,

The insulation resistance between two wires lying parallel to each other must be at least 100,000 ohms for 1,000 m. of conductor. The insulation resistance of any piece of apparatus or lamp, &c., must not be under 500,000 ohms. All apparatus before being connected is to be tested for insulation by the undertakers, or submitted to the Municipal Works for that purpose. Similar regulations apply to extensions to installations previously connected to the Municipal mains. The starting of an installation, *i.e.*, the putting in position of the lead fuses and the connection of the house-wires to the meter, is in all cases to be effected by the Municipal Electric Works. If any defect is found by the tests, the installation may be cut off from the mains at the cost of the undertakers until such defect is removed. A deposit of 1,000 marks is to be placed by undertakers in the hands of the Town Council; if on account of additions or improvements ordered by the Municipal Works this sum is reduced, the undertakers must make a fresh deposit to raise it again to its original value. The Municipal Works are entitled to charge the undertakers certain sums for inspection, testing, &c. These fees are for installations of

1 to	5	glow lamps (16 candle-power) or their equivalent ...	5	marks.
6 ,,	10	,,	... 10	,,

These fees, if not paid within eight days, may be deducted from the sum deposited with the Town Council.

ON THE FORM OF SUBMARINE CABLES FOR LONG DISTANCE TELEPHONY.*

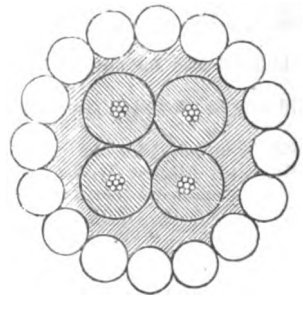
BY W. H. PREECE, F.R.S.

At the Newcastle meeting last year I gave the reasons and experiments which led to the conclusion that telephoning between London and Paris was practical. New and distinct aerial lines of four copper wires are now being erected by the respective Governments from each capital to the coast, and a new cable, the joint property of the two Governments, will be laid during this year, between the Kent coast and Sangatte, to connect these two lines. There will thus be two metallic circuits between the two capitals. The K R, that is the product of the capacity K, and the resistance R of each circuit, upon which the clearness of articulation depends, will be 5,900, indicating that speech should be excellent.

A somewhat similar circuit has been established, since October last, between Buenos Ayres and Monte Video, under my advice. The cables across the La Plata are each 28 miles long, for there are two separate single-wire cables, and the total distance between the two cities is 180 miles. Subscribers, who have metallic circuits in each city, have no difficulty whatever in speaking to each other from their respective offices, although the K R is as high as 10,400.

The cable across the Channel will be a four-wire cable, and the specification for its construction has been based on the following mathematical development by Mr. H. R. Kempe:—

The working capacity of the whole line is dependent upon the product of the total resistance, R, and the total capacity, K. Therefore, if we take the resistance of the aerial portion of the line to be a fixed quantity, there will be a particular size of cable conductor which will give the smallest possible size of dielectric, sufficient to enable a particular value of K R not to be exceeded. For, if we make the conductor larger than this size, and thereby diminish its resistance, we can, it is true, do with an increased



Section of the Telephonic Cable between England and France.

capacity; but the diminution in the thickness of the dielectric which could thereby be allowed, is more than compensated for by the fact that the surface of the conductor is larger; in other words, we increase the capacity in a greater proportion than we diminish the resistance. If, on the other hand, we diminish the size of the conductor, we increase the resistance in a greater proportion than we diminish the capacity. Strictly speaking, the requirements of the problem are to determine the size of cable core which shall *cost least*; but inasmuch as the costs of gutta-percha and copper, *bulk for bulk*, do not differ greatly, the problem resolves itself into the determination of the smallest outer diameter which can be employed.

Let r = total resistance of aerial line,
ρ = ,, ,, cable,
k = ,, capacity of aerial line,
κ = ,, ,, cable.

Then $$K R = (k+\kappa)(r+\rho).$$

Let D = diameter of dielectric of cable,
x = ,, conductor ,,

Then $$\rho = \frac{a}{x^2} \text{ and } \kappa = \frac{b}{\log_\epsilon \frac{D}{x}}$$

where a and b are constants.

We have, therefore,

$$K R = \left(k + \frac{b}{\log_\epsilon \frac{D}{x}}\right)\left(r + \frac{a}{x^2}\right).$$

* Abstract of Paper read before the British Association, Section G, Leeds, September, 1890.

Digitized by Google

Therefore

$$\log_\epsilon \frac{D}{x} = \frac{b\left(r + \frac{a}{x^2}\right)}{KR - k\left(r + \frac{a}{x^2}\right)}.$$

Therefore,

$$\log_\epsilon D = \frac{A + \frac{1}{x^2}}{B - \frac{C}{x^2}} + \log_\epsilon x = u, \text{ say,}$$

where

$$A = \frac{r}{a} \qquad B = \frac{KR - kr}{ab} \qquad C = \frac{k}{b}.$$

Now to make D a minimum we must make $\log_\epsilon D$ (that is, u) a minimum, and this we have to do by variation of x, therefore we have

$$\frac{du}{dx} = \frac{1}{\left(B - \frac{C}{x^2}\right)^2}\left\{\left(B - \frac{C}{x^2}\right)\frac{2}{x^3} - \left(A + \frac{1}{x^2}\right)\frac{2C}{x^3}\right\} + \frac{1}{x} = 0.$$

Therefore,

$$x^2 - x\frac{\sqrt{2(B + AC)}}{B} = \frac{C}{B}.$$

From which, by solving the quadratic equation, we get

$$x = \frac{\sqrt{B + AC} + \sqrt{B + AC + 2BC}}{\sqrt{2B}}.$$

Now, careful experiments made on aerial line of copper wire, weighing 200lb. per mile (diameter = 112 mils.), the wire being 30ft. above the ground, showed that the inductive capacity per mile was ·015 microfarads very nearly, consequently the capacity per mile is expressed by the formula ·061637/6·1583625 − log d, d being the diameter of the wire in mils. From this formula the capacity per mile of a wire weighing 400lb. works out ·0156 m.f. The average resistance per mile of this weight is 2·25 ohms.

Taking the distance between London and Dover to be 70 miles, and between Calais and Paris to be 180 miles, the total distance of the loop will be 500 miles, which for a 400lb. copper wire gives the resistance $r = 500 \times 2{\cdot}25 = 1{\cdot}125$ ohms.

Now, in the case of a looped wire, the total capacity equals half that of a single wire, hence $k = {\cdot}0156 \times 250/2 = 1{\cdot}95$.

Assuming the length of thecable to be 21 knots, we have approximately $\rho = 42 \times 74{,}402/x^2$ for copper of 98 per cent. conductivity at 60° F, so that $a = 3{,}124{,}884$.

The ordinary standard core used by the Post Office has a conductor diameter of 86·41 mils., and a gutta-percha diameter of 285 mils., and a capacity of 1/3 m.f. per knot, and as capacity per knot = const./ $\log \frac{D}{d}$, we have

$$\text{const.} = \frac{\log \frac{285}{82{\cdot}087}}{3} = {\cdot}18018997.$$

The capacity of 42 knots of looped cable will be half that of 21 knots of single cable, hence

$$\kappa = \frac{{\cdot}18018997 \times \frac{21}{2}}{\log \frac{D}{x}}.$$

so that $b = 4{\cdot}356481$.

We have then for 400lb. wire $a = 3{,}124{,}884$, $b = 4{\cdot}356481$, $r = 1{,}125$, $k = 1{\cdot}95$.

If we take K R = 7,500, which is the highest value that can safely be taken, we get B = ·000389779; A C = ·0001611454, so that $x = 97{\cdot}00014$ and extreme diameter of strand = 102·1054 mils. Since $KR = (k + \kappa)(r + \rho)$ we get $\kappa = 3{\cdot}197153$.

But

$$\kappa = \frac{1{\cdot}89199468}{\log \frac{D}{x}}$$

Therefore log D = 380 mils approximately.

If we take

$x = 95$	then	D = 378·94
,, 97·00014	,,	,, 378·86
,, 99	,,	,, 379·08

which proves the correctness of the calculation for a minimum.

The values of these diameters correspond very closely to a core, the weight of whose conductor is 160lb., and the weight of whose gutta-percha covering is 300lb., and it has therefore been decided to adopt these dimensions.

Although the calculation has been made on the assumption that the land lines on both sides of the cable are to be of 400lb. wire, the French Government have decided that the wires to be erected by them shall be of 600lb. weight; the result of this will be to reduce the value of K R to 5,900, as stated at the commencement of the Paper.

The specification of the cable states that:—(1) Each conductor shall be formed of a strand of seven copper wires all of equal diameter, shall weigh 160lb. per nautical mile, and shall at a temperature of 75° Fahrenheit have a resistance not higher than 7·632 ohms, or lower than 7·478 ohms per nautical mile.

(2) Each conductor shall be insulated by being covered with three alternate layers of Chatterton's compound and gutta-percha, beginning with a layer of the said compound, and no more compound shall be used than may be necessary to secure adhesion between the conductor and the layers of gutta-percha. The dielectric on each conductor shall weigh 300lb. per nautical mile, making the total weight of each conductor when covered with the dielectric 460lb. per nautical mile.

(3) The inductive capacity of such insulated conductor shall not exceed ·3045 microfarad per nautical mile.

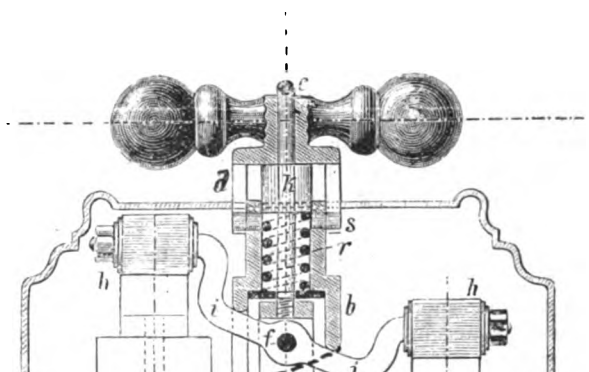
(4) The insulation resistance of such coil of core shall be not less than 500 megohms per nautical mile after such coil shall have been kept in water maintained at a temperature of 75° Fahrenheit for not less than 24 consecutive hours immediately preceding the test, and after electrification during one minute.

The cores (four in number) are to be served with the best wet fully tanned yarn, and with a sheathing of 16—280 mil. wires, each having a minimum breaking strain of 3,500lb., and a minimum of 10 twists in 6in. The section of the cable is shown by the figure.

THE MARCHER SWITCH.

A new switch that is being brought out by Herr Th. Marcher, of Neumarkt, near Nuremburg, appears to satisfy some of the more important conditions for this class of apparatus.

As may be seen from the figure, which shows a section through the centre, this switch (which is of the two-pole class) consists of a lever i, carrying the contact surfaces h, and working on the pin f. A hollow cylinder b, cut off helically at the base, is pressed down on to the lever by means of a spring r, which bears against the collar k on the fixed pin c. A second hollow cylinder, turning with the switch handle, is slotted at d, and rests on k. The slot d carries the pin s, which is fixed to the hollow cylinder b. The contacts h are insulated from the lever i.



Section of the Marcher Switch.

It will be clear that on turning the handle, so that the left-hand side moves downwards, the helical edge of the hollow cylinder b will slide over the arms of the lever i, the spring r thereby being compressed. As the pressures on both arms of the lever are equal, the contact is not disturbed until a half-turn is accomplished. The end of the helix has then arrived at the right-hand arm of the lever i, which is consequently suddenly released from all pressure on that side. The spring r then forces the cylinder b downwards, and the contact is instantly broken. Another half-turn causes the same action on the other side of the lever, and the circuit is suddenly closed again.

The only drawback to this ingenious arrangement is the nature of the contacts, which are solid brass wedges, forced between compact bundles of sheet copper. There is little, if any, sliding which is indispensable to a switch large or small.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October* 3, 1890.

Electric Traction.—Comparatively little new is occurring in electric circles just now. There is the usual crop of inventions of a more or less trivial character, and occasionally something more notable. A new supply system for street railways has just been patented, which is of some interest, albeit its merit is a matter for future experiment. It is of the same general character as the Pollock and Binswanger, Wheless, and several other recent tramways. The principal characteristic of this latest comer is an exceedingly ingenious system of cross wiring between consecutive sections, so that when a single one of the switches connecting a working conductor with a supply conductor is closed the operation will go on automatically as the car moves along without the necessity of carrying a battery on the car, or using any purely mechanical means of operating the successive switches. The Wheless is the only system of this character that has been given anything like a trial on this side of the Atlantic. There is a short experimental Wheless road in Washington, D.C., which operates fairly well, although it is not extensive enough to enable one to draw very sweeping conclusions as to its practicability on a commercial scale.

Electric Motors for Gunnery Purposes.—A novel use for the electric motor was shown a few days ago in the fitting of a Gatling gun, intended for use in the United States Navy, with a small motor to replace the crank by which that instrument of warfare is generally operated. The motor was supported by a bracket at the rear of the gun, and worked the breech mechanism through the medium of current. After the gun was thus fitted it was placed on one of the Government tugs and given a careful trial by the naval authorities. The result was highly satisfactory. A speed of firing as high as 1,000 shots per minute was attained without the least trouble, and the motor was so thoroughly controllable that single shots could be fired as readily as the gun could be operated at full speed. The officers present were much pleased with the results of the test, and it is not at all improbable that more weapons will be similarly fitted. In the same line is the electrical training of heavy guns. One of the new 8in. rifled guns is now being fitted with electrical training and elevating gear. Such an application, of course, is not novel, but it is new in the United States Navy, and all the improvements of former practice will probably be introduced into the present arrangements.

A Telephonic Central Station.—An attempt will, it is said, soon be made to organise a sort of telephonic concert company for furnishing music from a central station to regular subscribers at stated intervals. Experiments have been made on the details of telephones for reproducing music, and it may be that the plan will be carried through. Those who have it in hand seem to be quite in earnest about it, and say that a considerable number of subscribers can be obtained at once. At present, however, the telephone does not reproduce music with the fidelity that would be desirable if it were to be used on so large a scale.

CORRESPONDENCE.

MEASURING THE INSULATION RESISTANCE OF ELECTRIC LIGHT CIRCUITS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With regard to the method M. Boucherot suggests for the measurement of the insulation resistance of electric light circuits (*Electrician*, September 26, 1890), the idea of using the voltmeter in the manner described occurred to me, as an improvement on the dodge of putting lamps between the leads and earth, some time in 1887; and I have used it almost continuously since as a check on the insulation of the ship installations with which I have had to do.

The instrument is joined up so that it may be readily switched between the leads to measure the total voltage, or between one or other lead and earth, to measure the apparent voltage through the fault in the *opposite* lead—the ratio of the difference in these readings to the last giving the resistance of the fault in terms of the voltmeter resistance.

The arrangement is of great convenience, in so far as it enables the attendant to make sure that the circuits are free from serious leakage several times during the night; but I doubt with you that it would be very useful as a mode of obtaining reliable quantitative insulation tests, with an ordinary voltmeter, except in cases of rather long circuits.—Yours, &c.,

WALTER J. MURPHY,
Electrician in charge, Eastern Telegraph Co.'s C.S. Electra.
Malta, October 4, 1890.

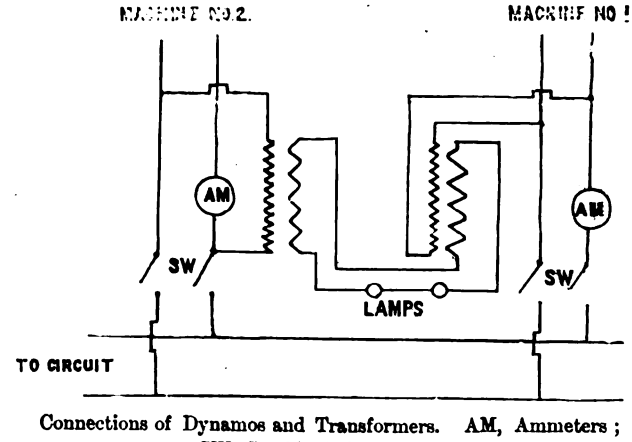
RUNNING ALTERNATORS PARALLEL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It may interest your readers to know that during the past few days we have tried running the Mordey Alternators here in parallel. The results have been in every way satisfactory.

As we had no synchroniser, we joined a transformer to each of the two machines, and put the secondaries in series with two incandescent lamps, so that when the two machines were in phase, the lamps were bright, as with an ordinary synchroniser. We tested the transformers for this by so connecting them both on to one machine that the two lamps in series were bright with the secondaries in series. We then transferred the primary wires of one transformer so as to connect it to the corresponding poles of the other machine.

We send you a sketch of the connections. From these you will see that any current passing from one machine to the other is registered on both the ammeters.



Connections of Dynamos and Transformers. AM, Ammeters; SW, Double Pole Switches.

The machines were first put parallel when the load on the one supplying current to the outside circuits was only five amperes. They went into step at once and kept so. The current going between the machines to keep them in phase was not sufficient to make the needles swing more than two ampere divisions on the ammeters. The load was transferred to either machine quite easily by speeding its engine up slightly by means of its governor.

The second dynamo was switched out of and into the circuit several times as the load went up. They were then run parallel till after the heavy load of the evening (about 40 amperes) was passed, each machine taking half.

During the heavier loads the swing of the needles was greater, showing that more current was being sent between the machines, but this would correspond to only three or four amperes.

When the load dropped under 30 amperes, the load was transferred to one dynamo, and the other switched out of circuit.

We have also made the experiment of switching them in parallel when not at the same voltage. The difference was about 3 per cent. The current which flowed between them was 10 amperes. This seems to indicate that a very large current indeed must have passed when Mr. Mordey made his experiment of putting a machine at 1,000 volts in parallel with one at 2,000 volts.—Yours, &c.,

Bath, October 15, 1890. GEO. S. HOOKER, Electrician.

TRADE NOTES AND NOTICES.

HELSBY TELEGRAPH WORKS.—We are informed by the Telegraph Manufacturing Company that a circular which has been issued by Mr. Slater Lewis, who, some eighteen months ago, resigned his position with them, is calculated to injure and annoy them. They inform us that the works mentioned by him as the original telegraph works at Helsby consisted of a wooden shed, and that he he did not commence to do any manufacturing until 1883.

TENDERS WANTED.—The Southend Volunteer Fire Brigade invite tenders for fitting up electric call bells and wires. Further particulars are given in our advertising columns, and full details of the work required may be obtained of Captain Baker, High-street, Southend-on-Sea. Tenders have to be in not later than the 27th inst.

SALE BY AUCTION.—Messrs. Wheatley Kirk, Price and Goulty announce the sale at an early date of the high-class and nearly new electrical plant used for a short period by the Westminster Electric Supply Corporation for lighting the House of Commons. The catalogue will shortly be ready, and will include a number of Goolden alternating-current and compound and shunt-wound dynamos, a pair of 16 horse-power compound horizontal engines by Marshall, shafting, motors, transformers, belting, instruments, pumps, &c. Further particulars will be found in our advertising columns.

SALE BY TENDER.—Mr. Charles Lee Nichols, the official liquidator of the Pontypridd and Rhonda Valley Tramways Co. (Limited), and the receiver and manager of its undertaking, offers for sale by public tender the undertaking of the Company, consisting of 3 miles 102 yards, or thereabouts, of single line complete, constructed and now working under an order of the Board of Trade confirmed by the Tramways Order Confirmation Act (No. 2) 1882. The special advantages claimed for this Company's system of tramways will highly commend it to the notice of electrical traction companies, the districts through which it runs, possessing, as they do, a large travelling population, necessitating a frequent service, and facilities of a most unusual character for the generation of electrical power by water or steam can be obtained along the whole length of the line. From a report dated March 31st, 1890, made by a well-known tramway engineer on this line, it is stated that the present net earning capacity of the line, properly managed, would be £1,200 per annum, which is equal to a £5 per cent. per annum dividend on a capital of £24,000. Tenders must be sent in to Charles Lee Nichols, 1, Queen Victoria-street, London, E.C., marked "Pontypridd Tramways Tender," on or before Saturday, the 25th inst., and tenders will be opened at 11 o'clock on the following Monday. Full particulars, with conditions and forms of tender, may be obtained of Messrs. Stevens, Bawhee, and Stevens, 73A, Queen Victoria-street, London, E.C.; and of C. L. Nichols, Esq., 1, Queen Victoria-street, London, E.C.; or of Messrs. Iliffe, Henley, and Sweet, 2, Bedford-row, London, W.C. Further details are given in our advertisement columns.

THE LEVER ARC LIGHT.—Our advertisement columns contain an announcement that the British and foreign patent rights and the stock of lamps and apparatus of the Lever light (invented by the late Mr. Charles Lever) are for sale. Particulars and all further information can be obtained of Messrs. Dendy and Pearson, solicitors, 5, Cross-street, Manchester.

THE ARCHER PIPE COMPANY.—This Company are offering their patent jointed stoneware pipes for carrying electric conductors. The joint consists of a double spigot, and is run solid with cement through holes provided for the purpose. A length of 4-in. pipes was put under a head of 13ft. of water by the jury at the Edinburgh Exhibition, and was found to be watertight. To test their bridging power, three 4in. Archer pipes, each 2ft. long, were supported at the ends and weighted at the centre, and broke at about 5cwt., the joints remaining intact. We are informed that these pipes can be delivered in London and laid at 1s. 1d. per yard run. These pipes are being both laid in the ground, and in concrete for conveying electric wires.

MESSRS. PRIESTMAN BROTHERS (LIMITED).—This firm have been awarded a gold medal for the oil engine exhibited by them at the Edinburgh Exhibition.

"RULES FOR CONCENTRIC WIRING," BY J. D. F. ANDREWS.—This pamphlet consists of a number of rules drawn up by the inventor of this ingenious system of wiring. Since we are not aware that anyone else employs the method, it appears that these regulations will apply only to himself. The pamphlet is, however, not so useless as might be imagined, for it indirectly describes the system, which has been most carefully worked out in many details.

PYROSTAT COMPOSITION.—This non-conducting composition received the silver medal at the Edinburgh Exhibition, where the main steam pipes were protected by it. Messrs. Haache and Co., whose fossil meal composition is well known, have made use of asbestos instead of vegetable fibre, and thus the composition can be applied to even red-hot surfaces.

SAXONIAN BRONZE WARE.—Messrs. Berend and Co., the representatives in this country of the Saxonian Bronze Ware Manufactory, have just received some elegant examples of electric light fittings, all of which display great taste in design. There are eight specimens in all on the sheet of plates before us, and special mention should be made of Nos. 2,385, 2,387, 2,389, 2,390, and 2,391.

MESSRS. PATERSON AND COOPER.—This firm have opened a West-end showroom at 3, Prince's Mansions, Victoria-street, S.W., where samples of their manufactures will be kept.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

COMPANIES' MEETINGS & REPORTS.

Woodhouse and Rawson United (Limited).

A general meeting of the shareholders of this Company was held at Winchester House, Old Broad-street, on October 10th, under the presidency of the Right Hon. Lord Aberdare, P.C., G.C.B.

The SECRETARY (Mr. George Worrall) read the notice convening the meeting.

The CHAIRMAN: Ladies and Gentlemen,—Before moving the adoption of the report there are two points in it to which, for fear of misapprehension, I desire to call your attention. One is, that the ordinary shares, on which half the capital remains uncalled, are the shares taken by the public. The shares allotted to the vendors are, of course, fully paid, as shown by the balance-sheet. The other point to which I desire to refer is this—we mention in our report that the Sociédad Española del Electricidad in Barcelona has placed its lighting in the hands of this Company. The actual contract, however, was made between that Company and Woodhouse and Rawson (Limited). The contract was taken over by us, and at the present time the Barcelona Company is engaged in carrying out our suggestion. There are two ways in which a Board of Directors may report to their shareholders their proceedings for the past year: they may either present a report containing net results in the briefest and most succinct form, leaving to the Chairman the task of supplying in his speech the facts and events which he thinks likely to interest the shareholders; or they may add to the bare statement of results a detailed account of their operations and of the development of their undertaking, thus enabling those interested to form an estimate of their actual position and to forecast the prospects of the future. This latter method, which has the advantage of placing on permanent record the actual position of the Company, and of giving to absent shareholders information which would otherwise be denied them, seems specially advisable at the first meeting of a Company conducting operations of so varied and extensive a description as ours; for it is clear that much may be stated in a printed report which would be tedious and out of place in a Chairman's speech. We have, therefore, chosen the latter alternative, which has this further advantage—that it relieves the Chairman from the necessity of making a long speech. Those who have carefully studied the report will see how numerous and important our operations are. To some they may, perhaps, seem incongruous, although a little reflection will show that in reality they are closely connected with each other. The manufacturing, supply, and contract departments explain themselves. The development of the business of taking up and bringing out new inventions, by the purchase of patents, by manufacturing under royalties to inventors—all these items of electrical work are closely connected with yet another large and lucrative portion of the business—that of aiding in the formation of Companies to work patents which require capital beyond their means, and to supply the experience which they do not possess. All these branches of electrical business were undertaken by the several Companies which were purchased and absorbed into ours at the time of its formation. They have in their various departments been extended as rapidly as the short period of our existence has permitted. The manufacturing, supply, and contract departments show no inconsiderable improvements in actual performance, and give what I may venture to call well-grounded promise of greater expansion and profits hereafter. With those the report has dealt, I think, at sufficient length, presenting altogether a picture of great activity at home and abroad. In my opinion, these three branches of manufacture, supply, and contract constitute

Digitized by Google

the solid basis on which the ultimate success of the Company should rest. But it is obvious that expectations of large profits from these sources can only be gradually realised. Time is needed. We must sow before we can reap. It is unusual and unadvisable to enter minutely into the source of profits of the year in the case of a manufacturing company like ours; but this much I may say: the large profits of the present year, which have enabled us to recommend a dividend at the rate of 15 per cent. per annum, without availing ourselves of the £75,000 deposited with us by the Woodhouse and Rawson (Limited) as a guarantee for a dividend of that amount for three years, which have enabled us to place £25,000 to reserve funds, and to carry forward over £16,000 to next year's account, after writing off £742 against the estimated value of our patents—these large profits have been mainly derived from the fourth branch of our business, as described in the report, viz.:—"The testing and proving of new patents and inventions connected with electrical and engineering science, and their introduction to the public, either by arrangements for working such inventions by this Company, or by assisting the owners in forming separate Companies for working them." Such was the operation of Woodhouse and Rawson (Limited) in introducing the Elmore process, which the present Company are, with every prospect of success, extending over the chief commercial countries of Europe. Such was the formation of the International Okonite Company described in the report. Such, although only incidentally connected with our business, was the disposal of a portion of our premises at West Kensington to the West Kensington Co-operative Stores (Limited)—an operation advantageous to ourselves, and, I trust, to the Company which acquired our property and was launched under our auspices. That there is a certain risk involved in the introduction of new inventions it would be absurd to deny. But this I can honestly say, that these operations have never been undertaken without the most careful inquiry; and that all the judgment, experience and knowledge of affairs possessed by the Board have been exercised before embarking in them. They represent, in fact, but a small, and a very small, portion of the proposals for the Board's assistance in one form or another; the vast majority of which were rejected, not always from distrust of their merits, but because we limited ourselves to the selection of such only as seemed thoroughly sound and of intrinsic value. I have said that the Board had brought its combined faculties to the consideration of all schemes adopted by them; but it is the merest act of justice to our Managing Director, Mr. F. L. Rawson, to say that the success which has hitherto attended us is mainly due to his initiative, and to the extraordinary energy and ability of which he has given proof. Nor can I refrain from expressing my personal sense of gratitude to our vice-chairman, Sir Rawson Rawson, for his great exertions, and for his unremitting attention to the affairs of the Company, especially during the long period when a severe illness with its debilitating consequences had prevented me from giving to those affairs the attention which may fairly be expected from the Chairman. Never was personal aid, at the cost of great labour, more cheerfully given or more effectually. To my other colleagues I venture to tender my grateful acknowledgment of their indulgence to my shortcomings. The report refers, in by no means exaggerated terms, to the unusual demands on the time of the staff, due to the pressure on a new Company engaged in such extensive operations. I beg to add my own acknowledgments, and to recommend warmly to your acceptance the adoption of the resolution for the formation of an employés' pension fund. May I, as my parting contribution to the conduct of your affairs, venture to make some suggestions, the fruit of the past year's experience in the working of the Company? First, I think it very desirable that our capital should be increased, and I trust that the Directors will ere long submit resolutions to you with this object—not, of course, at this meeting. The report has told you that we have already extended considerably the business, and the business premises of the companies we were formed to acquire and consolidate. I am satisfied that these extensions cannot be fully developed, nor made as profitable as they might be, without an addition to your working capital. At present we have, as you know, the use of the capital of the £75,000 deposited with us by Woodhouse and Rawson (Limited), but this money must be replaced at latest two years hence. It might well be worth while to repay it at an earlier date if we can come to a satisfactory arrangement with the liquidators, on fair conditions as to discount and other allowance. It would doubtless be a great advantage to the liquidators to have it repaid, so that they might finally complete their liquidation. This is matter for the future, but I think it advisable to prepare you for possible proposals in this direction. 2nd. My other suggestions relate to an increase in the numbers of your Board, and of the working staff. I have already referred to the labour and responsibility which have rested on your Board, consisting, I may remind you, of only seven members—during the past year in the conduct of your general business, and in sifting the various schemes which have been brought before them. I need not enlarge upon this. The most cursory consideration of the report must make it clear to you that such a business cannot be properly carried on without great expenditure of time and labour, and long and frequent discussions. I see little probability of the diminution of the Directors' work in the near future; and I do not think that the present pressure upon them can long be continued, or that it ought to be. I would, therefore, venture to suggest, with a view to a more effectual division of the work among Committees, that the Board should be increased to nine, the full number authorised by your Articles of Association, and that their remuneration should be increased by the allowance of a percentage on the net profits of the year. I am clearly of opinion that the present remuneration is inadequate for gentlemen who are obliged to give so large a part of their time to the superintendence of this great and growing business, and that your interests will gain by treating them more liberally. Now as to the working staff. With the best will in the world, the Board of Directors can be little more than a consultative and critical body. The initiative, no less than the details of the Company's operations, must rest with the executive staff. Ours is excellent as far as it goes, but no man ought to be called upon to do all the work which is imposed on many of your officers, and more especially on your Managing Director. There must, I venture to assert, be some further division of labour, the cost of which will be inconsiderable as compared with the increased efficiency of external and internal management. If you approve in principle of these suggestions you will doubtless intrust the Board with the duty of working them out. It now only remains for me to thank you for the patience with which you have listened to me, to echo the congratulations of the report on the achievements of last year, and on the present position and prospects of the Company, and to express the earnest hope that you will, with a unanimous vote, support the Board in their efforts to give stability to an enterprise which has begun so well. The report mentions my resignation, and the reasons for it, and I trust you will think them sufficient. My habitual residence during the greater part of the year is nearly 200 miles from London, and I am thus compelled to choose between the exhaustion of long and frequent journeys or absence from the meetings of the Board. I cannot reconcile myself to either alternative, and therefore resign. Let me, however, congratulate you on the new Director proposed for your acceptance. The high character of Sir Edward Thornton for ability and honour, and his distinguished career as a Foreign Minister, give ample pledge of his capacity to watch over and advance the interests of your Company. Should you re-elect Sir Rawson Rawson as a Director, it is right to inform you that it is the intention of the Board to request him to assume the chairmanship. After what I have already said of my appreciation of Sir Rawson Rawson, I need hardly say how entirely I concur in the propriety of their choice. There is one other point which I desire to refer to, namely, that I am happy to inform you that the affairs of Woodhouse and Rawson (Limited) may be considered settled. You cannot know how long and vexatious has been the endeavour to bring that settlement to an earlier conclusion; but it is now happily arranged, and I am glad to hear that the shares are now on their way to the long-expectant shareholders. I now beg to move:—

"That the Directors' report and accounts for the year ending June 30, 1890, be and are hereby approved."

Sir RAWSON W. RAWSON, K.C.M.G., C.B., seconded the motion.

Mr. ROTHERHAM: I notice that in the balance-sheet the number of ordinary and fully-paid shares is 34,633, and in January last the Company issued a statement to the effect that 36,316 had been issued. I will also ask whether £31,000 is not an unusual amount of cash to be kept in hand. When it is spoken of as being in hand, is it meant that it stands on current account at the bank, or is it in the absolute possession of the Company?

Mr. FREDERICK L. RAWSON: With regard to the first question, I have not the figures before me to answer at a moment's notice; but whatever may have been said, the speaker may be sure that the statements that have been made are absolutely correct. On the next point, namely, cheques and cash in hand, £31,000, odd, that is easily explained when I say that there was a cheque for £30,000 on one transaction that was not paid into the bank on the actual night of closing the balance-sheet, and therefore that has to appear as cheques and cash in hand.

Sir RAWSON RAWSON: It was paid immediately afterwards.

Mr. ROTHERHAM: You say here that the amount of share capital in January, 1890, was 40,000 ordinary shares of £5 each, of which 36,000 odd had been subscribed, including those taken by the vendors.

Mr. RAWSON: At the date of the balance-sheet we had not yet allotted some of the shares to the vendors. The Chairman explained that the shares had just been allotted to the shareholders of Woodhouse and Rawson (Limited). We could not allot them until we were instructed to do so by the liquidators of that Company; but immediately we were so instructed we called a special Board meeting and allotted them. Therefore those shares are now allotted; in fact, the full capital is allotted, as stated in the report, but at the actual date of the balance-sheet the vendors' shares had not been allotted.

Colonel DICKENS: With reference to the £99,000 odd which is put down as profit, what proportion of that has come from *bonâ fide* trade earnings as opposed to the other matters which the Chairman has pointed out?

The CHAIRMAN: I may as well answer this question, and the reply is simply this—that we must decline to enter into those questions. I have told you a large proportion of the profits has been obtained from the other sources; but I do not think it in the interests of the Company, and neither is it usual in the case of a manufacturing Company like ours, to give those explanations, though I quite admit that the question is one which very naturally would arise in the minds of shareholders.

Colonel DICKENS: I only thought it might interest the shareholders that the question should be answered.

Mr. J. B. LEONARD: Will the Chairman state what is the exact position with regard to our obtaining a quotation on the Stock Exchange?

Mr. RAWSON: The position is this: we considered it advisable to run no risk of having our quotation either refused or turned back, and thought it more advisable, although we had made our application to the Stock Exchange for our quotation shortly after the Company was issued, to ask the Committee to keep it back—and they were glad to do so under the pressure of business they were then experiencing—until we had completed our purchase and the capital was all allotted. The papers are now before the Committee, who required certain alterations which we made, and since then they have required some small information. I understand that the application is coming up before the Committee in about a week's time—next Friday, or next Monday week—in order that our quotations may be granted.

The CHAIRMAN then put the motion, which was carried unanimously. He next proposed—

"That this meeting hereby sanctions the declaration by the Directors of a dividend at the rate of 7½ per cent. on the ordinary shares, and 4 per cent. on the Preference shares, making, with the interim dividend of 7½ per cent.

Digitized by Google

already paid upon the ordinary shares and 4 *per cent. already paid on the Preference shares, a dividend at the rate of* 15 *per cent. per annum on the ordinary shares and* 8 *per cent. per annum on the Preference shares.*"

I may recall to the minds of our shareholders that our Preference shares are 7 per cent.; but they are entitled to an extra 1 per cent. each year that the ordinary shareholders receive 10 per cent. per annum.

Sir RAWSON RAWSON: I second that. The resolution was carried unanimously.

Sir Rawson W. Rawson and Sir Edward Thornton were re-elected as Directors, and Messrs. Pixley and Co., as Auditors; after which

The CHAIRMAN said: I have been asked to read this resolution:—

"*That the remuneration of the Directors be increased as from the* 30*th day of June,* 1890, *by a commission of* 2 *per cent. per annum upon the net profits of the Company.*"

I have already stated my own strong impression that the amount of their remuneration should be increased. I will not, however, propose this resolution, although I am not interested in it.

General DAVIS seconded the motion.

A SHAREHOLDER: Is the proposed commission on the net or the gross profits?

The CHAIRMAN: On the net profits.

Mr. F. L. RAWSON: As you are aware, it is the intention of the Directors to increase the number of the Board, and this will enable them to recompense the new members.

Mr. HOSTER seconded the motion, which was carried.

Sir R. W. RAWSON proposed a vote of thanks to Lord Aberdare, not only for presiding on the present occasion, but for the part he had taken, and the interest he had shown in supporting the prosperity of the Company.

Mr. SAMUEL POPE, Q.C., in seconding the motion, said: I am seconding this resolution, but I want to disburden my mind of one or two other things as an independent investor. Of course, nobody could imagine that £99,000 a year profit is one capable of being made by manufacturing and supplying electrical apparatus. I am interested in other electrical Companies, because, being of a speculative turn of mind, one is apt to take up new industries as they may arise, in hopes of their development; and one therefore knows pretty much what scale of profit may be possible in such a business. I venture to think that it would not be desirable that we should disclose to those who are our competitors in that class of business the exact profits we may make. They are, no doubt, good profits, but to declare them if they were very large would be to provoke competition, and to declare them if they were very small would be to disclose an unfortunate state of affairs. I think the shareholders may be well content with the amount of profit which is placed to their credit, without being over anxious to ascertain what the particular source is to which it can be attributed. I do invite shareholders at all times most carefully to investigate the accounts, and see that the profits which are placed to credit are real profits, and not merely imaginary or paper profits. That, I should think, would be a matter of considerable interest to every shareholder; but this fact is certified by the accounts, and you must, I think, be well content that you are shareholders in a concern which will pay 15 per cent. upon the capital which you have only had invested for about 12 months. I also desire to say that as long as I sit at the Board I shall certainly advocate the maintenance of strong reserve funds to provide against contingencies. Precisely that which has actuated the shareholder just now in asking us from what source the profit was derived, and your acquiescence in my view that it is impossible to suppose that a great proportion of these profits must not have arisen by the promotion and assistance of other companies, it seems to me that, to be perfectly plain, in order to secure the stability of the business we must of necessity appropriate a certain portion of the profits made, so to speak, to the contingency of their not being permanent profits. In other words, we must strengthen our reserve fund so as to increase the amount which we have to depend upon if in the course of the experience of any year similar success is not obtained in a business, which, after all, is not as steady as a regular trading business, being more or less of a speculative character. On that ground I cheerfully assented to the balance-sheet, because we commence well by setting aside £25,000 of our profits clearly to reserve, and carrying over another £16,000, in fact, appropriating half our profits to contingencies of the future, rather than dividing them greedily now for the purpose merely of increasing the dividend. I do not know that I am revealing any confidence, but since the balance-sheet was made out our profits have not fallen off. We hope to present as satisfactory a balance-sheet next year as we have produced this; but if we should fail to reach that amount we have the reserve. We are acting as prudent shareholders by allowing the accumulation of our profits to meet these contingencies rather than insisting on their immediate division. Those are the principles upon which the business has been conducted. I will not say they are principally or largely due to Mr. Frederick Rawson, but I will say that he has developed a great amount of capacity and energy in carrying them out, whilst the prudence has come from Lord Aberdare and Sir R. W. Rawson. You are, I think, well officered. You have in your managing director a man of the most untiring energy, and speaking for myself (and I do work sometimes)—(laughter)—his work perfectly appals me, and also the energy he brings to bear upon it. In season and out of season, night and day, I believe he has nothing upon his brain but Woodhouse and Rawson United. Sir Rawson, on the other hand, and Lord Aberdare have dealt with our finances in the prudent way which appears in the report. The prudence is due to them; the energy is due to the managing director, and, altogether, I venture to think that we have got reason to congratulate ourselves.

Mr. F. L. RAWSON: I should like, with Lord Aberdare's leave, to call the attention of the shareholders to a fact that it is due to me was not mentioned by his lordship earlier—that is with respect to the employés' pension fund. By the applause that has greeted this reference, I see that it is scarcely necessary to call attention to the advisability of building up such a fund which will give the employés reason to believe that when their work is over they will find that they have done well in remaining with the Company, and not looking about to change whenever any rosy-hued opportunity presents itself to them. I mention this, because we are a little out of order in putting the matter on one side, as we have done. It will be necessary next time we call you together, to have probably an extraordinary general meeting to sanction this proposal; but I feel in the meantime that the Directors have the moral support of the shareholders in dealing with the question in this way.

On the motion of Sir RAWSON W. RAWSON, seconded by Mr. POPE, a cordial vote of thanks was passed to Lord Aberdare.

The CHAIRMAN thanked the meeting for the heartiness of their vote, and a vote of thanks to the Directors for their services in the past year having been carried, the proceedings terminated.

Eastern Extension Australasia and China Telegraph Company (Limited).

Report and accounts of the Directors for the half-year ended June 30, 1890, to be submitted to the thirty-fourth ordinary general meeting, to be held at Winchester House on October 22, 1890, at 2 o'clock:—

The gross receipts, including Government subsidies, have amounted during that period to £254,856. 18s. 10d., against £256,757. 3s. 2d. for the corresponding half-year of 1889.

The working and other expenses, including £24,508. 3s. 10d. for cost of repairs to cables and expenses of ships, absorb £76,670. 9s. 3d., against £73,773. 10s. 2d. for the corresponding period of 1889, leaving a balance of £178,186. 9s. 7d. From this is deducted £2,960. 19s. 7d. for income tax, and £38,549. 14s. 7d. for interest on debentures and contributions to sink-

ing funds, leaving £136,675. 15s. 5d. as the net profit for the half-year. Against this £1,642. 11s. 11d. has been charged for additions to staff quarters, and £712. 16s. 1d. for expenses in connection with the recent Paris International Telegraph Conference, leaving an available balance of £134,320. 7s. 5d.

One quarterly interim dividend of 1¼ per cent., amounting to £31,250, has been paid during the half-year, and another of like amount will be distributed on the 15th instant, leaving £71,720. 7s. 5d. to be carried forward.

The duplication of the New Zealand Cable and the partial renewal of the Madras-Penang section referred to in the last report have been successfully carried out during the half-year under review; and the cost amounting to £188,433. 15s. 6d. and £80,848. 1s. 3d. respectively has been charged to the general reserve fund, which, after being credited with the profit of £21,103. 3s. 4d. made on the sale of investments, and the interest received during the half-year, now stands at £472,713. 15s. 3d.

The subsidy granted by the Spanish Government in respect of the Manila Cable expired on May 1st last, when the balance of the Five per Cent. Debentures issued to provide the capital for this cable was paid off; and as the interest and sinking fund contributions have now ceased, there will in future be a saving of revenue on this account of about £5,000 per annum.

The Company's £320,000 Six per Cent. Debentures mature for payment at par on February 1, 1891, and your Directors have decided to pay them off on that date by issuing a similar amount of Four per Cent. Mortgage Debenture Stock. An extraordinary general meeting will be held immediately after the ordinary meeting, at which the necessary resolution will be submitted for the shareholders' approval.

Negotiations have been entered into with the Governments of Australasia for the establishment of reduced rates to Australia and New Zealand, and the matter is now under consideration in the colonies.

Arrangements have also been made with the Indian Government for improving the international service; in connection with which the Company has decided to duplicate the Madras-Penang Cable, and a contract has accordingly been entered into with the Telegraph Construction and Maintenance Company for carrying out the work, which is expected to be completed early next year.

During the half-year the Tonquin-Hong-Kong section has been partially renewed by the insertion of 67 nautical miles of new cable, and the operation will be continued as opportunities occur until the line is put into good order.

The Company's maintenance ships have been employed on various cable repairs, but no interruptions materially affecting the revenue have occurred during the past six months. Unfortunately, however, since the close of the half-year telegraphic communication with Australia has been totally interrupted, from the 11th to the 20th July, in consequence of the sudden and simultaneous breaking, through volcanic action, of the three Java-Australian Cables near Banjoewangie (Java). This was the more disappointing as it was only last year that the cable to Western Australia was laid mainly with a view to averting such a contingency; but as only two interruptions from volcanic causes have been experienced during a period of nearly 20 years, it is hoped the cables will now have a long immunity from further trouble of this nature.

Brazilian Submarine Telegraph Company (Limited).

Report of the Directors and the accounts for the half-year ended 30th June, 1890, to be submitted to the thirty-fourth ordinary general meeting, to be held in Room 174, Winchester House, Old Broad Street, E.C., on the 22nd October, 1890, at 12 o'clock noon:—

The revenue for the period amounted to £121,873. 19s. 9d., and the working expenses to £16,492. 5s. 3d. After providing £12,880 for debenture interest and sinking funds, and £1,559. 17s. 1d. for income-tax, there remains a balance of £90,941. 17s. 5d.; to this is added £9,975. 0s. 8d. brought forward from 31st December last, making a total of £100,916. 18s. 1d. A quarterly interim dividend amounting to £19,500 has been paid, and £40,000 transferred to the reserve fund, increasing that fund to £352,626 2s. 11d.

The Directors now recommend the declaration of a final dividend of 3s. per share, making, with the interim dividends, a total dividend of 6 per cent. for the year, and also the payment of a bonus of 3s. per share, both free of income-tax, which together will amount to £39,000, being a distribution in the aggregate of 7½ per cent. for the year ended 30th June, 1890, leaving a balance of £2,416. 18s. 1d. to be carried forward. The dividend and bonus will be payable on the 23rd instant.

On the 31st July last, the sum of £15,300 was transferred to pay off the 153 bonds of the 1884 Issue, drawn for redemption in April last. This repayment reduces the Debenture Debt to £144,200.

The receipts for the half-year include the sum of £1,500 dividend to 31st December, 1889, on the Company's Shares in the African Direct Telegraph Company (Limited).

The various sections of the Company's line are in good working order.

Sir James Anderson and Mr. Frederick Youle retire by rotation at this meeting, and being eligible for re-election as Directors offer themselves accordingly. The two Auditors, Mr. Henry Dever and Mr. John Gane, also offer themselves for re-election.

NEW COMPANIES REGISTERED.

BULLERS (LIMITED).—Registered by Waterlow Brothers and Layton (Limited), 24 and 25, Birchin-lane, E.C., with a capital of £200,000 in £10 shares. Object: to acquire, upon such terms as may be thought fit, all or any of the assets, and to undertake all or any of the liabilities, of the business of engineers, contractors, and otherwise heretofore carried on by a company named Buller, Jobson and Co., now in voluntary liquidation, and to carry on, develop, and extend the said business when acquired; to manufacture, sell, let on hire, and generally to acquire, dispose of, and deal in electrical plant, and in electricity and electric power and other forms of power and energy. The first subscribers are E. Buller, 49, Charlotte-road, Birmingham; H. Jobson, Summer Hill, Kidderminster; E. J. Chambers, Lingwood, St. James-road, Dudley; W. Greenhill, Dudley; E. P. Jobson, Dudley; A. T. Buller, Greystoke, Penrith; J. T. Harris, The Kayes, Stone, Staffordshire. There shall not be less than two nor more than seven Directors. The first are Ernest Wentworth Buller and Howard C. Jobson. Qualification, 100 shares.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended October 10th amounted to £5,479.

DIRECT SPANISH TELEGRAPH COMPANY (LIMITED).—Notice is given that an extraordinary general meeting of this Company will be held at the Company's offices, Winchester House, E.C., on Tuesday, the 21st inst., at 2 o'clock, for the purpose of confirming the following Special Resolution passed at the extraordinary general meeting held on the 30th ult.:—"That Article 71 of the Articles of Association of the Company be and is hereby repealed, and, instead thereof, the following be a regulation of the Company:—The Directors shall receive, as remuneration for their trouble in the execution of their office, the sum of £600 per annum, or such other sum as the Company in general meeting may, from time to time, determine; and such remuneration shall be apportioned by the Directors among themselves in such manner as they shall from time to time think fit."

DIRECT UNITED STATES CABLE COMPANY.—The Board of this Company have declared an interim dividend of 3s. 6d. per share, free of income tax, being at the rate of 3½ per cent per annum, for the quarter ending September 30, 1890; such dividend to be payable on and after the 24th inst.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ending October 10, 1890, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £4,321.

THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSES.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FACTORY.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

MOSSES & MITCHELL, 70, Chiswell-st., London, E.C.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 649.—Vol. XXV. FRIDAY, OCTOBER 24, 1890. Price Fourpence.

NOTES.

Many of the details of the Westinghouse system have been fully explained in Dr. Fleming's recent articles on Electrical Distribution by Transformers; and these are naturally followed in our present issue by the first part of an account of the Sardinia Street Station of the Metropolitan Electric Supply Company. This station has the special interest of being a typical American station equipped throughout with American machinery and appliances. With one exception, none of our leading dynamo makers care to build their own engines. Not only do the Westinghouse Company undertake this work, but their engines are scarcely less remarkable for their originality than are their dynamos; and we understand that no less than forty are kept in stock ready for delivery.

It will be interesting to see how, with imported machinery, the Westinghouse Company, after showing by this excellently arranged station what they can do, will be able to compete with our home manufacturers. One of the solitary advantages to us of American Protection is, that the cost of their labour and material is so high that they cannot compete on the same grounds, nor will their labour-saving devices help them permanently, unless they are continually improved more rapidly than they are adopted in our workshops. But the American manufacturer has an immense advantage in the limitation of his standard sizes. Our dynamo builders are fully alive to the fact, but they continue to offer a very much larger choice of standard sizes, and they generally need but little inducement to build machines to suit the special requirements of an order. The magnificent catalogue of the Westinghouse Company relating to "incandescent apparatus" offers only five sizes of alternating-current dynamos for 1,000 or 2,000 volts. In the latest price list of English manufacture that we have received we find five sheets of continuous-current dynamos at five different voltages, with twelve different sizes on each sheet. These may be shunt, series, or compound wound, making no less than 180 varieties. Few makers of dynamos offer less than a dozen or fifteen sizes, and in most cases they denote them by mysterious combinations of letters and figures. It is difficult to explain why our manufacturers cannot rid themselves of a fashion which must necessarily increase the cost of production, and one that greatly reduces the immense usefulness of the interchangeable system, which is by no means uniformly adopted even among our best firms.

We print in this issue an instructive Paper, by Mr. Kennelly, dealing with the design of optical ammeters and voltmeters. The investigation will be studied with interest, although it does not tend to the conclusion that instruments of this type are at all likely to successfully compete with others as standards of current or potential. If such optical instruments could be made sufficiently sensitive, they would, undoubtedly, possess many great advantages. The indications would be strictly proportional to current strength; there would be no error due to heating or local magnetic disturbances; and, owing to the absence of any delicate moving parts, the apparatus would be portable and capable of withstanding somewhat rough usage. Unfortunately this is not the case; and, in order to obtain indications of sufficient magnitude, the current density must be increased till a serious heating error is introduced. This arises not in the ordinary way from change of resistance, but more indirectly by alteration of the electro-optic constant of the substance composing the core of the solenoid. The core must be homogeneous for the indications to be sharp; and partly for this reason a liquid is usually employed. If the heating affected different parts of the core equally, the error would not be so serious; but the most efficacious layers of the core are most influenced by the heating, and the indications are not only altered owing to the change of temperature, but at the same time rendered less precise owing to the unequal distribution of heat.

It is often claimed as an advantage possessed by instruments of this type that the current strengths are obtained in absolute measure, from the geometrical dimensions of the solenoid and the optical constants of the core. This is no doubt the case if these quantities are accurately known; but unless that is the case the difficulty of measuring them is so great that it is practically far more convenient and accurate to determine the constant from a calibration with a copper voltmeter, in the same way as used by Sir William Thomson for his standard instruments, than from any such calculations. Neither Sir William Thomson's instruments nor the optical ones can claim to be very easy to manipulate in practice; but the former may be set to a predetermined reading and the current gradually altered till of the right amount, which is then known with great accuracy; while with the latter precision is impossible, owing to the fact that the indications are never very sharp. Any attempt to increase the sensibility seems, moreover, to bring in other defects. Thus, Lord Rayleigh found it inadvisable to increase the rotation by reflecting the light back-

Digitized by Google

wards and forwards through the core, as, after several reflections, the light was very much diminished by absorption, and the increase of sensibility so obtained was more than counterbalanced by the indistinctness of the indications.

A ROUGH test for arriving at the efficiency of a transformer appears in a recent number of *Industries*. The primary current is to be measured when the secondary is open, by an alternating current ammeter, and the volts are to be read on a suitable voltmeter such as is always to be found in stations. Half the product of the volts into the current is said to give the loss in the iron. The loss in the copper at any load is calculated from the product of the resistance into the square of the current. An example is given of an efficiency of 85·9 per cent., the value for the same transformer, according to Professor RYAN, being 86·3 per cent. This rough method, says the writer, gives the loss in the iron well within 10 per cent., that is to say, gives the efficiency within 1 per cent. This appears at first to be too good to be true, and does not bear any external evidence of the why and the wherefore. We understand, however, that it is arrived at by considering that the area of the well-known hysteresis curve for low magnetizations is approximately one half of that of the rectangle formed by its limiting co-ordinates. But in the curves which we have examined with this feature in view, we find that the error is very considerably more than 10 per cent.

ELECTRIC lighting has a sufficiently hard struggle with competition by gas and oil, with obstruction by local authorities, with embarrassment by over-legislation, with restraint by innumerable "safety" rules, though these can be met with more or less success by properly organised efforts; but a far more prejudicial and by no means unimportant annoyance to the industry is caused by the sensational accounts in the daily press of accidents connected with electricity. The daily newspaper selects with care and pays with liberality its musical and art critics, and seeks experienced men for war correspondents and reviewers. But when any scientific or even engineering matter has to be dealt with, it is apparently handed over to the dramatic or the melo-dramatic critic. The public are beginning to learn that most of the American overhead-wire accidents are grossly exaggerated or without foundation; and, what is more important, that hardly anything of the kind take place in this country. This week an account, couched in the most alarming language, has been going round the papers, describing the explosion of accumulators on a yacht. "The electricians," it is said, "who have investigated the matter, express themselves quite unable to account for the disaster; and regard it as an entirely new experience from every point of view."

THE accounts which we have seen do not contain sufficient evidence to prove that the smashing of the batteries was due to anything connected with themselves or with electricity; but we are ready to admit that towards the end of the process of charging them, the hydrogen given off may, if confined in an entirely unventilated chamber, form an explosive mixture with the atmosphere, and that an explosion might thus ensue. But we must add that such accidents are extremely rare, no more serious case has ever yet been recorded than that which occurred on a tramcar in July last, and we have heard of the occasional blowing off of the lid of a cell. The sting of these paragraphs lies in their mysteriousness; scientific men are appealed to; the electric light as a non-explosive is said to be still a matter for future invention. The room or closet containing accumulators should be ventilated under any circumstances; and, even if the accommodation is so small as to consist merely of a box or case, there is little difficulty in providing for sufficient access of fresh air to prevent the formation of an explosive mixture.

Magdeburg.—The town of Magdeburg is about to raise a loan of 33 million marks, of which 1½ million (£75,000) will be applied to the erection of a central lighting station.

Blankenburg.—The municipal authorities have decided to accept the tender of Messrs. Naglo Bros., of Berlin, for the equipment of an electric light installation, at a cost of 127,000 marks.

Penzance.—The Town Council have decided to oppose the application of the Penzance Electric Lighting Company for a Provisional Order, and have resolved to obtain an Order themselves.

Chiswick Local Board.—At the last meeting of this Board the Clerk submitted the Parliamentary notice of application for Provisional Order authorising the Board to manufacture and supply electric light in the parish of Chiswick.

Stuttgart.—The telephone network at Stuttgart has reached such proportions that a further extension of overhead wires has been forbidden by the authorities, who have accordingly ordered that in future the lines must be laid underground.

Submarine Telephonic Communications.—Experiments in telephonic communication between Cuxhaven and Heligoland by the North Sea cable have recently been made by the German Post Office authorities. The results were very satisfactory. The distance is about 50 miles.

The United States Telpherage Patent.—In the interference action with regard to the application of Rudolph H. Hunter, filed May 22, 1886, and the patent No. 305,194, to Fleeming Jenkin, granted September 16, 1884, on application filed February 1, 1883, the examiners-in-chief of the United States Patent Office have reversed the decision recently made by the examiner of interferences in favour of Hunter.

Whitby.—At a special meeting of the Whitby District Local Board, held on Monday last, the notices served on the Board by the Yorkshire House-to-House Electricity Company and the East Coast Electric Light and Power Supply Company were taken into consideration. It was unanimously decided that the Board should apply for a Provisional Order, and a sub-committee was appointed to see the matter carried into effect.

Exeter.—At their last meeting the Town Council refused consent to the Exeter Electric Light Company's Provisional Order, and decided to apply for an order themselves This decision was come to owing to the Special Committee being unable to agree with the Electric Light Company as to the purchase clauses to be inserted in the Company's proposed Order.

Keswick Electric Light Company.—In consequence of the large consumption in Keswick of the light supplied by this Company, the Directors find it necessary to increase the plant so as to enable them to meet the growing demand. In order to put down a new turbine, dynamo and exciter, an outlay of at least £1,400 will be required. They have, therefore, resolved to issue the remainder of the shares.

The Institution of Electrical Engineers.—The conversazione of the Institution of Electrical Engineers will be held on Wednesday evening, November 19th, in the Galleries of the Royal Institute of Painters in Water Colours.—The second annual dinner of the Institution will be held at the Criterion Res-

Digitized by Google

taurant, on Thursday, November 20th. Members who desire to attend should give notice as early as possible to the secretary, Mr. F. H. Webb.

Telegraphic Extensions in Northern Russia.—The Russian Imperial Telegraph Department propose next spring to run a telegraph line from Kola, on the Arctic Ocean, to the Scandinavian frontier, which is distant some 90 miles. Kola is the most northern town in European Russia, and is a provincial capital of some importance. Hitherto the only means of communication between Kola and the Scandinavian frontier has been a bi-weekly postal service.

Flamborough.—Efforts have from time to time been made to carry out the construction of a railway from Flamborough to the North-Eastern Station, two and a-half miles away from the town, but the promoters have hitherto failed to realise their schemes. The last proposal is to construct an electric railway. The need for some sort of railway between Flamborough and the inland towns is great, and the idea of an electric railway is meeting with considerable support.

Electric Traction v. Cable Traction.—On August 1, 1873, early in the morning, says *Electric Power*, the first trial trip of the cable railway system was made in San Francisco. The inventor was A. S. Hallidie. To-day, after 17 years, there are 44 cable railways in the United States. In August, 1884, the first electric railway was started in Cleveland, Ohio, on the Bentley Knight conduit system. To-day, after six years, there are 263 electric railways in operation or under construction in this country.

Electric Tramway at Bremen.—There have been several unfavourable notices in the local papers on the working of this line. According, however, to the *Elektrotechnische Zeitschrift*, a well-known electrical engineer reports that the service is in every way satisfactory. The cars are said to take the gradients easily and safely; while it is only when the rails are very gritty that any sparking is discernible at the wheels. The lighting of the interiors of the cars is also said to show a great improvement.

Engineering at Cambridge University.—The electors to the Professorship of Mechanism and Applied Mechanics, at Cambridge University, will meet on Wednesday, November 12th, for the purpose of electing a successor to Prof. Stuart. The electors are the Vice Chancellor, Mr. W. Airy, Dr. Besant, Dr. Cayley, Mr. H. Darwin, Mr. Martin, Dr. Phear, and Lord Rayleigh. An engineering laboratory is to be established, for the equipment of which it is thought there will be little difficulty in raising funds. The salary attached to the post will be £700 a year.

Melbourne.—At a recent meeting of the Melbourne City Council a resolution was carried, thanking the Gas Company and the Union Electric Light Company for the efforts they had made to keep the city lighted during the present dispute in the shipping trade. The Public Works Committee reported that the Mayor had entered into an arrangement with the Union Electric Company to erect 15 arc lamps at the chief street intersections, and to keep them lighted all night, as well as 45 other arc lamps already fixed by the Company in the streets, at a cost of £48 per week.

O.S.A. Dinner.—On Friday last the annual dinner of the Old Students' Association of the City and Guilds of London Institute was held at the Holborn Restaurant. About sixty members and several visitors enjoyed a most agreeable evening. Among other speakers, Mr. Saunders, Q.C., replied for the Institute, and Sir Owen Roberts for the visitors. It was evident that a cordial feeling exists not only between the professors and the students, but between the latter and the governing body, who take a warm interest in their concerns, and appreciate the great success which has attended their efforts.

Telegraph Cable Construction.—The following communication has been issued by the Foreign Office:—A despatch has been received from Her Majesty's Ambassador at Madrid, enclosing copies of a Royal decree authorising fresh tenders to be invited for the construction of the telegraph cables between the Peninsula and the Spanish possessions on the North Coast of Africa. The new conditions are slightly different to those previously laid down. None of the tenders received in answer to the first application have been accepted. The conditions (in Spanish) may be seen at the Commercial Department of the Foreign Office between the hours of 11 and 5.

London Electric Supply Company.—The machinery at the Deptford station is working in a highly satisfactory manner. The current that is now being daily generated is greater than any that has yet been supplied. Both the 1,500 horse-power engines and dynamos are working without any hitch, and have been supplying current continuously to about 40,000 lamps every night for about a fortnight through the Ferranti mains. The disturbing effect on the telegraph lines has now been reduced to an insignificant and hardly appreciable magnitude. For reasons which are not yet thoroughly understood there is a rise of pressure of nearly 50 per cent. at the ends of the mains.

The Frankfort Electrotechnical School.—The Frankfort-on-Main Physical Society has founded an electrotechnical school, where it is intended that the technical education of lads who have served their time in mechanical workshops should be completed. It is proposed to impart sufficient theoretical and practical instruction to enable the students to become trustworthy foremen capable of looking after installation and other electrical work. Candidates for admission to the courses have to produce their certificates of apprenticeship, and to give evidence of possessing sufficient knowledge of elementary mathematics to obtain the full benefit of the instruction given. The annual fee is 100 marks, *plus* a deposit of 10 marks, which goes to the repair of instruments accidentally injured in experimental work.

Electrical Fog Signal.—Experiments with the Andrews electrical fog-signal have recently taken place at Bowes Park, on the Great Northern Railway, in the presence of a large number of railway engineers and directors. In this system an insulated rail is laid down parallel with the ordinary rails; and the current is conveyed to the engine by means of a metallic brush affixed to the footboard. There is an illuminated dial fixed on the weather-board of the engine, with a miniature signal and a gong to direct the attention of the driver to the sign given on the engine. In the signal-box are other miniature signals showing the signalman that the driver has received correctly the signal. The signal may be brought into action by the signalman immediately upon a fog coming on simply by moving a switch.

Cataphoric Medication.—The question of the absorption into the skin of solutions by means of electric currents has been "says Dr. S. Ehrmann, of Vienna," the subject of many experiments with me since Prof. Wagner first started the discussion by his researches on the cataphoresis of cocaine; and I have at last hit on a very simple experiment. Take two similar glass vessels, with zinc electrodes at the bottom, and filled with a very weak solution of methyl-blue; and if an individual places one of his hands in each vessel, then when a constant current of from 10 to 20 milliamperes is allowed to pass for five or ten minutes the hand in the anode vessel becomes covered with blue spots, whilst the other is not marked. The spots appear most on the back of the hand, where the hair and fatty glands are situated. In the palm and round the nails they do not occur.

The Endowment of Research and Invention.—According to *La Lumière Electrique*, the French Government recently proposed to divide the quarter of a million sterling arising from the Henri Giffard bequest among the several Government departments, for the purpose of assisting various urgent departmental schemes; and the necessary decrees were presented to the President of the Republic for his signature. Energetic protests were, however, made against this mode of appropriating this fund, and the intention of the authorities now is to found an institution for the purpose of stimulating and assisting the spirit of invention and research, to help men having "happy ideas" to put them into practice, and to endow France with an institution which shall be free from scientific and administrative routine without becoming a refuge of utopians. As our contemporary remarks, "this problem is not an easy one, and we may anticipate that there will be numerous experiments before a thoroughly satisfactory solution is arrived at."

The Pazzalo-Lugano Funicular Electric Tramway. — The funicular electric tramway between Pazzalo and Lugano has lately come into operation. Theline, which is of one metre gauge, is close upon a mile long, and runs along the shore of the Lake of Lugano and up Mont Salvatore. Power is obtained from a waterfall which actuates two Girard turbines, each of which drives a dynamo. One of these machines is an alternator, and supplies lights at Lugano and Pazzalo. The second dynamo is a continuous current machine, and gives 1,800 volts and 22 amperes at 700 revolutions; the motor at Pazzalo develops 40 horse-power at the same speed. The maximum gradient is one of 38 per cent. The track being double, a car is attached to either end of the cable, so that the tractive effort required is considerably reduced. Each car weighs 4½ tons, and can carry 32 passengers. A 50 horse-power steam engine is kept in reserve at Pazzalo.

The Canadian Fire Insurance Companies and the Electric Light.—The Canadian Board of Fire Underwriters are talking, says the *Electrical, Mechanical and Milling News*, of compelling the electric light construction companies to pay the cost of a special inspector to look after properties in which electricity is used as an illuminant. Our contemporary is of opinion that the arguments in favour of this course are scarcely logical. The insurance companies say that they consider electric lighting, when properly installed, to be the safest known method of artificial illumination. At present the insurance companies pay the cost of inspection themselves, and why they should now want to tax the "safest method" with an inspector's salary is beyond comprehension. The total amount paid in the City of Toronto for losses by the insurance companies on account of electric lighting during the past seven years has been *ten dollars;* two dollars of which was refunded, with exceptional honesty, by their client because his repairs only cost him eight!

Jamaica Exhibition.—A meeting of the English committee of this Exhibition was held last week at the Hôtel Métropole. Lord Knutsford, the honorary president, being unable to attend, the chair was occupied by Mr. C. Washington Eves. The Chairman announced that an Imperial grant of £1,000 had been approved by Parliament and paid. Mr. S. Lee Bapty, having been appointed general manager, was introduced to the meeting by the Chairman. Mr. Bapty reported that a large number of applications to exhibit had been received. He anticipated that more applications would be received from Great Britain than could be accommodated. Progress was reported with regard to the building operations, and letters were read from Governor Sir H. A. Blake expressing confidence in the success of the Exhibition. An additional annexe, providing accommodation for exhibits to the extent of 26,000 square feet, had been determined upon, and a fine art gallery was being arranged. Canada and several of the West India colonies would be well represented. Reports were submitted as to electric lighting and other matters.

Edinburgh Exhibition.—The following firms, amongst others, have received awards at this Exhibition:—Complimentary list of exhibitors: Diploma of honour—Robey and Co., steam engines; Ruston and Proctor, 25 horse-power compound engine. Gold medal—Andrew and Co. (Reddish), Double-acting gas engine; Priestman Bros., petroleum engine. Silver medal—Bertrams (Edinburgh), engine-driving dynamo.—General list of exhibitors:—Diploma of honour — Crossley Brothers, gas engines. Gold medal—Davey, Paxman, and Co, engine and boiler; Davis and Timmins, machine screws, electrical fittings, &c.; Elmore's Patent Copper Depositing Company, copper piping made by Company's process; Fielding and Platt (Gloucester), gas engine. Silver medal—Dick, Kerr, and Co., gas engines; Gandy Belt Manufacturing Company (Liverpool), cotton belting; King, Brown, and Co. (Edinburgh), high-speed engine; Rossendale Belting Company (Manchester), hair belting with anti-friction edge. We understand that there is a difference between the awarding and the presentation of a medal in the case of the Edinburgh Exhibition. Those who wish to have actual medals may obtain them by paying for them.

Lighting of the Reading Library.—The contract between the Reading Library Committee and the Reading Electric Lighting Company, according to a communication by the Librarian, specifies that the sum of £80 per annum shall be paid for supplying the current to the eight arc lamps in use in the library and reading-rooms, for providing the necessary carbons, and for keeping the lamps in order. It was considered that 100 glow lamps, of eight candle-power each, would be required to illuminate the library and rooms for reading purposes only, and to supply the electric current and renewals to these lamps would cost £150 per annum. To supply the current and renewals to a sufficient number of large incandescent, or "Sunbeam" lamps, of 300 candle-power each, would cost about £250 per annum. The arc lamps in operation at Reading are nominally of 1,200 candle-power each; some 50 to 60 per cent. of the illumination is, however, absorbed by the globes. The total illuminating power at the library is, therefore, equal to about 4,320 candles. The cost for the gas consumed in the library and reading-rooms last year was £79 odd, while the total illuminating power was equal to some 1,360 candles.

Konigsberg.—The five-wire central station at Königsberg, the first of its kind in Germany, will shortly come into operation. The total capacity of this station is at present 600 horse-power. There are two groups of engines and dynamos, each comprising two triple-expansion engines, and four dynamos. The larger group which has to do the regular evening work consists of two 200 horse-power triple-expansion Schischau engines, each driving two 64 kilowatt dynamos. During the few hours of heaviest work, when two-thirds of the 8,000 lamps are alight, this group will be assisted by the smaller one, consisting of two 100 horse-power engines, each of which drives two 32 kilowatt dynamos. The fall of potential in the leads amounts to 10 volts at full load; the mains and distributing leads are all placed in Monnier conduits. The network is calculated for the supply of 24,000 lamps. Accumulators are used, and special devices have been arranged to prevent them from being placed in the charging circuit before the right tension is reached. During their discharge, if their E.M.F. should fall, additional cells are automatically switched in. Any difference in the voltage of the different parts of the network is shown by a specially-constructed differential voltmeter.

The Behaviour of Lubricating Oils.—In a Paper read at the recent meeting of the American Association for the Advancement of Science at Indianapolis, Mr. J. E. Denton says:—Experiments to determine the coefficient of friction between lubricated rubbing surfaces have been prosecuted for 200 years, and have resulted in the construction of many forms of satisfactory apparatus for such measurement, and such machines are now used by large consumers of oil as a means of discriminating between the lubricating value of the numerous oils offered by manufacturers, and which, while practically alike in fluidity and general oily qualities, are nevertheless claimed to differ in their lubricating qualities. The only difference of behaviour of these lubricating oils shown by the oil-testing machines is such differences of frictional resistance as can be ascribed to the variation in viscosity of the substances in the fluid condition, and this difference of friction fails to account for the well-attested fact that some of the oils are unable to prevent excessive heating and cutting on heavy machinery bearings, which exhibit no such action when lubricated with other oils. Experiments made with a special apparatus constructed for the Lubricating Committee of the Standard Oil Company prove that the overheating of bearings is due to accidental abrasion of the rubbing surfaces, caused by the gradual and inevitable variations of the smoothness of these surfaces by metallic wear. This abrasion generates a comparatively intense heat at some point of the bearings, and tends to vaporise some oils more than others. Oils which are incapable of resisting excessive vaporisation by such accidental heating are those which permit bearings to more frequently overheat than do others not so affected by temperature. The prevailing oil-testing machines fail to reveal such differences in oils. Mr. Denton, therefore, concludes that in order to enable mechanical oil tests to reveal actual differences of lubricating value, each oil must be tested with a series of conditions of the rubbing surfaces and practical feeding devices which involve opportunities for abrasion and overheating.

ON THE BEST DIMENSIONS FOR STANDARD OPTICAL AMMETERS AND VOLTMETERS.

BY A. E. KENNELLY.

Attention has recently been called to the application of the optical galvanometer to the measurement of current strength, utilising the electro-optical laws of Faraday, Becquerel, Weidermann, and Verdet. The advantage possessed by the method is its almost complete freedom from local magnetic disturbances to which galvanometers as a class are subject, and also its capability of rendering current strengths in absolute measure from purely geometrical data, having given a good rotatory polarication apparatus of the saccharimeter type, and a pure chemical medium for the light to traverse, with a reliable electro-optic constant. Such an instrument is unfitted for practical indicators of current or E.M.F. in engineering practice, and can at present be only used advantageously for standard measurements. In these, however, it possesses a very fair degree of accuracy, and a convenience in manipulation second only to that afforded in the use of the gravitational measurers of Sir William Thomson. It is proposed to discuss the conditions that lead to the best construction of the instrument, as these apparently have not yet been published. The liquid meduim generally adopted is bisulphide of carbon, which can be obtained in the requisite degree of purity without difficulty, which possesses a high, though by no means the highest specific rotatory power among liquids, and which has probably received the most careful determination of that power under the title of the "Verdet Constant."

It will be advisable to examine mathematically the best conditions for securing the greatest amplitude of rotation for any given current, and the limitations to which that amplitude is subject. The practical formulas for determining the best winding for the various classes of instruments will then directly follow.

Let c be the current flowing through the helix (amperes).
" e " " E.M.F. acting on the helix, or the potential difference between its terminals, asssumed steady (volts).
" r " " resistance of the helix (ohms).
" l " " length of the helix (centimetres).
" a " " internal radius of. the helix (centimetres).
" b " " external radius of the helix (centimetres).
" m " " mass of the helix (grammes).
" n " " number of turns in the helix per centimetre of its length.
" N " " total number of turns in the helix or ln.
" σ " " specific gravity of the conductor in the helix.
" d " " diameter of the conductor (centimetres).
" D " " diameter of the covered wire.
" v " " magnetic potential difference between the ends of the helix axis of the liquid column in absolute measure.
" ϕ " " "Verdet Constant," or the rotation in the medium of a plane polarised series of luminous vibrations, with given frequency, for unit electromagnetic potential difference expressed in minutes of arc.
" θ " " observed angle of rotation (minutes).
" ρ " " resistivity of the conductor at working temperature (ohms per cubic centimetre).
" h " " heat developed by the current in the helix per square centimetre of its external surface per second (watts).

Then the fundamental electro-optic law is:—

$$\theta = v\phi \quad \ldots\ldots\ldots \quad (1)$$

To a first approximation, very nearly accurate for a long, thin helix,

$$v = \frac{4\pi}{10} c\,\mathrm{N} = \frac{4\pi e n l}{10 r} \quad \ldots\ldots \quad (2)$$

The correction for the reduction in magneto-motive force due to the influence of the free solenoidal poles is a simple one. It can be deferred for the moment if it is remarked that in virtue of this correction the actual length (l) of the helix becomes a virtual length, L, where $\mathrm{L} = l - \lambda$, and consequently equation (1) becomes strictly

$$\theta = \frac{4\pi n e \phi \mathrm{L}}{10 r} \quad \ldots\ldots\ldots \quad (3)$$

In what follows, the uncorrected length l only will be considered, since the correction is usually small, and can always be separately introduced.

Developing N and r of (2) in terms of the dimensions of the solenoid,

$$\mathrm{N} = \frac{l(b-a)}{\mathrm{D}^2} \quad \ldots\ldots\ldots \quad (4)$$

$$r = \frac{4\rho l (b^2 - a^2)}{\mathrm{D}^2 d^2} \quad \ldots\ldots\ldots \quad (5)$$

This is on the assumption, realisable with care in practice, that the wire is uniformly and accurately wound on the solenoid without paper or other insulating material between the layers or turns. This assumption is involved in all that follows. Substituting in (1) and (2)

$$\theta = \frac{\pi e \phi d^2}{10\rho(b+a)} \quad \ldots\ldots\ldots \quad (6)$$

This shows that the amplitude of rotation obtainable from a helix for a given potential difference between the terminals, that is when used as a voltmeter, does not in the first instance depend upon the length of the helix, but varies as the sectional area of the wire directly, and as the mean radius of the winding inversely. This means that for a given winding space, the amplitude would increase indefinitely with the sectional area of the wire used in winding the instrument. Practically, however, the limit is reached owing to the strength of the current in the helix, and the heat that current would generate during the measurement. This heat not only alters r, affects to a certain extent the specific rotary power ϕ, but also interferes with the working of the apparatus by setting up differences of density in the liquid column, thus refracting, scattering, and obscuring the beam of light. A jacket of insulating circulating water, if inserted between the tube and helix, would certainly act as a shield, but would by no means add to the convenience of the instrument, while it would tend to reduce its effectiveness in another direction by increasing the radius of the helix. In any case, the variation in r due to any considerable rise of temperature would interfere greatly with the use of the apparatus for standard measurements. It therefore becomes necessary to so limit d that the heat generated may escape from the surface of the helix without materially raising its temperature, or that h may not exceed a certain limiting value.

This value is, strictly speaking, a function of a and b; but for practical purposes we may fairly consider the limit to be $h = 0{\cdot}02$ watts per square cm. for intermittent and measuring currents, and $h = 0{\cdot}01$ for a helix that has to remain in circuit and sustain a permanent current.

Expressing d in terms of h and the general dimensions

$$d^2\mathrm{D}^2 = \frac{8 h l b \pi l^2 \rho (b^2 - a^2)}{e^2}, \quad \ldots \quad (7)$$

and

$$b = a\sqrt{1 + \frac{4m}{\pi q}\left(\frac{\mathrm{D}}{d}\right)^2}, \quad \ldots\ldots \quad (8)$$

where $q = \pi a^2 \sigma l$, or the mass of the space within the helix if converted into copper

Hence,

$$d^2 = \frac{l}{e}\sqrt{\frac{32 h \rho m b}{\pi \sigma}}, \quad \ldots \quad (9)$$

and

$$\theta = \frac{4\pi\phi}{10}\sqrt{\frac{lm}{a}} \times \sqrt{\frac{2h}{\pi\rho\sigma}} \times \frac{b}{a+b} \quad \ldots \quad (10)$$

The last equation shows that when the current in the helix reaches the heat limit the rotation obtainable is independent of the E.M.F., varies approximately as the square root of the mass of copper in the winding, and also as the square root of the dimensional ratio $\frac{l}{a}$. In other words, the same amplitude should be obtainable from all well-designed instruments, whether am-

Digitized by Google

meters or voltmeters, and it is almost useless with a given weight of wire to increase the length of helix, notwithstanding the greater service obtained, if the internal diameter be increased in the same proportion.

Taking $\sigma = 8{\cdot}95$, $\rho = 1{\cdot}8 \times 10^{-6}$ values for copper.

$$\theta = 250\phi \sqrt{\frac{lmh}{a}} \times \frac{b}{a+b}. \quad . \quad . \quad . \quad . \quad . \quad (11)$$

For the D line of the sodium flame ϕ is given by Lord Rayleigh and A. Koepsel at 18°C, as $4{\cdot}20 \times 10^{-2}$, so that

$$\theta = 10{\cdot}50 \sqrt{\frac{lmh}{a}} \times \frac{b}{a+b}. \quad . \quad . \quad . \quad . \quad . \quad (12)$$

For intermittent currents and $h = 0{\cdot}02$

$$\theta = 1{\cdot}485 \sqrt{\frac{lm}{a}} \times \frac{b}{a+b}. \quad . \quad . \quad . \quad . \quad . \quad (13)$$

For permanent currents, and $h = 0\ 01$

$$\theta = 1{\cdot}05 \sqrt{\frac{lm}{a}} \times \frac{b}{a+b}. \quad . \quad . \quad . \quad . \quad . \quad (14)$$

It is difficult to make l more than one metre, if only from the absorption of light in so long a column; also it is difficult to make the internal diameter of the helix less than 1 cm.; hence the practical limit of $\sqrt{\frac{l}{a}}$ may be estimated at 10. Again, a fair maximum for m would be 10,000, or 22lb. of copper, and with the superior limit of the fraction $\frac{b}{a+b}$, namely, unity, we have for intermittent currents, maximum $\theta = 1485'$ or 24°45', and for permanent currents, maximum $\theta = 1050'$ or 17°30'.

It might be possible to double the amplitude of rotation by arranging a mirror at one end of the tube and causing the light to traverse the length of the liquid column twice in succession, but this is not only inconvenient but probably needs an increase of illumination and of internal radius. It is also to be regretted that no simple and definite standard of illumination can yet be adopted with a higher frequency than the sodium flame. Thus a monochromatic flame radiating violet light of the wave length G would more than double the amplitude of rotation.

Assuming the above, then, to be the practical limits of amplitude with instruments operating at their maximum capacity, the degree of accuracy obtainable depends only upon the degree of precision with which the amplitude can be measured. With a good polarimeter, and particularly with a repeating circle to eliminate errors of eccentricity, the limit of precision on steady currents should certainly not exceed 2′ of arc; and in fact when repeated measurements can be made, a mean rotation can always be found whose probable error is less than 1′, so that the degree of precision at full capacity attainable is certainly one part in 750, and probably one part in 1,500 with care and under the most favourable circumstances.

The best windings for such instruments may next be considered, and first for voltmeters. Suppose the length of the helix given, the internal radius a, and the total mass of wire m to be wound, the maximum voltage to be measured being also given. It is to be remarked that the degree of precision in the observations with any instrument diminish as the current measured descends below the maximum current so that they work best at full load. The diameter of the wire to be used can be found from equation 9. In solving it a trial value can be given by estimation to the fraction $\left(\frac{D}{d}\right)^2$, and if this value should be found inaccurate by the result, the formula should be used again with the adjusted value. As an example, let it be required to determine the best winding for a voltmeter to operate at a maximum limit of 130 volts, the length of the helix being 62cms. between flanges, and its radius 1·1cms., allowing 10lb. of wire in the helix, and a heat limit of 0·02 (intermittent currents).

Assuming $\left(\frac{D}{d}\right)^2 = 1{\cdot}2$, formula (8) gives

$$b = 1{\cdot}1 \sqrt{1 + \frac{4 \times 10 \times 453{\cdot}6 \times 1{\cdot}2}{3{\cdot}142 \times 3{\cdot}142 \times 62 \times 1{\cdot}21 \times 8{\cdot}95}}$$
$$= 2{\cdot}277$$

then by (9) $d^2 = \frac{\sqrt{62}}{130} \sqrt{\frac{32 \times 0{\cdot}02 \times 1{\cdot}8 \times 10^{-6} \times 4536 \times 2{\cdot}277}{3{\cdot}142 \times 8{\cdot}95}}$

$$= 12{\cdot}46 \times 10^{-4}$$

or, $$d = 3{\cdot}53 \times 10^{-2} = 0{\cdot}0139''.$$

When covered this wire would have, say, a diameter of 0·017″, so that $\left(\frac{D}{d}\right)^2$ would be 1·474. Repeating the reckoning with this value in place of 1·2, b becomes 2·468, and d 0·0142″, in this case practically the same result.

The amplitude to be expected from the instrument at 130 volts would be by (13)

$$= 1{\cdot}466 \sqrt{\frac{62 \times 4536}{1{\cdot}1}} \times \frac{2{\cdot}468}{2{\cdot}468 + 1{\cdot}1}.$$

$= 519'$ or 8°·39′ ± subject to correction for polar influence.

Ammeters.—If the instrument is intended for an ammeter, it will be necessary to wind it with coarse wire up to the heat limit. The diameter which will attain this for a given maximum current c ampere, is expressed by the equation

$$d^2 = \frac{c}{\pi} \sqrt{\frac{8\,a\,m\,\rho}{h\,q\,b}}, \quad . \quad . \quad . \quad . \quad (15)$$

where $$b = \sqrt{1 + \frac{4\,m}{\pi\,q} \left(\frac{D}{d}\right)^2}, \text{ as before.}$$

For example, suppose it were required to determine the most effective winding for an optical ammeter of 50 amperes maximum capacity, the length of the tube being 80cms., the winding diameter 1·3, and the weight of copper wire 8lb., the instrument to be kept permanently in circuit ($h = 0{\cdot}01$), since the wire will be coarse $\left(\frac{D}{d}\right)$, will be 1·02, say, then,

$$b = 1{\cdot}3 \sqrt{1 + \frac{4 \times 8 \times 454 \times 1{\cdot}02 \times 1{\cdot}02}{3{\cdot}14 \times 3{\cdot}14 \times 1{\cdot}3 \times 1{\cdot}3 \times 80 \times 8{\cdot}95}}$$
$$= 1{\cdot}956;$$

and $$d^2 = \frac{50}{3{\cdot}14} \sqrt{\frac{8 \times 1{\cdot}3 \times 8 \times 454 \times 1{\cdot}8 \times 10^{-6}}{0{\cdot}01 \times 3{\cdot}14 \times 1{\cdot}3 \times 1{\cdot}3 \times 80 \times 8{\cdot}95 \times 4{\cdot}8}}$$
$$= 0{\cdot}5489,$$
$$d = 0{\cdot}741, \text{ or } 0{\cdot}292''$$

The amplitude obtainable at full load in this case would be by (2) and (4).

$\theta = 235'$, or 3°·55′, subject to slight correction for polar influence.

When the instrument is needed for an ammeter in a circuit containing resistance in such degree that the heat limit cannot be reached, the above formulas no longer apply.

Let E be the E.M.F. of the circuit, and β its resistance.

Then $$c = \frac{E}{\beta + r}$$

whence $$\theta = \frac{4\,\phi\,E}{10(b+a)} \sqrt{\frac{m}{\rho\sigma}} \times \frac{r}{\beta + r}$$

Differentiating this with respect to r, and equating to zero, we have for the maximum value of θ, $r = \beta$, or the resistance of the instrument should equal that of the rest of the circuit, and then

$$\theta = \frac{E\,\phi}{5\sqrt{\beta}\,(b+a)} \sqrt{\frac{m}{\rho\sigma}} \quad . \quad . \quad . \quad . \quad (16)$$

Substituting the values already stated for ρ, σ, and ϕ

$$\theta = \frac{2{\cdot}09\,E}{b+a} \sqrt{\frac{m}{\beta}} \text{ where } b \text{ is found from (8)} \quad . \quad (17)$$

To find d in this case, we have the relation

$$d^2 = \frac{4}{\pi} \sqrt{\frac{m\,\rho}{\beta\,\sigma}} \quad . \quad . \quad . \quad . \quad (18)$$

or $$d = 0{\cdot}0239 \sqrt[4]{\frac{m}{\beta}} \quad . \quad . \quad . \quad . \quad (19)$$

Digitized by Google

Thus, suppose the most effective winding to be found for an instrument to indicate the E.M.F. of one Leclanché's cell of 1·5 volts, having a resistance of 1 ohm, using 10lb. of wire, and with the dimensions $l = 6{\cdot}0, a = 1{\cdot}2$, and $m = 4536, \left(\frac{D}{d}\right) = 1{\cdot}18$.

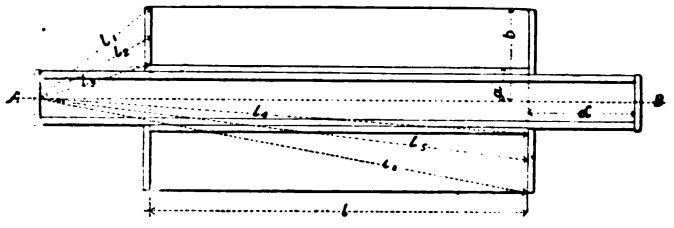
Here $$b = 1{\cdot}2\sqrt{1 + \frac{4 \times 4536 \times 1{\cdot}18 \times 1{\cdot}18}{3{\cdot}14 \times 3{\cdot}14 \times 1{\cdot}2 \times 1{\cdot}2 \times 60 \times 8{\cdot}95}}$$
$$= 2{\cdot}49$$

and $$\theta = \frac{2{\cdot}09 \times 1{\cdot}5}{2{\cdot}49 + 1{\cdot}2}\sqrt{\frac{4536}{1{\cdot}0}}$$
$$= 57' \pm$$

while $$d = 0{\cdot}0239^4\sqrt{\frac{4536}{1}} = 0{\cdot}196 = 0{\cdot}077''.$$

The above formula enable the best size of wire to be found for all the conditions that are usually met with in practice. They have been proved practically reliable by experiment, in the Edison laboratory, the only constants about which there remains any uncertainty being the heat values 0·01, and 0·02, which are estimates fairly reliable.

The formula of correction for the polar influence of the helix upon its *m.m.f.* may be given in conclusion. Let the figure represent a longitudinal section through the axis of the tube



and encircling helix. The tube is supposed to be set symmetrically in the helix, so that the distances d from the extremities to the terminal planes of winding are equal. While not essential, this adjustment is generally easy, and abbreviates the correctional formula. Let l_1, l_3, l_4, l_6, be the distances as shown from one extremity of the axis in the tube, to the circumferences of the coil, while l_2, l_5, are the corresponding distances to the mean circumference. Then equation (3) becomes more strictly

$$\theta = \phi\left\{\frac{4\pi}{10} N c \left(\frac{l_5 - l_2}{l}\right)\right\}. \quad . \quad . \quad . \quad (20)$$

This formula corrects the length of the helix for the polar influence of a similar solenoid of like length and current turns, but of indefinite thinness fixed at the mean circumference. The amount of the correction is with long tubes so small that this approximation is sufficient. When the correction needs to be made with more care the formula is

$$\theta = \frac{2\pi c \phi N}{10 l (b-a)}\left\{b(l_6 - l_1) - a(l_4 - l_3) + D^2 \log_\epsilon\left(\frac{l_6 + b}{l_4 + a}\right) - d^2 \log_\epsilon\left(\frac{l_1 + b}{l_3 + a}\right)\right\} \quad . \quad . \quad . \quad . \quad (21)$$

where $D = l + d$.

This formula is often independently useful for the determination of magnetic differences of potential between points measured along the axis of a homogeneous coil, and equidistant oppositely from its midplane.

As an example suppose the sodium line rotation to be required by computation from a uniform helix of 50,000 turns of length $l = 30$, and radii $a = 2$, $b = 4$, when carrying 0·1 ampere over a tube 34 cm. long.

Formula (3) gives $$\theta = \frac{4}{10} \times 3{\cdot}142 \times 4{\cdot}2 \times 10^{-2} \times 50{,}000 \times 0{\cdot}1$$
$$= 263{\cdot}9' = 4°{\cdot}23'{\cdot}50''.$$

By formula (20) $$\theta = 4{\cdot}2 \times 10^{-2} \times \frac{4}{10} \times 3{\cdot}142 \times 50{,}000 \times 0{\cdot}1 \times \left(\frac{32{\cdot}14 - 3{\cdot}61}{30}\right) = 251{\cdot}1' = 4°{\cdot}11'{\cdot}6''.$$

By (21) $$\theta = \frac{2 \times 3{\cdot}14 \times 0{\cdot}1 \times 4{\cdot}2 \times 10^{-2}}{10 \times 30 \times (4-2)} \times 50{,}000 \times \left\{4(32{\cdot}25 - 4{\cdot}47) - 2(32{\cdot}06 - 2{\cdot}83) + 1024 \log_\epsilon\left(\frac{32{\cdot}25 + 4}{32{\cdot}06 + 2}\right) - 4\log_\epsilon\left(\frac{4{\cdot}473 + 4}{2{\cdot}829 + 2}\right)\right\}$$
$$= 250{\cdot}5' = 4°{\cdot}10'{\cdot}5.$$

The rotation obtained for a given current really varies slightly with the temperature of the bisulphide of carbon liquid.

M. Pichat has given the following formula for reducing the rotation observed at one temperature to that at another:—

$$R_t = R_0(1 - 0{\cdot}00104t - 0{\cdot}000{,}104t^2)$$

where R_t is the rotation at t°C., R_0 being the rotation at zero. From the standard value of $\phi = 4{\cdot}2 + 10^{-2}$, and this formula we have the following table of temperature values for the Verdet constant of $C S_2$:—

t°C	φ	t°C	φ	t°C	φ
0	0·04300	10	0·04249	20	0·04186
1	0·04295	11	0·04244	21	0·04179
½	0·04290	12	0·04238	22	0·04172
3	0·04285	13	0·04232	23	0·04165
4	0·04281	14	0·04226	24	0·04158
5	0·04276	15	0·04220	25	0·04151
6	0·04271	16	0·04213	26	0·04143
7	0·04266	17	0·04207	27	0·04136
8	0·04261	18	0·04200	28	0·04128
9	0·04255	19	0·04193	29	0·04120

Resumé.

The amount of rotation obtainable from an optical ammeter or voltmeter varies as the square root of the weight of copper used in the winding when used most effectively. It also varies as the square root of the ratio of length to internal diameter of helix, so that the length should be as great as possible, and the internal diameter as small as possible, consistent with good optical conditions. There exists a practical limit to which the rotation obtained from any such instrument is subject, owing to the heat developed in the coil by the current. This limit is about 25deg., according to the estimates here given for currents of short duration, and 18deg. for instruments permanently in circuit. No theoretical limits are, however, prescribed if the thermal effects can be obviated. The best sizes of wire to employ for different instruments when the dimensions of the tube and weight of wire have been decided upon, are given in formulæ with examples, together with correction for virtual length, by which currents can be determined from good apparatus in absolute measure with an accuracy of at least one part in 750.

THE CENTRAL STATIONS OF THE METROPOLITAN ELECTRIC SUPPLY COMPANY.

BY DR. J. A. FLEMING.

The Metropolitan Electric Supply Company was formed in August, 1888, for the supply of electric energy from distributing and generating centres, and its work of establishing these centres in London has been pushed forward with great energy since that date. Under its Provisional Orders, this Corporation has assigned to it large and important areas of electric lighting in the Metropolis. These areas include in the aggregate more than 80 miles of streets, a large number of which run through some of the wealthiest portions of London. Under these circumstances, electrical engineers and the public generally will note with interest the progress being made in meeting the demand for electric lighting in these areas; and, by permission of the Directorate, we propose to give some description of the various central stations now actually in operation by this Company, taking them in order of completion.

Sardinia Street Station.

One of the largest of these, now completely finished and in active operation, is in Sardinia-street, Lincoln's Inn-fields. The erection of this station was begun in August, 1888, and

Digitized by Google

on September 21, 1889, current was first supplied from it. The dynamo plant and engines were constructed by the Westinghouse Company, and it was arranged and fitted up by this last-named corporation in consultation with the engineering staff of the Metropolitan Electric Supply Company. The Sardinia-street station is a very complete and typical station for the supply of electric currents on the alternating-current transformer system. It consists of a substantial two-storey building, in the construction and design of which the highest possible architectural and engineering skill has been applied to cope with the difficulties which might arise from noise or vibration in a building so placed in the centre of a closely inhabited Metropolitan area. It may broadly be described as a box within a box; that is to say, the central portion, or machinery rooms, are enclosed in a building which is itself contained in a closed-in space; and the communication of aerial vibration is thus greatly limited by the double walls with intervening space which separate what may be called the vitals of the station from the external space. The communication of vibration through the foundations has been prevented by the most carefully arranged methods, and, generally speaking, the whole problem of installing a steam plant of the magnitude required in such a manner as to avoid the difficulties inherent in such a work, has been dealt with in a manner which speaks highly for the skill and experience invoked. The general plan of the station is shown in Figs. 1, 2 and 3. The chimney shaft is of white glazed brick externally, and the whole building is lined internally with white glazed brick, which gives it a very clean appearance. The ample space in the dynamo, engine, and boiler house render the working of the station most comfortable to the staff.

On the ground or entrance floor are placed the engines (*see* Fig. 3). The dynamos and exciters are on the floor above, and driven by belting passing up through the floor. The boiler-house is on a lower level than the engine-room, and the coal store is so arranged that the coal is shot down from the street level direct into it.

Entering on the engine-room level, which opens into a covered yard, we find a double row of Westinghouse compound engines. Five of these engines are each of 250 horse-power, and five are of a rather larger size, making in all a provision for the actual production of about 3,000 horse-power. Behind one series of these main engines stand

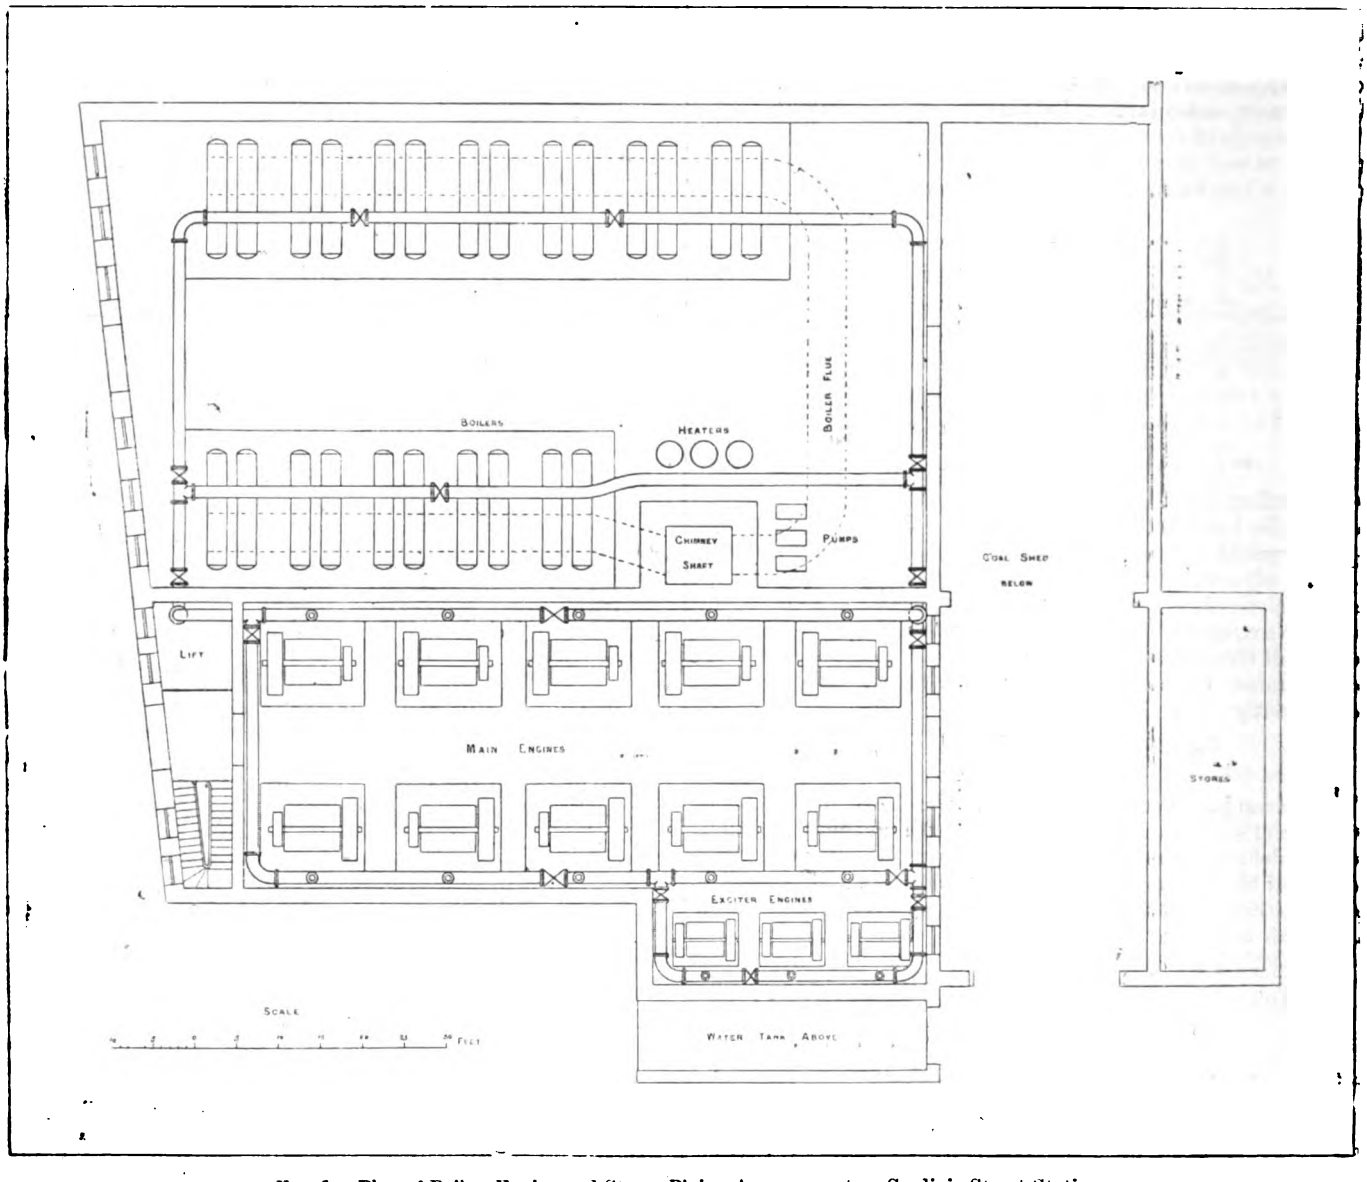


Fig. 1.—Plan of Boiler, Engine and Steam Piping Arrangements. Sardinia Street Station.

three Westinghouse engines of 65 horse-power, each of which serve to drive the exciter dynamos. The main engines have high-pressure cylinders of 14in. diameter, and low-pressure cylinders of 24in. diameter and 14in. stroke, and are technically known as 14 × 24 × 14 engines. The exciter engines have high-pressure cylinders of 10in. and low-pressure cylinders of 18in. and 10in. stroke. These Westinghouse engines are so well-known that space need not be occupied by detailed description of them. They are high-speed engines, making 200 revolutions per minute, and having a piston speed of 653ft. per minute. At Sardinia-street they are worked non-condensing. Each engine is built up on a brick and concrete platform which rests on a bed of felt and sheet lead, this in turn reposing on

Digitized by Google

the concrete foundations. By this device the communication of "thump" through the foundations is prevented. This series of separate engines forms a steam plant, which can be divided up and operated in such a manner as to secure that the engines actually in use are being worked as nearly as possible at their full power. Each engine drives its own alternating current dynamo on the floor above by means of a leather belt. These belts are 20in. in width and made of the finest leather, spliced with bevelled joints to avoid any double thickness at a joint. The engines take steam from a ring steam main and exhaust into a single exhaust pipe large enough for 3,000 horse-power. Each section of the ring steam main can be isolated by stop valves, so that any section can be cut out without affecting the rest. Descending down one flight of steps into a lower level we find ourselves in the boiler-house, in which are erected 12 Babcock and Wilcox water-tube boilers, each capable of evaporating 6,000lb. of water per hour. These boilers are set in two rows face to face down the sides of the boiler-house, the length of the house being about 100ft. Ample space to stoke is left between the furnaces; and down the centre of the gangway runs a tram-line, on which the coal trolleys are run from the coal store to the furnace mouth. Underneath this gangway are the blow-off tanks and piping.

The boilers are supplied with water by three Worthington steam-pumps, any two of which will do the whole work; and the feed is so arranged that it can be taken either through the feed-water heaters, of which there are three, or by a by-pass direct into the boilers. The boilers are fed from both drums. The water tank is large enough for twelve hours' work at full load, and there is also a water supply direct from the mains. The boilers can be thus supplied either direct from the mains or from the water tank, though the water can be taken either through the feed-water heaters or direct into the boilers. The floor of the boiler-house is about eight or ten feet below the level of the street, so that dirt cannot be carried into the engine-room. The boiler-house has a glass sky-light roof, and is comfortable and spacious. At the end of the boiler-house is the coal store, capable of holding a month's supply of coal for the station when working at full load. Into this store the coals can be shot down from the coal carts in the street above by shoots. There it is handled into the coal trolleys and goes at once by the boiler-house tramway to be delivered at each ashpit. It is thus seen that the minimum of labour is required both in stoking and in coal handling. The boilers all feed their steam into a ring main, the general plan of the steam piping being shown in Fig. 1.

Ascending on to the first floor, above the engine room we find ourselves in a large and well-lighted dynamo room (*see* Fig. 2). Here are ten Westinghouse alternate-current dynamos, of 125 kilowatts out-put each, providing, therefore, for a total output of 1,250,000 watts, or for a supply of 20,000 50-watt lamps, all burning at one time. These dynamos are respectively driven by the belting coming up from the associated engine on the floor below. The belts and pulleys are covered in with belt shields. Each dynamo generates an alternating current at a pressure of about 1,050 volts when running at its normal speed of 1,030 revolutions per minute. These dynamos are technically known as the "No. 3" size. The dynamos are bolted down on strong wooden frames, and have the usual belt tighteners and screws. All moving parts of the dynamos are supplied with oil from sight-feed lubricators, which are themselves fed from an oil tank placed at a higher level. From this oil tank proceed a system of oil pipes to each dynamo. The waste oil runs away down-stairs by waste pipes; is cleaned, filtered, and pumped up again to the oil tank by a small pump. By this excellent arrangement, which

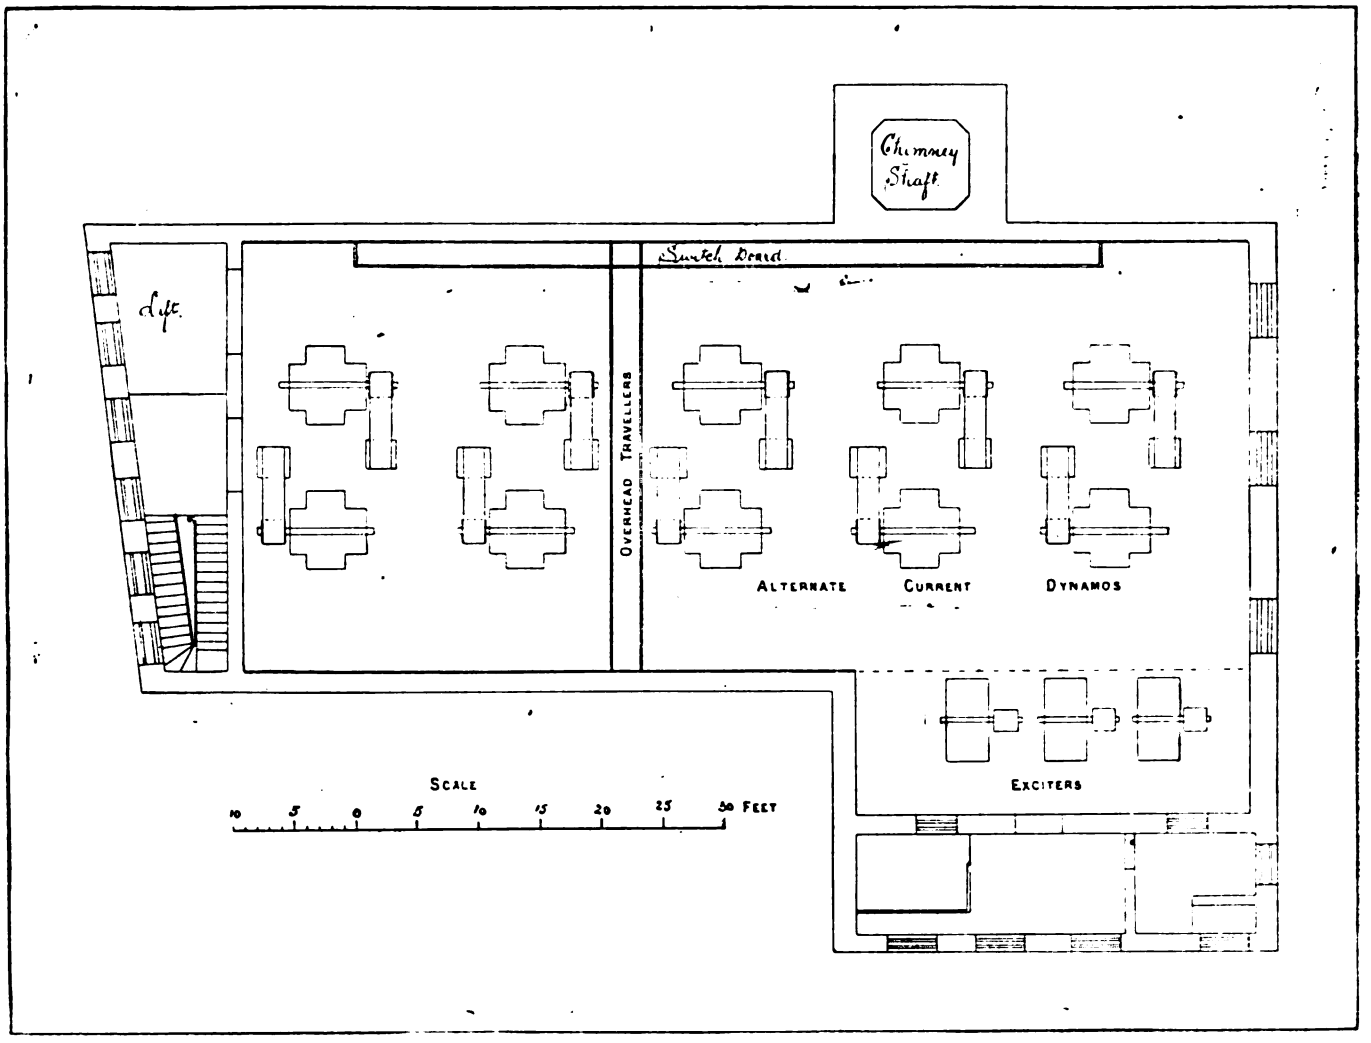

Fig. 2.—Plan of Dynamo Room. Sardinia Street Station.

Digitized by Google

is characteristic of American engineering, the use of oil cans is rendered entirely unnecessary. The detailed description of this size and type of Westinghouse alternator

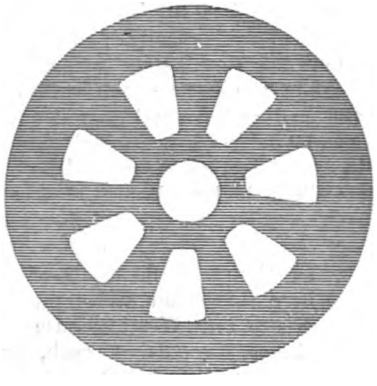

Fig. 4.—Sheet-Iron Disc of Westinghouse Armature Core.

has been given in *The Electrician* of October 3, 1890, p. 603. A few further details of its construction may here be given. The armature is composed of sheet-iron discs, which are punched out in the centre so as to leave wheel-shaped iron laminæ (*see* Fig. 4). These sheets are put together without paper between them; but previously, however, being slightly oxidised or rusted. It is found that the thin layer of oxide has sufficient electric non-conductivity to arrest eddy currents; but yet not any disadvantageous magnetic non-conductivity. These iron discs are assembled on the steel shaft, and compressed by massive screw-nuts between end plates. The soft-iron plates are carefully annealed after being punched, so as not to require touching with tools after this annealing. On this iron core is laid a layer of asbestos and mica, and then on this the flat, link-shaped coils of insulated wire. These coils consist of one layer of wire formed into a flat coil of 13 turns. Each coil is 27in. long in the straight part, 5·5in. wide; and the aperture of the coil, which is filled in with a wooden lathe, is 1in. wide (*see* Fig. 5). Hence there are $27 \times 26 = 702$in. of active wire on each coil. These coils are laid on the drum, and

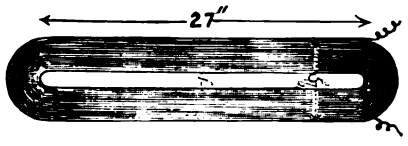

Fig. 5.—Single-Flat Coil of Westinghouse Armature.

are just so long that the curved ends of the coils can be bent over the end of the drum. Sixteen such coils are laid on, having one-quarter of an inch space, occupied by a wood strip, between adjacent coils. The coils are then bound on the drum with brass wire, the wire of the coils being protected by asbestos and mica insulation. The surface of the core is quite smooth, and the flat wire coils are kept in position and driven round simply by the friction due to the binding wire. The coils on each half of the drum are joined up in a series of eight, and the two series are joined together in parallel. Hence, each coil contributes 125 volts to the electromotive force, which is at the rate of less than six inches of wire to the volt. The wire of the armature coils is double cotton-covered and insulated with a special insulating varnish. The ends of the coils where they are turned over the flat end of the drum are defended by bronze shielding plates. The whole

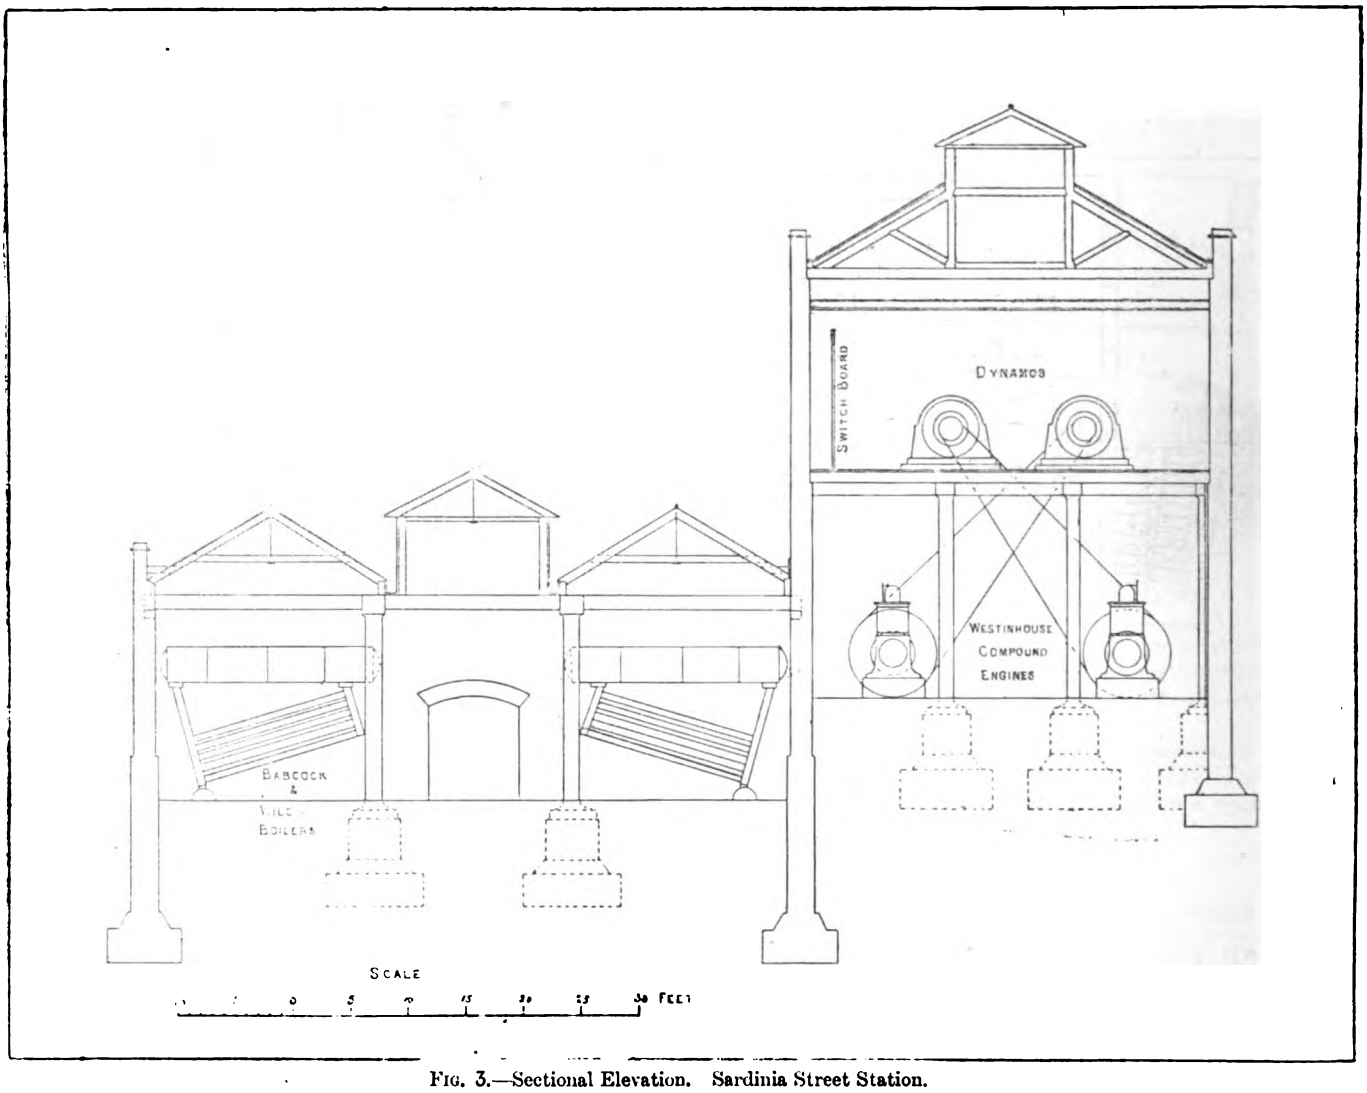

Fig. 3.—Sectional Elevation. Sardinia Street Station.

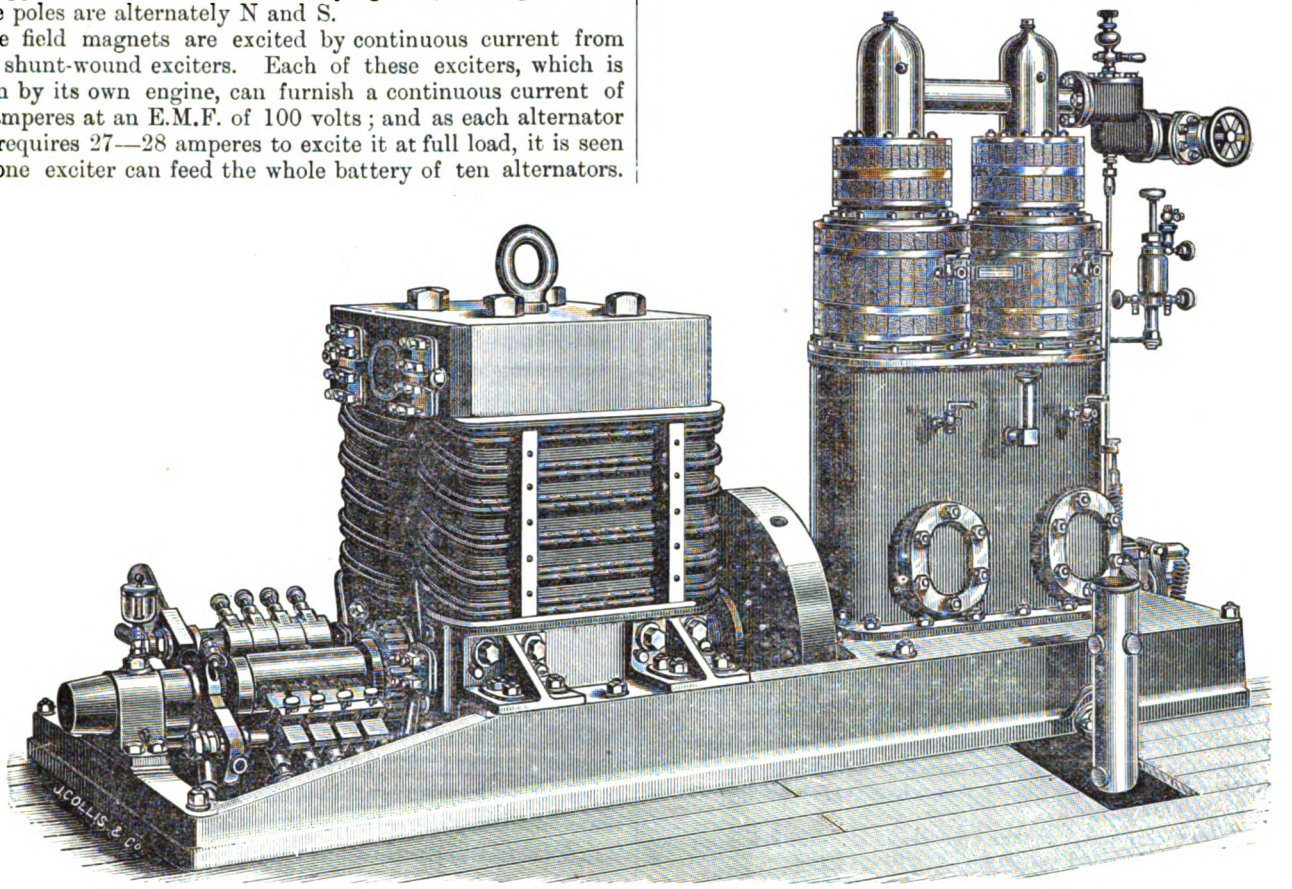
Digitized by Google

armature is thirty inches in diameter over all. In addition to the end plates another disc is provided at one end, with radial strips which act as a centrifugal fan and draw air through the apertures in the core to assist in keeping it cool.

The armatures of all the machines being exact facsimiles are interchangeable. By means of an overhead traveller, which runs the whole length of the dynamo-room, it is a matter of a few moments to lift off the top half of the field-magnet of any dynamo, lift its armature out of its bearings, and replace it by another. This construction of armature is both simple to repair, and admits of very high insulation being attained in practice. The ring-shaped field-magnet frames carry sixteen magnet poles projecting inwards. These poles are solid cast iron, and are 27in. long, 2·5 wide, and 8in. long. On to these poles are slipped the shells or frames carrying the field-magnet coils. These poles are alternately N and S.

The field magnets are excited by continuous current from three shunt-wound exciters. Each of these exciters, which is driven by its own engine, can furnish a continuous current of 300 amperes at an E.M.F. of 100 volts; and as each alternator only requires 27—28 amperes to excite it at full load, it is seen that one exciter can feed the whole battery of ten alternators.



Edison-Hopkinson Fifty-Three Kilowatt Dynamo and Willan's Central Valve Engine.

The exciters are ordinary horizontal double-magnet shunt-wound continuous-current machines. They have pulleys with paper driving surface, and are the usual form of Westinghouse exciters.

From these exciters leads run to the switch-board, to be described in another article, at which all combinations and interchanges are effected.

(To be continued.)

EFFICIENCY OF THE EDISON-HOPKINSON DYNAMO AND WILLAN'S CENTRAL VALVE ENGINE.

Various tests have been published from time to time of the efficiency of Messrs. Willan's and Robinson's Central Valve Engine, and the several types of dynamos with which they are combined. At a recent test made at Thames Ditton with a large Edison-Hopkinson dynamo, constructed by Messrs. Mather and Platt, of the Salford Ironworks, Manchester, a result has been obtained giving an efficiency superior to anything previously attained. The results show an efficiency of engine and dynamo combined, *i.e.*, the ratio of the electrical power available for useful work outside the dynamo to the indicated power of the engine, of 86·7 per cent.

The following are particulars of the engine and dynamo, shown in the accompanying illustration: — Compound double crank engine with low pressure cylinders 14in. diameter, stroke 6in., to work with 120lb. steam pressure, driving direct an Edison-Hopkinson dynamo, constructed for an output of 110 volts 475 amperes at 430 revolutions per minute. The dynamo has a bar armature, and is shunt-wound only. It is fitted with a commutator of hard drawn copper with mica insulation, with four brushes on each rocking arm. The resistance of the magnets is 16 ohms and that of the armature 0·0055 ohm. The indicated horse-power of the engine was 83·3, and the useful electrical horse-power given out by the dynamo was 72·2 Hence the efficiency was 86·7 per cent. The consumption of water per indicated horse-power was 21·6lb The consumption of water per electrical horse-power was 25lb.

In the test made on this combination both engine and dynamo were worked to a somewhat higher load than their normal or specified load, and this, no doubt, would be to a slight extent favourable to the efficiency. Another test was made on a similar combination working at its normal load, with the following results:—Resistance of armature, 0·0058 ohm; resistance of magnets, 15·6 ohms; indicated horse-power, 85·3; electrical horse-power, 70·0. Efficiency, 83·3 per cent.

The electrical losses in the first instance are:—Loss in magnet coils, 756 watts = 1·4 per cent.; loss in armature coils, 1,386 watts = 2·6 per cent. Electrical efficiency = 96·0 per cent. From this it follows that the loss in friction in the engine and dynamo combined is 10 per cent. of the indicated horse-power.

Messrs. Mather and Platt have constructed a large number of dynamos for combination with the Willan's engine. Those referred to above are part of a number constructed to the order of Mr. Hargreaves for the City installation of Messrs. Spiers and Pond. Others of a considerably larger output are in progress for Messrs. Gatti's central station in the Strand, and for the Westminster Electric Supply Corporation's installations.

SUBWAYS FOR SUPPLY MAINS.

The formidable opposition which was brought to bear last Session, upon the Subway and Overhead Wires Bill of the London County Council resulted, as our readers will remember, in its ultimate rejection; in spite of the fact that by the time that the Bill received its quietus its scope had been much curtailed, thanks to the petition of the Kensington Company which has pioneered the making of conduits in our streets. At present it appears that the municipal control of electric mains is limited to the general assent of the Local Authority to the Provisional Order of the supply company, and to the specific consent which is given from time to time to the notice of intention to lay mains in certain streets. The Board of Trade prescribes the conditions under which conductors are to be laid, and defines the state of efficiency as which they are to be maintained, besides giving rules as to the construction of conduits in the regulations which are now issued with Electric Lighting Orders. The *canalization*, as it is called in France, has therefore been taken in hand and controlled by one of the most paternally disposed departments of the Government; and it does not appear why the County Council need trouble themselves about it. A system of subways has a fascinating air of completeness, and, to the municipal mind, it appears to possess the additional attraction of affording a possible means of "relieving the rates." If it were only proposed to make such a charge as would pay for the interest on the cost of such subways, and for their maintenance, there would be less injustice in the scheme; but, it must also be remembered that if the supply companies make a success of their business, their property will surely be taken over by the Local Authorities in forty-two years, or earlier; and by that

Digitized by Google

time they would have more than repaid their share of the cost of the subways. It seems to us, however, that the Metropolis is not altogether a suitable place for an elaborate system of subways, although there are some short lengths in existence at present, since, in the construction of several of the important thoroughfares, opportunity has been taken to construct subways which have up till now been but little used. It is true that electric mains could be placed thus under constant supervision, and it would be easy to obtain access to any part of them; but it is part of the scheme that they should be laid side by side with gas and water mains, and these are quite as apt to leak, and, unlike electric mains, are liable to burst. They will, therefore, much more probably damage the electric mains than be damaged by them. That the present gas mains leak to a considerable extent is evident whenever the streets are opened. In the absence of any Board of Trade regulations as to leakage, some companies seem to rely on the pressure of the surrounding soil to keep their joints tight, and the escape of a million feet or so does not affect them much. A leak of gas in a subway would, however, be a very different matter, and it is impossible to estimate the damage which would be caused in such a case by an explosion, such as that which occurred at Streatham last week, or the probable effect on the electric mains of the bursting of a high-pressure hydraulic power main in a confined tunnel. It seems that both gas and water pipes are best left where they are. The inconvenience of the present arrangement is chiefly that of the obstruction of the traffic when alterations or repairs are necessary. The conveniences of the subway system may have to be compared with the possible destruction of life and property.

It is not always easy to impose conditions on already existing institutions, but any difficulty there may be fades into nothing by the side of the gigantic task of undertaking and completing such a feat of engineering, and then compelling the various supply companies to make use of it. The mere tunnelling under the main thoroughfares would be serious enough; but it was proposed to re-lay within the subway all service mains for gas, water, and electricity, and possibly for compressed air and steam. The existing distribution would be disorganized at an immense cost and inconvenience to the public. The question may well be raised as to the fitness of any corporate body, the members of which are continually changing, to undertake a work of this magnitude, not only on account of the changes which are likely to take place in the administration of it when complete, but of the unity of plan which is necessary during the execution of the work. The great works of antiquity that by reason of their public convenience bear some analogy to the one under consideration, the immense aqueducts constructed by the Roman Emperors were begun and carried out to a successful termination by one master-hand, who supplied the element of continuity of supervision which is essential for such undertakings. We have misgivings as to a municipal system of subways, until the County Council prove that they are able to carry out important works, and show more appreciation for the services of engineers who are able to design and execute them.

Another difficulty of scarcely less magnitude is that of finance. To ensure that the roadways shall be free from future disturbance—and this is after all the main object—it will be necessary that the subways be well designed, well constructed, and large enough to accommodate any reasonable future increase in the demand for their use. All this needs money. We have some recent American estimates, which, though no more valuable as a guide than are most American figures, since their prices and requirements differ so largely from our own—may be taken at all events as a guide to the difficulty of the task. We ought then, perhaps, scarcely to be surprised to find that the cost is calculated at £89,000 per mile. Still, in spite of this heavy expenditure, certain members of the County Council have it in their minds to do a good stroke of business, and actually relieve the rates by charging a heavy rental from those whom they propose to compel to use the subways. Some conception of the rentals that might be charged may be gained from those at present asked in New York, where the preposterous sum of £200 per mile per annum is demanded for a three-inch duct. A rental of anything like this description would heavily tax electric supply companies, who are already sufficiently handicapped in their competition with gas.

At the present time, several electric lighting companies have made arrangements with the railway companies to lay their mains along the cuttings, tunnels, and bridges. The conductors so placed are readily accessible by authorized persons, and are not likely to be interfered with by others. They can be placed thus at a less expense than in any other manner, and the arrangement has already been found to be very advantageous and satisfactory. There was a question or two as to the price charged by the railway companies for this accommodation at the Board of Trade enquiry, but the supply companies did not care to disclose their bargains. They would doubtless take advantage of subways if they could be used at a fair rental; but the only method by which such a rental could be judged, from the supply companies' point of view, would be to compare it with the cost of making and maintaining a conduit, or other method of laying their mains. Those who are content to lay an armoured cable immediately below the foot pavement would not care to pay much for the use of a subway, while others who construct carefully-built and cemented conduits, and put down bare copper strips with numerous insulators, straining gear and manholes, might be more inclined to give the matter their consideration. Such companies are sinking a good deal of their capital in their conduits and mains, and this capital cannot for some time be considered as producing a fair return; for a conduit has to be constructed, not for the supply of to-morrow, but to take the conductors that will probably be required hereafter, when present leases have run out and more houses are wired. The conductors, too, are heavier in most districts than are needed for the present demands, and although the generating plant may be added to, the distributing mains will be an incubus for the first few years, and the expenses connected with them must reduce, if not extinguish, dividends until the demand has increased sufficiently to utilise them more fully.

The cost of generating a unit of electrical energy is now pretty well known, but the cost of distributing it to the consumers' terminals is very difficult to estimate, depending as it does upon the cost of laying the mains and the extent to which they are employed. It would be, therefore, no easy matter to estimate the value of the accommodation offered by a subway for a new main, and if a high charge were made it would merely be taxing the consumers of electricity for the convenience of the public who use the streets. The suggestion that supply companies should at their own expense re-lay their mains and pipes in subways to be constructed by the Local Authority but to be paid for by the users, is too wild an idea for serious consideration. Now that a thoroughly experienced and reliable business man is Chairman of the County Council it is, we hope, less likely that such a proposal will be made again.

ELECTRICAL DISTRIBUTION BY TRANSFORMERS FROM CENTRAL AND ECCENTRIC STATIONS.*

BY DR. J. A. FLEMING, M.A.

(Continued from page 679.)

§ 15. **Typical Westinghouse Transformer Stations.**—One of the largest stations for the supply of electric current by the Westinghouse transformer system is at Pittsburgh, Pa., in the United States. The boilers at this station are of the water-tube type, heated by natural gas. The engines are of the well-known standard Westinghouse engines, and stand on square blocks of concrete or masonry, the blocks for the size used, burgh is about 9ft. high and 14ft. long, and stands away from the wall of the dynamo room about 3ft. to enable access to be had behind it for making all connections.

One single exciter dynamo is used, another being in reserve, to provide exciting current for several machines, and convenient switches are placed on the board to enable the excitation to be effected by either of the exciters. The general details of the board, as well as the arrangements for measuring and regulating the pressure at the far end of each feeder, have been already described. This station furnishes current for about 13,000 incandescent lamps (1890).

A very typical Westinghouse station, operating overhead primary conductors, is that at East Liberty, Pa., U.S.A. The service from this station covers a very extended area, com-

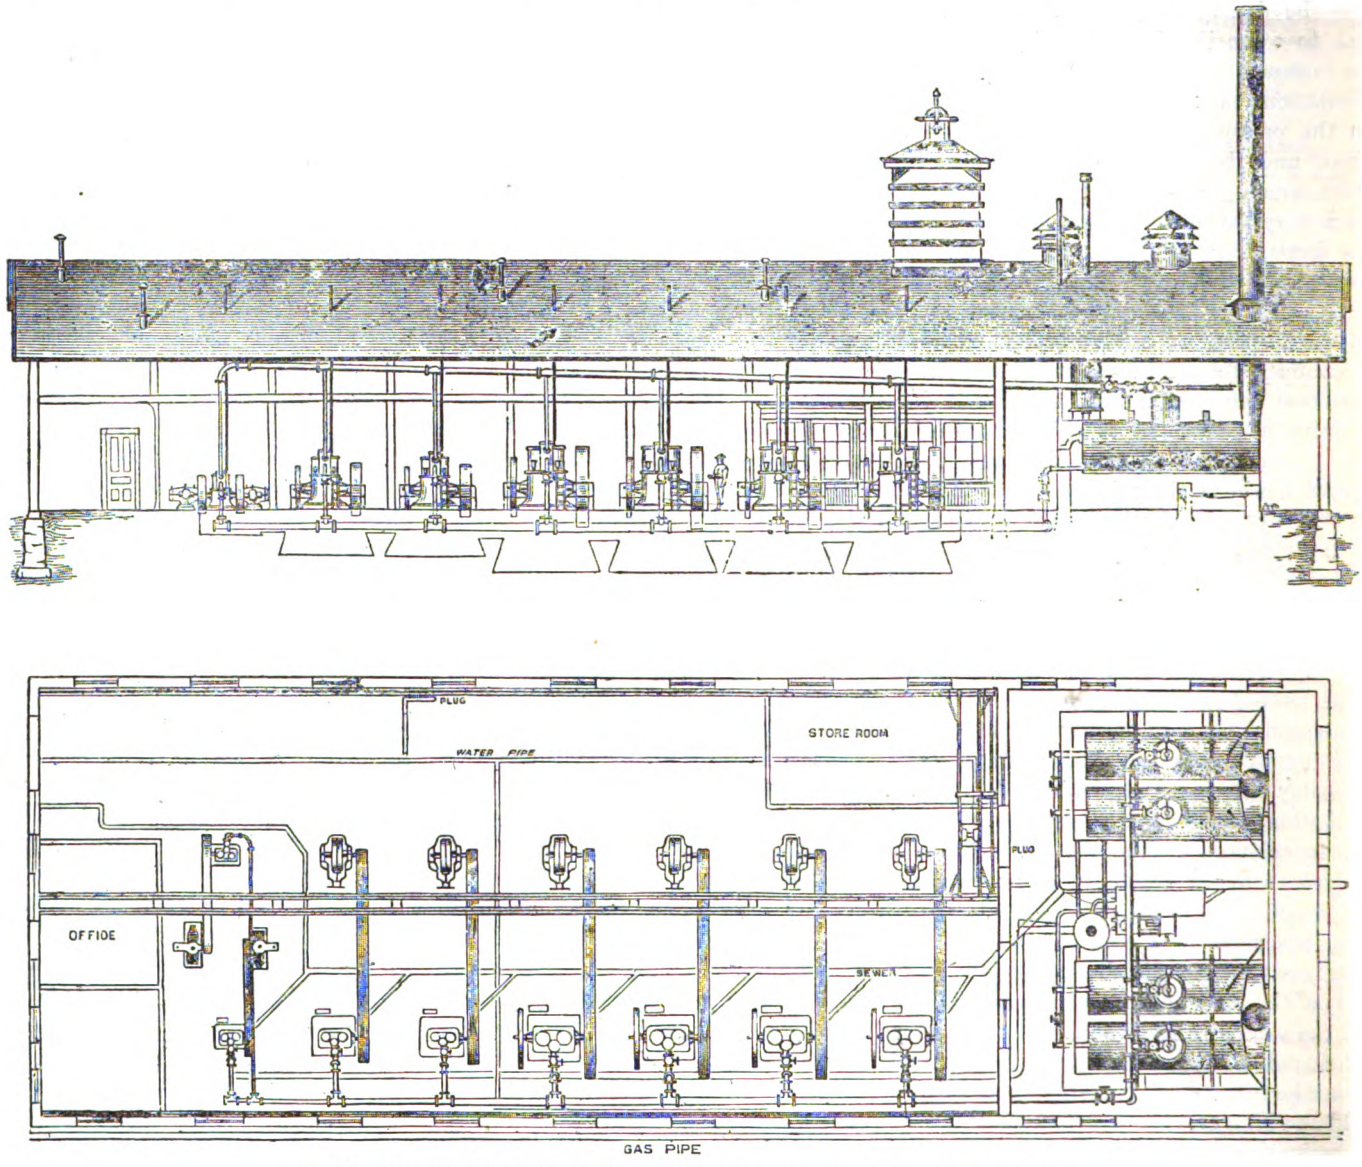

Fig. 47.—Elevation and Plan of Westinghouse Central Station at East Liberty, Pa.

250 horse-power, being about 7ft. by 5ft. Five of these engines drive five alternating current dynamos, each having a capacity for 2,500 16 candle-power incandescent lamps. Besides this there is a Corliss engine, driving another dynamo. The exciters are driven from separate smaller engines. The engines driving the alternating dynamos make 250 revolutions per minute, and the dynamos 1,050. The power of the engines is conveyed to the dynamos, which are placed on a floor above, by belts. Each dynamo is fixed on a sliding bed, so that the belt can be tightened. The general construction of these alternators has been described in a previous section. From the dynamos the mains are run to the switch-board in troughs cut in the joists supporting the floor. The switch-board at Pitts-

prising the business portion of the city, which lies at an average distance of half a mile from the station, ramifying through an extended series of residence streets, and carrying a special line to a distant suburb in which the last lamp is four-and-a-quarter miles from the dynamo. The arrangement of the building is shown in Fig. 47. A one-storied brick building contains offices, stores, dynamos, and boiler room. The plant has an aggregate capacity of about 8,000 lights. Dynamos and engines are on the same floor, every part of which is under the eye of a single attendant. The engines and dynamos stand on brick foundations. Each engine is belted to its own dynamo. The steam pipe is brought along overhead, and the engines exhaust into a main laid in a covered trench underneath the floor. Two exciters are provided as shown on the left of the dynamo room,

each adequate to supply current to the entire station, and each driven independently by its own engine. Only one exciter and engine is operated at once. The position of the exciters and engines is such that by changing a belt either engine can drive

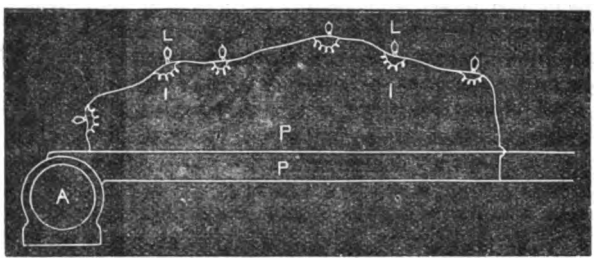

FIG. 48.

either exciter. Two overhead cranes traverse the whole length of the buildings over the engines and dynamos. Using natural gas to fire the boilers, attendance is reduced to a minimum, and one attendant in the dynamo room can give

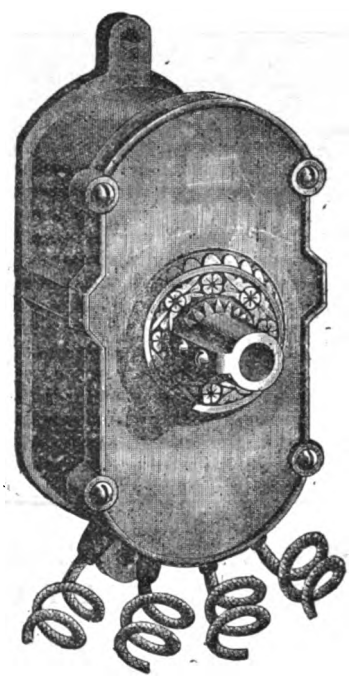

FIG. 49.—Westinghouse Impedance Coil for Series Lighting.

all necessary attention to the engines, dynamos, exciters, and switch-board. The reduction of labour to a minimum is especially made an object in the design of these American stations.

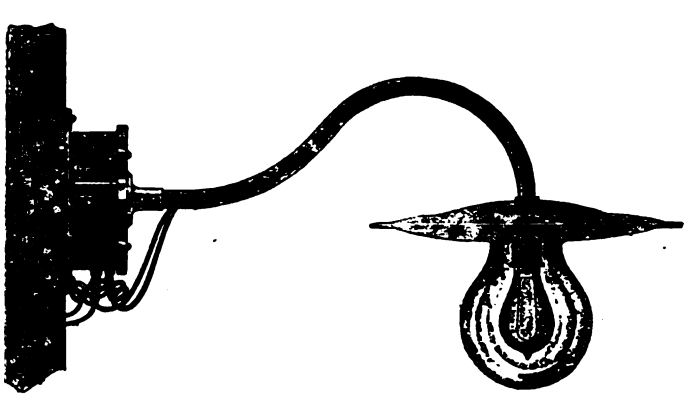

FIG. 50.—Series Street Lamp and Impedance Coil.

In connection with these transformer stations, a system of street incandescent lighting has been worked out, which is very efficient, and enables a large amount of street lighting over scattered areas to be taken up, but which would not be remunerative if primary mains and transformers had to be placed along the whole route. Starting anywhere from one primary main or feeder, P (*see* Fig. 48), a single line is run following the route of the proposed street lighting; and at every place where a street light, L, is required, an impedance or choking coil, I, is placed having a low-resistance series incandescent lamp across its terminals. This line is then so run that it terminates at some distant spot on the other member of that same primary line or feeder. Suppose that the primary pressure is 1,000 volts, and that 10 volt low-resistance lamps are used, there can be 100 such coils and lamps on that series line. The impedance coil is contained in a box on the bracket that carries the lamp (*see* Figs. 49, 50). If any lamp breaks, the impedance coil is thereby thrown into the circuit and lowers the current just by that amount which keeps the rest of the lamps on that circuit from being over burnt. Hence the breakage of any of the lamps does not affect the light of the rest, nor does the removal of one lamp in any way affect the operation of the others, although the lamps are all in series.

(To be continued.)

SIR WILLIAM THOMSON'S NEW ELECTRICITY METER.

This supply meter, which was exhibited and described before Section G at the recent meeting of the British Association, records on a train of counting wheels the amount of current which has passed through it during any given time; and forms, also, an indicator by which the strength of current passing at any given instant can be read off on a scale.

The indicator consists of a light aluminium girder, free to turn about a horizontal axis, having at its top end a flat coil of fine copper wire, *c* (Fig. 1), and at its lower extremity a train of counting wheels, ω (Fig. 2). The frame is supported on knife-edges, and a current is conducted into and out of the fine wire coil by two spirals of fine copper wire. The resistance of this coil is about 30 ohms, and it is joined in series with an anti-inductive platinoid resistance, R, of 970 ohms. When the meter is in action a small current is kept passing through the circuit. The whole current to be measured is conducted through a fixed coil, C (Fig. 1), of copper ribbon, which is placed with its plane parallel to the plane of the fine wire coil when the latter is in its zero position. A scale, S (Fig. 1), divided to give readings in amperes, is attached to the indicator, on which the strength of current passing through the fixed coil can be read off by means of an index fixed to the case of the instrument.

The recording apparatus consists of the train of counting wheels ω, with a plain rolling wheel on the first arbor, and a revolving cam or barrel, K, driven by clockwork, which is kept in motion by a weight, W. The cam is kept revolving at a uniform rate, and, when a current is passing through the instrument, at each revolution it lifts up the trailing wheel on the first arbor of the counting train, which it causes to turn round, and so makes a record.

The profile of this cam is diagrammatically indicated in Fig. 1 by a slanting line; but is more clearly shown in Fig. 3, and its surface is shown unrolled or developed in Fig. 4. The curved line of its edge is, in fact, the curve giving the law of repulsion of the light shunt coil by the fixed main coil. The driving gear is controlled by a centrifugal governor shown below the cam (Figs. 1 and 2), giving a continuous rotation of the cam once in six minutes.

The action of the meter may be shortly stated as follows:—When no current is passing the indicator stands at zero on the scale, S, the movable coil being about one millimetre from the fixed one, and the trailing-wheel on the counter-train being quite clear of the cam, so that no record can possibly be made. When a current is passing through the fixed coil the top end of the indicator is repelled *outwards*, and the counting-train of wheels is brought *inwards* towards the cam to a position depending upon the strength of current which can be read

Digitized by Google

off on the scale. In this position, at the proper time of revolution, the trailing-wheel is lifted by the cam, and runs over a shorter or longer path in proportion to the strength of current. For small currents, the trailing wheel rolls on the barrel surface of the cam for only a short period during each revolution; but, with heavier loads, it travels over a path of considerable length. Thus, if the current passing through the fixed coil be 5 amperes, the counting-wheels might record 20 for every revolution of the cam; whereas, were the current 10 amperes, the trailing-wheel would roll over twice as long a path, and the record would be 40. Any slight inaccuracy in the parallelism of the axes of the trailing wheel and of the cam would cause

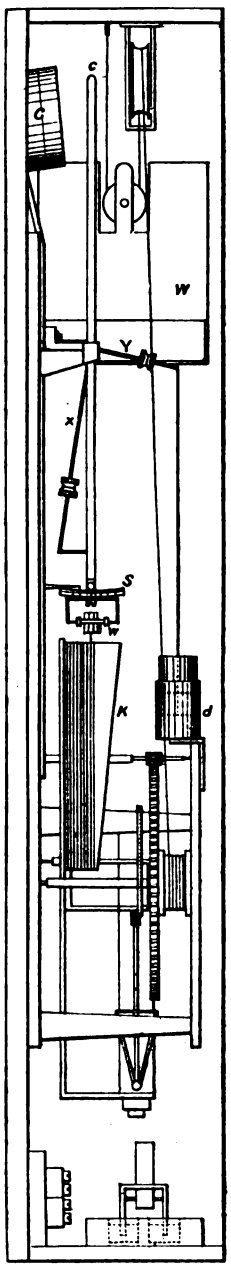

Fig. 1.—Side View.

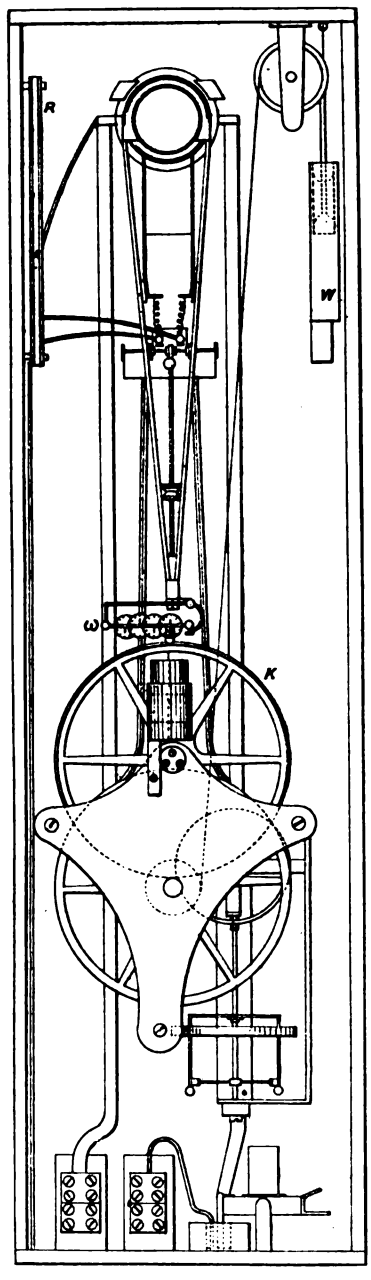

Fig. 2.—Front View.

the former to describe a helical path on the cam. To avoid this, the surface is cut into fine grooves on the part corresponding to the higher readings, and in one or other of these the trailing wheel runs. These grooves are much more numerous than are shown in Fig. 3, where the trailing wheel is shown running in the second one. The part of the cam corresponding to the lower ranges is left smooth, as it has been found easy to adjust the counter to record correctly throughout the most sensitive portions of its range.

Two screwed rods are so attached to the indicator, that one, x (Fig. 1), is vertical, and the other, y, is horizontal, when the beam is in its zero position. These rods are provided with adjustable nuts, those on the vertical being to adjust the sensibility of the instrument, while those on the horizontal rod are for the adjustment of the zero. By means of the former the constant of the meter can be quickly varied if found convenient. Thus a meter which is suitable for measurement from 1 to 20 lamps can be altered in a few minutes to suit ranges of from

Fig. 3.—Side View of Cam.

1 to 50 or from 1 to 100 lamps. This adjustment can be made by an inspector, without the use of any auxiliary instrument. All that has to be done is to hang on a weight of a given amount on the knife-edge stirrup at the end of the horizontal arm, and raise or lower the nuts on the vertical arm till the indicator shows a given reading on its scale. By this means also the constant of the meter can be checked at any time.

Fig. 4.—Development of Cam $\frac{1}{10}$ Full Size.

As at present arranged the driving weight requires to be wound up periodically by means of a revolving disc on the front of the case. It is intended that this should be done by the consumer, and an arrangement is made by which the current is automatically cut off from the house when the weight is allowed to run down. Several very ingenious precautions are also taken to prevent any fraudulent tampering with the instrument.

ON THE ELECTROSTATIC FORCE BETWEEN CONDUCTORS CONVEYING STEADY OR TRANSIENT CURRENTS.*

BY DR. OLIVER LODGE.

At the last meeting of the Physical Society this session Mr. Boys described some attempts he had made to detect mechanical force between a pair of Hertz resonators delicately suspended and immersed in a region of electro-magnetic waves.

The attempt, so far, had not been successful; but Mr. Boys, by attending to the energy manifested by Mr. Gregory's method and by another method of his own, showed good reason why the force, if any, was just too small to be observed, even with his extremely delicate appliances, and conjectured that a moderate increase in sensitiveness would be necessary in order to detect the effect. Everyone must have full confidence that if any such mechanical effect exists Mr. Boys will show it us before long; but, in common with Prof. Fitzgerald, I feel provisionally and tentatively doubtful whether any mechanical effect really exists between electric pulses travelling along wires with the velocity of light. In a wire subject to electric stationary waves, there are obvious electrostatic pulses at either end, and electrokinetic pulses at the middle; but Mr. Boys had alloyed for all that, and arranged that the opposing effects of ends and middle should conspire to assist each other in causing rotation. What I felt doubtful about was, whether, even in infinite wires, wherein all complication by reflection and stationary waves was avoided, a pair of pulses travelling side by side, like a pair of humps (or a hump and a hollow) on a pair of parallel cords, would exert any force on each other. It

* Abstract of a Paper read before the British Association, in Section A, Leeds, September, 1890.

Digitized by Google

is known that two charged bodies flying side by side with the velocity of light will exert no such effect (Mr. Heaviside has shown that this is equivalent to saying that two elements in the same wave-front exert no mechanical force on each other); but whether the same thing is true of two wire-conducted pulses has not, as far as I know, been examined by mathematicians.

If it should turn out that pulses at full speed have no effect, then two straight oscillators in similar phases should repel each other, by the electrostatic effect of the slackening and stationary pulses which are being reflected at the ends.

Such an action seems optically rather interesting. Maxwell predicted that a reflector or absorber would be repelled by light; though, as we know, the complication of the more vigorous molecular action of material surroundings prevented Mr. Crookes from detecting this precise effect. We know, however, that it must exist; and the repulsive effects between alternating magnets and copper discs, detected by Faraday and recently made much of in an interesting manner by Prof. Elihu Thomson, are examples of this very thing. We can even say what the stress caused by full sunshine ought to be, viz, about 50 microbarads*—that is, the weight of half a milligramme per square metre; but it has not yet been experimentally observed. If Mr. Boys finds his effect, at least if he finds it in the form I suggest, as an overbalancing static repulsion, it will represent an action between two sources of light or between two similarly illuminated bodies.

First, consider the action of currents in general on each other, and find the ratio between their electrostatic and electrokinetic forces. So far as I know, the electrostatic force between two steady currents is usually overlooked.

No advantage in generality is gained by treating two separate circuits, a movable portion arranged near a fixed portion of one and the same circuit is sufficient.

Steady Currents.—With steady currents the ratio of the static attraction to the magnetic repulsion is on every possible system of units a pure number.

To get a notion of its value, suppose the wires to be round and of radius ρ, the distance between them a; then the capacity per unit length of the two conductors is

$$S_1 = K/4 \log \frac{a}{\rho};$$

and since

$$\frac{1}{\mu K} = (\text{the velocity of light})^2 = \left(\frac{30 \text{ ohms}}{\mu}\right)^2,$$

the above-mentioned numerical ratio is

$$\frac{F}{F_1} = \frac{S_1^2 R^2}{\mu K} = \left(\frac{\text{number of ohms in the wire R}}{120 \log \frac{a}{\rho}}\right)^2.$$

Suppose, for instance, the wires were 50 diameters apart, or $4 \log a/\rho = 18{\cdot}4$, the two forces would be equal, and just balance each other, if R was 552 ohms.

With any resistance greater than this the electrostatic force would have the advantage, and two opposite currents in the given wires would *attract*.

Transient Currents.—Proceeding to consider the transient current of a Leyden jar discharge round the same circuit, unless the waves are much shorter than usual, the ultimate effect on a short length will be very little different from the effect of a uniform potential alternating sinuously in time, the difference of potential at any instant between the fixed and movable wire being

$$V = P C,$$

where P is the impedance of the intervening portion of the circuit.

And the ratio of the two impulses is

$$\frac{\phi}{\phi'} = \frac{S_1^2 P^2}{\mu K}$$

Taking as an example the same round wire conductor as before, with

$$S_1 = \frac{K}{4 \log \frac{a}{\rho}}, = \frac{K}{18{\cdot}4} \text{ say,}$$

and considering $\frac{L}{L_0}$ as $\left(\frac{18{\cdot}4}{20}\right)^2$, for instance, the two impulses will be equal and just balance each other if the length representing L on the magnetic system of units be 400 times as great as the length representing S on the electrostatic system. Any wire longer than this gives attraction the advantage; any wire shorter than this favours repulsion.

Or, with different jars discharging round a given circuit, small jars will exhibit the electrostatic impulse, big ones the electrokinetic.

Illustrating numerically still further: A length of 30 metres of No. 16 copper wire opened out into a single large loop has a self-induction of 500 "metres," or 50 micro-secohms. Using this as the wire R between the two suspended conductors, the critical-sized Leyden jar which should excite no force when discharged through them is about $1\frac{1}{4}$ "metres," or ·00014 microfarad; *i.e.*, smaller than the ordinary "pint" size.

With the help of an adjustable condenser, an instrument for measuring the L of well-insulated coils free from iron suggests itself here.

Measure of "v."—In applying an experimental observation of this kind to a determination of the product of the ether constants μ, K, (and it just strikes me that it is after all only a modification of the method by which Maxwell himself made one of the early determinations), is will be better to use round wires rather than strips, because linear dimensions then come in only under a logarithm, and, moreover, are such as can be measured with considerable accuracy without difficulty. Some of Mr. Boys' quartz-fibre and aluminium-tube devices ought to permit the zero of force to be sharply got, and thus a good measure of v to be made.

We should have to observe very exactly the neutralisation of all force between the suspended and fixed conductors while a steady current was passing through them, with an interposed wire of known resistance, and then use the relation

$$\mu K = S_1^2 R^2,$$

or

$$v = \frac{S_1}{K} \frac{R}{\mu} = \frac{\text{resistance of wire expressed as a velocity}}{4 \log \frac{a}{\rho}}$$

By filling the vessel containing the acting conductors with other insulating media, it is possible that the v for them could be directly measured.

Action of Moving Charges and Pulses.—If, by reflection at distant unjoined ends of an open circuit, the pulses be turned from progressive into stationary waves, then localities can be found on the wires at which attraction or repulsion permanently occurs; the sinuous distribution of current lags a quarter period behind the sinuous distribution of charge. Hence, at a given instant, there will be places where the current force is a maximum and the static force zero; while at a quarter wave-length on either side, the current force is zero and the static force a maximum. Half-way between these places only will the two forces be equal, but with alternate agreement and disagreement of sign. A readjustment of phase between the conductors will now make all the difference; a shift of a quarter wave-length changing from maximum to zero, and a shift of half a wave-length bringing about reversal of sign.

According to all this, therefore (if it be correct), it follows that the simple ideas on which Mr. Boys set to work are right after all, and that he will detect the forces in the way he expects.

Variation with Distance.—A few words as to the magnitude of the effect to be expected. Hertz has shown (*see* "Nature," vol. XXXIX., p. 404) that, at a reasonable distance from a rectilinear oscillator, one or two wave-lengths being practically sufficient, the electric force (or electromotive intensity) is per-

* Langley's recent estimate, that a square centimetre fully exposed to sunshine receives 2·34 C.G.S. thermal units per minute, is equivalent to an energy of 67 ergs per cubic metre of sunshine, or 67 microbarads. (A "barad" means an erg per cubic centimetre, or a dyne per square centimetre.)

Digitized by Google

pendicular to the radius vector from middle of oscillator, and is of magnitude

$$E = \frac{Q l q^2}{K \rho} \cdot \sin(q\rho - pt) \cdot \sin\theta ;$$

where ρ and θ are the polar co-ordinates of the place, and $q = 2\pi/\lambda$.

To get an idea of the magnitude of this intensity at any considerable distance from the axis, write $Q = S V$, where V_0 is measured by the length of spark employed at the oscillator, and write for q^2 its value $\frac{\mu K}{L S}$; then the amplitude of the electric force reduces to

$$E = \frac{V \sin^2\theta}{2rc},$$

when an approximate value for L is substituted. Take as a numerical example any convenient oscillator, say, the small oscillator drawn to scale on page 54 of the *Philosophical Magazine* for July, 1889, which emits waves 1 metre long; let its constant $c = 4\frac{1}{2}$, and its spark be, as there quoted, 8 millimetres, so that V_0 is about 26,000 volts. Then the initial electric intensity at a distance of a couple of wave-lengths in the equator is

$$E_0 = \frac{26000 \text{ volts}}{18 \text{ metres}}$$

$$= 14{\cdot}4 \text{ volts per centimetre.}$$

Putting therefore at this distance of 2 metres a parallel wire half a wave-length long as receiver, it utilises 50 centimetres of the above electromotive force, and gives a maximum sparking potential of 720 volts, which corresponds to a spark-gap of about a tenth of a millimetre between flat surfaces.

Energy of Radiation.—The mean energy of the radiation per unit volume is (Maxwell, Art. 793), $\frac{K E^2}{8\pi}$; which in the present case is equivalent to

$$\frac{K}{8\pi} \cdot \frac{V^2 \sin^2\theta}{4\rho^2 c^2}.$$

Taking the same oscillator as above, with $c = 4\frac{1}{2}$ and $V = 88$ electrostatic units, the mean energy of the radiation per unit volume at any considerable distance r, say 2 metres, in the equator, is

$$\frac{K V^2}{32\pi c^2 r^2} = \frac{88 \times 88}{25 \times 81\, r^2} = \frac{3{\cdot}8}{r^2} = \frac{3{\cdot}8}{4 \times 10^4} \text{ barads}$$

$= 95$ microbarads, at a distance of two metres.

This will cause a momentary pressure on a metallic surface normally exposed to it, of 95 microdynes per square centimetre, or a milligram weight per square metre; and is nearly twice as strong as full sunshine while it lasts.

At 1 metre distance, I need hardly say, the energy and the pressure are four times as great.

The area of energy absorbed by a fine wire linear receiver may be estimated roughly by finding the closeness of a grid of parallel wires which would just not let any radiation pass through it. Suppose, for instance, that a grid with wires 10 centimetres apart satisfies this condition; then each wire mops up energy for a breadth of five centimetres on either side of itself. The heat generated in such a wire at each spark is

$$\frac{3}{2} \cdot \frac{b l}{4\pi r^2} \cdot \frac{1}{2} S V_0^2.$$

This, in the numerical case already taken, with $\frac{S}{K} = 1{\cdot}4$ centimetre and $K V_0^2 = (88)^2$ dynes, gives, at a distance of 1 metre $= 32{\cdot}5$ ergs per spark; which, repeated 100 times a second by a suitable contact-breaker, would yield 3,250 ergs per second, or one ordinary thermal unit every $3\frac{1}{2}$ hours.

Appendix.—It is in accordance with theory to assert that the action of two given magnets on each other varies inversely with the permeability of the medium; that the action of two currents on each other varies directly as the permeability of the medium; and that the action of a current on a given magnet is independent of the properties of the medium.

To avoid misunderstanding, it must be perceived that the statement refers to a given magnet, not to a magnet of numerically specified strength, because about that there would be some ambiguity according to the medium in which it was measured.

Similarly, the static action between two charges is inversely as a dielectric constant of the medium; the action between a given charge moving at the approximate light-speed and a given magnet is independent of the medium; except in so far as its properties affect the velocity of light; while the dynamic action between two given charges moving together at the light-speed is proportional to the permeability.

It may be as well to have direct experimental verification for some of these things.

COMPARATIVE TESTS OF LEATHER AND CANVAS-RUBBER BELTS.*

BY SAMUEL WEBBER, C.E.

The question of belting for driving the high-speed dynamos in electric light and power stations is one of considerable importance; and one on which I am often called to express an opinion. In the first place, let me lay down as a general law, too often neglected, that the value and driving-power of a belt depends upon its complete flexibility, and also on its evenness and softness of surface, which two qualities combined permit perfect contact with, and close adhesion to, the surface of the pulleys. The next point is the weight of the belt itself, which should be as light as possible, consistent with the extreme power to be transmitted by it. This not only saves waste of power in keeping the belt itself in motion, but reduces the centrifugal action that tends to keep the belt from coming in proper contact with a small pulley at high-speed. This matter, though important, is often overstated, much of the trouble often noticed being due to the rigidity and inflexibility of the belt, particularly if a double one, rather than to its centrifugal action. If any one has ever noticed the action of one of the great cotton mill belts at Lowell or Fall River running at a speed of a mile a minute, on a pulley 5, 6, or 7ft. in diameter, he will remember that he has never seen much centrifugal action keeping the belt away from the pulley; but if he has seen a double belt even at 3,000ft. per minute run on a 12in. pulley, he will have noticed a perceptible loss of contact. For these reasons I would always discourage the use of a double belt, when a single one will answer the purpose on any reasonable width of pulley, or in any case when the pulley is less than 12in. diameter. Belts can be run as fast as 6,000ft. per minute with perfect safety, and, if flexible, will cling to the pulley and lose nothing by centrifugal action. The consideration of weight leads me to disapprove of the so-called "link belts." Even with the latest and I believe the best of these belts, the "Acme" belt of the Page Belting Company, of Concord, N.H., the weight of the belt is given me as 4lb. 4oz. per square foot, of which 3lb. 3oz. is leather, and 1lb. 1oz. iron. Now, a first-class single leather belt, $\frac{3}{16}$ in. thick, weighs just about 1lb. per square foot, and I believe that an equal weight of leather in its normal and natural condition will transmit more power, with less loss, than if chopped up into scraps and bolted together again in any way whatsoever.

The cost of leather has led to very many experiments to provide an economical substitute, and the first one of these to notice is the "rubber belt," or, in other words, a belt composed of several folds of canvas, covered and cemented together with a solution of india-rubber. For work in dye-houses and bleacheries this has proved very valuable; but it is soon destroyed by heat and dust, and I am not aware that it has been successfully used as yet for electrical purposes; in fact, with one exception, the cotton-leather belt, of which I shall speak later, I do not yet know of anything to contradict the old saw, "There's nothing like leather."

I give herewith the results of a series of experiments made by me at the factory of the Underwood Belting Company, Tolland, Conn., to test the comparative driving capacity of various entirely new belts.

The first test I will note was of an entirely new Hoyt belt, one of the best known on the market. This had been in stock some time, but was tested as it was for the sake of information. This belt was 12in. wide, $\frac{1}{4}$in. thick, 31ft. long, and weighed $34\frac{1}{2}$lb. With a tension of $43\frac{1}{2}$lb. it drove seven horse-power (at 754ft. per minute) and then slipped off from stiffness and lack of sufficient tension. The strain was then increased to $62\frac{1}{2}$lb. per foot, and the

* From the *Electrical World* of New York.

Digitized by Google

belt shortened, in doing so, 4½in. It now carried 7·77 horse-power at 697ft. per minute, and with a load of 11·64 horse-power slipped 10½ per cent., and slipped off when the load was increased. The strain was then increased to 83⅓lb. per inch, which shortened it 2½in. more, and it now carried 8 88 horse-power at 697ft. per minute without slip. As more load was added it began to slip, increasing until with a load of 14·77 horse-power at 660ft. per minute it slipped 13 per cent. and with increased load slipped off. The belt was then reversed, bringing the softer flesh side to the pulley, the hair side having been previously used. It now carried 16·85 horse-power at 662ft. per minute, and then "jumped the pulley" suddenly with increased load, without having shown any perceptible slip previously. This test showed that on the polished iron pulley, the soft-flesh side *held* better than the harder *grain*. A pair of Dodge's wooden pulleys were now put on and the belt replaced, with the hair side to the pulley. We now got 15·29 horse-power without slip, at 739ft. per minute, but additional load caused a slip which increased with the load, so that little more power was shown, and the test was stopped at 15·80 horse-power, with the belt still on the pulleys, showing a horse-power for each inch of width, at 562ft. per minute. The next test was to cut the belt down to 8½in. wide, which gave an apparent strain of 117·6lb. per inch, as it was simply relaced in the old holes. This on the wooden pulleys gave 10·19 horse-power without slip at 711ft. per minute, and 11·79 horse-power with a slip of 3·77 per cent. at 699lb., and then went off with increased load. A pair of paper pulleys from Westinghouse, Church, Kerr, and Co., were then substituted, and the belt replaced as in the last trial. It now gave on these pulleys 15·69 horse-power without slip at 704ft. per minute, or at the rate of 1 horse-power per inch, for 374ft. velocity. This finished the trials of this belt, which came out as good as new, and had not stretched an inch when we got through with it.

We will now compare this with a series of tests of a very soft and flexible belt, known as the "Schultz Rawhide Belt," under the same conditions. This belt, 31ft. long, 12in. wide, and 3-16in. thick, weighed 29lb. It was first tried, as before, with a strain of 43lb. per inch on iron pulleys, grain side to the pulley. This likewise proved to be an insufficient strain, and after giving 6 horse-power without slip, and 9·48 horse-power with a slip of 8·43 per cent. ; at 725ft. per minute, it went off the pulley with increased load. With the increase of strain to 62½lb. per inch it gave 11·10 horse-power at 697ft. per minute, and 16·27 horse-power with 5 66 per cent. slip at 675ft. per minute, slipping off with increased load. With a strain of 83⅓lb. per inch we got 15·79 without slip at 667ft. per minute, and 19 horse-power with 5·66 per cent. slip at same speed, going off with increased load. This showed 421ft. per minute per horse-power per inch. We then put on the wooden pulleys, relacing the belt in the old holes, and got 19·80 horse-power without slip at 691ft. per minute, and 26·16 horse-power with a slip of 3 per cent. at 705ft. per minute. With an additional load we got 26·87 at 693ft. per minute with a slip of 4·59 per cent., and with more load "stalled the engine." This last test showed 309ft. per minute per horse-power for each inch of width, and fairly illustrates the difference between a stiff and a flexible belt. We, however, split this belt down as we had the other one to 8½ins. wide and repeated on the wooden pulleys. Lacing in the old holes, we now got the strain of 117·6lbs. per inch, which proved too much for the belt, for although we now got 22 horse-power, at 691ft. per minute, *without slip*, or at a speed of 261ft. per minute for each inch of width, the belt "jumped the pulleys" with the next increase of load, and when we tried it on the paper pulleys we only got 16·46 horse-power without slip, at 739ft. per minute. The belt slipped off with the next increased load, and on applying the scales we found that the tension had fallen to 77·7lbs. per inch, and on taking it off we found it permanently stretched 1⅞ins. We were perfectly aware all the time that we were overloading the belt, but our object was to find how much it would stand.

These experiments confirm the already well established fact that a leather belt will safely bear a strain of 350lb. per square inch of area, or 87½lb. per inch of width for a belt one-fourth inch thick, or 66lb. for one of $\frac{3}{16}$in., or an ordinary single belt, and that the latter in good condition, soft and flexible, will easily convey one horse-power for each inch of width at 600ft. per minute. They also show very plainly the difference in the hold on the pulley of rigid and flexible belts, and this difference would increase with the velocity on small pulleys, as both the centrifugal force and the entrainment of air would be greater. An ingenious perforated belt for high speed has been introduced lately by Messrs. Charles A. Schieren and Co., of New York, which I have not seen in operation, but of which the samples impress me favourably. The slight longitudinal perforations are not sufficient to materially weaken the belt, while at the same time they afford an easy passage for entrained air.

I may be thought severe on "link-belts," but my opposition to them is based on sound mechanical principles for high speed, and if a great power at low speed is required. When shafts and gears are impracticable I should use a metallic link or chain on "sprocket pulleys," rather than trust to friction. With these remarks I will leave the subject of "leather," and turn to my notes on canvas belts of different kinds.

The series of experiments to which I have referred shows a test of a simple canvas or duck belt without any preparation. This belt, 31ft. long, 12in. wide, $\frac{3}{16}$in. thick, weighed 21½lb. It stretched 13¼in., with a strain of 43⅓lb. per inch, gave 4·86 horse-power without slip at 754ft. per minute, slipped 3·83 per cent. with 5 horse-power, and slipped off with increased load. When saturated with size, under a strain of 83⅓lb. per inch, it carried 5·75 horse-power without slip, at 739ft. per minute, then began to slip as the load was increased, until it went off after giving 10·35 horse-power with 9 per cent. slip.

Next came a "Main" or "Gandy Belt," 31ft. long, 12in. wide, and 38-16 thick, weighing 41½lb. It was composed of heavy cotton cloth, folded and stitched, and saturated with oil and red paint. It stretched 13¼in. before lacing with a strain of 43⅓lb. per inch. It carried 7·20 horse-power without slip at 754ft. per minute ; with 8·43 horse-power it slipped 8½ per cent., and went off with increased load. With a strain of 62½lb. per inch it stretched 2in. more, and drove 8·08 horse-power without slip at 725ft. per minute, slipped 8·70 per cent. with 9·48 horse-power, and then slipped off. With 83⅓lb. per inch it stretched 3in. more, and carried 10·48 horse-power without slip at 732ft. per minute. With 14·22 horse-power it slipped 10 per cent., and then went off.

Next came a four-ply duck belt, weighing just one pound per foot, and saturated with linseed oil and plumbago. This stretched 7¾in. with 43⅓lb. per inch, and drove only 2·40 horse-power without slip, it having been dusted with powdered soapstone, to keep it from sticking together in the fold. The soapstone got rid of, and the strain increased to 62½lb. per inch, it carried 13·27 horse-power without slip, and went off with an increase of load. At 83⅓lb. per inch, it carried 16 65 horse-power without slip at 697ft. per minute, but slipped 5·71 per cent. with 17·28 horse power, and then off.

A first-class rubber belt of same dimensions, weighing 37lb., showed *no slip* in any test until it finally *jumped* the pulleys, giving 8·07 horse-power at 725ft. per minute, with 43⅓lb. strain ; 13·68 horse-power at 660ft. per minute, with 62½lb. strain, and 18·61 horse-power at 650ft. per minute, with 83⅓lb. strain, the last test starting the rubber covering. The variations in speed were due to the incapacity of the engine to carry these loads in addition to its regular work.

We now come to the cotton duck leather-lined belt already mentioned. This belt was a four-ply duck, with a soft leather lining cemented on, and weighed 37½lb. of the same size as the others, but was ¼in. thick, or $\frac{3}{16}$in. duck and $\frac{1}{16}$th leather. It stretched 2¼in. with 43⅓lb., and drove 10·80 horse-power without slip at 754ft. With 12·4 horse-power, it slipped 13 per cent., and then slipped off. With 62½lb. per inch strain, it carried 11·88 horse-power without slip at 747ft. per minute, stretching 2¼in. It carried 19·40 horse-power, with 14·7 per cent. slip at 711ft., and then slowed down the engine without going off. With the steam increased to 83⅓lb., it carried 16·98 horse-power without slip at 711ft. per minute, and with 21 horse-power and 9 per cent. slip slowed down the engine to 690ft., and the test was stopped with the belt still on. All these last tests were on iron pulleys. We now changed to the wooden ones, and got 27·87 horse-power without slip, stopping the engine. We then split the belt down to 8½in., or 117lb. per inch, and on the same pulleys got 25½ horse-power, with 1 per cent. slip. Changing to paper pulleys, we got 25·30 horse-power *without* slip, but exhausted our power as before ; and on applying the scales, found the belt to still hold its strain of 1,000lb. As will be seen from the above tests, we could not get higher speed with these belts, so we took a five-ply belt of same kind, 5in. wide, $\frac{5}{16}$in. thick, 31ft. 2in. long, weighing 19lb. This stretched 2¼in. under a strain of 77lb. per inch, and gave 7·20 horse-power on iron pulleys without slip at 754ft. per minute. With 9·80 horse-power it slipped 3½ft., and with increased load slipped off. On wooden pulleys it drove 10·19 horse-power without slip at 711ft. per minute, or at the rate of 348ft. of belt per minute for a horse-power to each inch. We then put back the iron pulleys and increased the strain to 117 pounds per inch, and got 10·29 horse-power without slip at 718ft., and 12·63 horse-power at 698ft., with 5·65 per cent. slip. We then put on a larger pulley to increase the speed, and under the same strain got 18·62 horse-power without slip at 1,301ft. per minute, and 24 horse-power with 1·50 per cent. slip at 1,276ft., 24·59 horse-power with 3·10 per cent. slip, and 24 horse-power with 5 50 per cent. slip at 1,222ft. per minute, slowing down the engine, so that we could not continue the tests. These last two tests, however, go to prove that the slip does not increase with the velocity, and the last three were all stopped in good order, with the belts still on the pulleys. I think they go to prove that a strong light-woven belt, with a leather lining, if the cement is perfect, will be the belt of the future for all magneto-electro machines, as they combine great strength with light weight and great clinging properties.

Digitized by Google

I do not propose to enter into any discussion which may involve patent rights, but will simply say that while these cotton-leather belts tested were made by the Underwood Manufacturing Company, a very promising belt of the same materials is also made by the Page Belting Company, of Concord, N.H., differing in construction thus:—Two canvass belts are used, meeting in the centre, with a single leather lining, which acts as a hinge, and permits the belt to adapt itself closely to a *coned* pulley.

THE ELECTRO-MAGNET.*

BY PROF. SILVANUS P. THOMPSON.

(Continued from page 686.)

We are now in a position to understand the bearing of some curious and important researches made about forty years ago by Dr. Julius Dub, which, like a great many other good things, lie buried in the back volumes of Poggendorff's *Annalen*. Some account of them is also given in Dr. Dub's now obsolete book, entitled "Elektromagnetismus."

The first of Dub's experiments to which I will refer relates to the difference in behaviour between electro-magnets with flat and those with pointed pole ends. He formed two cylindrical cores each six inches long, from the same rod of soft iron, one inch in diameter. Either of these could be slipped into an appropriate magnetising coil. One of them had the end left flat, the other had its end pointed, or rather, it was coned down until the flat end was left only ½in. in diameter, possessing therefore only one-fourth of the

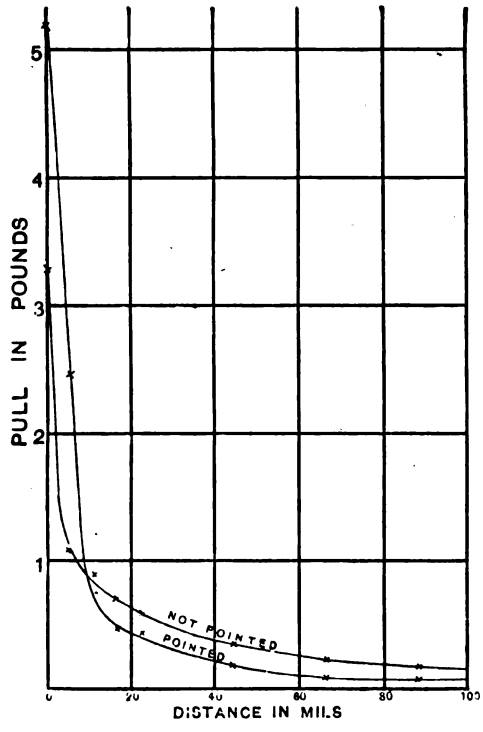

FIG. 35.—Contrasted Effect of Flat and Pointed Poles.

amount of contact surface which the other core possessed. As an armature there was used another piece of the same soft iron rod, 12in. long. The pull of the electro-magnet on the armature at different distances was carefully measured, with the following results:—

Distance apart in inches.	Pull on flat pole (lb.).	Pull on pointed pole (lb.).
0	3·3	5·2
0·0055	1·1	1 8
0·0110	0 9	0·75
0·0165	0·71	0·50
0 022	0 60	0·42
0·044	0·38	0·20
0·088	0·19	0·09

* A series of four Cantor Lectures delivered before the Society of Arts, January—February, 1890.

These results are plotted out in the curves in Fig. 35. It will be seen that in contact, and at very short distances, the reduced pole gave the greater pull. At about ten mils distance there was equality, but at all distances greater than ten mils the flat pole had the advantage. At small distances the concentration of magnetic lines gave, in accordance with the law of traction, the advantage to the reduced pole. But this advantage was, at the greater distances, more than outweighed by the fact that with the greater widths of air-gap the use of the pole with larger face reduced the magnetic reluctance of the gap and promoted a larger flow of magnetic lines into the end of the armature.

Dub's next experiment relate to the employment of polar extensions or pole-pieces attached to the core. These experiments are so curious, so unexpected unless you know the reasons why, that I invite your especial attention to them. If an engineer had to make a firm joint between two pieces of metal, and he feared that a mere attachment of one to the other was not adequately strong, his first and most natural impulse is to enlarge the parts that come together—to give one as it were a broader footing against the other. And that is precisely what an engineer, if uninstructed in the true principles of magnetism, would do in order to make an electro-magnet stick more tightly on to its armature. He would enlarge the ends of one or both. He would add pole pieces to give the armature a better foothold. Nothing, as you will see, could be more disastrous, Dub employed in these experiments a straight electro-magnet having a cylindrical soft-iron core 1in. in diameter, 12in. long; and as armature a piece of the same iron, 6in. long. Both were flat-ended. Then six pieces of soft iron were prepared of various sizes to serve as pole pieces. They could be screwed on at will either to to the end of the magnet core or to that of the armature. To distinguish them we will call them by the letters A, B, C, &c. Their dimensions were as follows, the inches being presumably Bavarian inches:—

Piece.	Diameter.	Length.
	inches.	inches.
A	2	1
B	1⅝	1¼
C	1⅜	2
D	2	½
E	1½	1
F	1	2

Of the results obtained with these pieces we will select eight. They are those illustrated by the eight collected sketches in Fig. 36. The pull required to detach was measured, also the attraction exerted at a certain distance apart.

Experiment.	On magnet.	On armature.	Traction.	Attraction.
I.	none	none	48	22
II.	D	none	30	10
III.	E	none	32	11·5
IV.	C	none	35	13·5
V.	D	A	20	7·5
VI.	none	B	50	25
VII.	none	D	43	25
VIII.	none	C	50	18

It will be noted that, in every case, putting on a pole-piece to the end of the magnet diminished both the pull in contact and the attraction at a distance; it simply promoted leakage and dissipation of the magnetic lines. The worst case of all was that in which there were pole pieces both on the magnet and on the armature. In the last three cases the pull was increased, but here the enlarged piece was attached to the armature, so that it helped those magnetic lines which came up into it to flow back laterally to the bottom end of the electro-magnet, while thus reducing the magnetic reluctance of the return path through the air, and so increasing the total number of magnetic lines, did not spread unduly those that issued up from the end of the core.

The next of Dub's results relate to the effect of adding these pole-pieces to an electro-magnet 12 inches long, which was being employed, broadside on, to deflect a distant compass needle. (Fig. 37.)

In another set of experiments of the same order a permanent magnet of steel, having poles *n s*, was slung horizontally by a bifilar suspension, to give it a strong tendency to set in a particular direction. At a short distance laterally was fixed the same bar electro-magnet, and the same pole-pieces were again employed. The results of attaching the pole-pieces at the rear end are not very conclusive; they slightly increased the deflection. But in the absence of information as to the distance between the steel magnet and the electro-magnet, it is difficult to assign proper values to all the causes at work. The results were :—

Pole-piece used.	Deflection (degrees).
None	8·5
A	9·2
B	9·5
C	10
D	8·8

When, however, the pole-pieces were attached to the distant end of the electro-magnet, where their effect would undoubtedly be to promote the leakage of magnetic lines into the air at the front end without much affecting the distribution of these lines in the space in front of the pole, the action was more marked.

F	10·1

Still confining ourselves to straight electro-magnets, I now invite your attention to some experiments made in 1862 by the late Count Du Moncel as to the effect of adding a polar expansion to the iron core. He used as his core a small iron tube, the end of which he could close up with an iron plug, and around which he placed an iron ring which fitted closely on to the pole. He used a special lever arrangement to measure the attraction exercised upon an armature distant in all cases one millimetre from the pole. The results were as follows : –

—	Without ring on pole.	With ring on pole.
Tubular core alone	11	10
Ditto, with iron plug	17	14
Core provided with mass of iron at distant end	27	25
Ditto, ditto, with iron plug	38	33

After hunting up these researches, it was extremely interesting to find that so important a fact had not escaped the observant eye of the original inventor of the electro-magnet. In Sturgeon's "Experimental Researches" (p. 113) there is a footnote, written apparently about the year 1832, which runs as follows :—

An electro-magnet of the above description, weighing three ounces, and furnished with one coil of wire, supported 14lb. The poles were afterwards made to expose a larger surface by welding to each end of the cylindric bar a square piece of good soft iron; with this alteration only the lifting power was reduced to about 5lb., although the magnet was annealed as much as possible.

We saw that this straight electro-magnet, whether used broad-side-on or end-on, could act on the compass needle at some distance from it, and deflect it. In those experiments there was no return-path for the magnetic lines that flowed through the iron core save that afforded by the surrounding air. The lines flowed round in wide-sweeping curves from one end to the other, as in Fig. 26, the magnetic field being quite extensive. Now, what will happen if we provide a return path? Suppose I surround the electro-magnet with an iron tube of the same length as itself, the lines will flow along in one direction through the core, and will find an easy path back along the outside of the coil. Will the magnet thus jacketed pull more powerfully or less on that little suspended magnet? I should expect it to pull less powerfully; for if the magnetic lines have a good return path here through the iron tube, why should they force themselves in such a quantity to a distance through air in order to get home? No, they will naturally return short back from the end of the core into the tubular iron

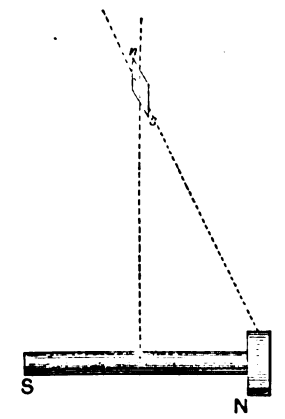

Fig. 37.—Dub's Deflection Experiment.

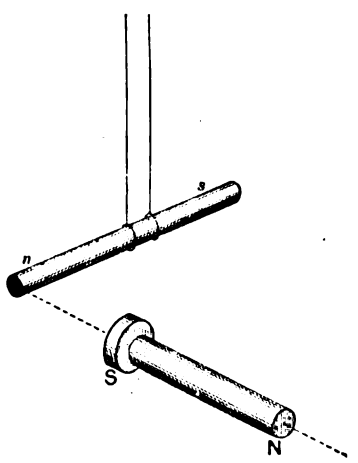

Fig. 38.—Deflecting a Steel Magnet having Bifilar Suspension, Pole-piece on Near End

Digitized by Google

jacket. That is to say, the action at a distance ought to be diminished by putting on that iron tube outside. Here is the experiment set up. And you see that when I turn on the current my indicating needle is scarcely affected at all. The iron jacket causes that magnet to have much *less* action at a distance. Yet I have known people who actually proposed to use jacketed magnets of this sort in telegraph instruments and in electric motors, on the ground that they give a bigger pull. You have seen that they produce less action at a distance across the air, but there yet remains the question whether they give a bigger pull in contact? Yes, undoubtedly they do; because everything that is helping the magnetism to get round to the other end increases the goodness of the magnetic circuit, and therefore increases the total magnetic flux.

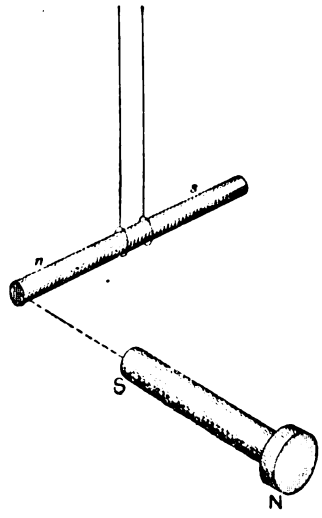

FIG. 39.—Deflecting Steel Magnet, Pole-piece on Distant End.

We will try this experiment upon another piece of apparatus, one which has been used for some years at the Finsbury Technical College. It consists of a straight electro-magnet, set upright in a base-board, over which is erected a light gallows of wood. Across the frame of the gallows goes a winch, on the axle of which is a small pulley with a cord knotted to it. To the lower end of the cord is hung a common spring balance, from the hook of which depends a small horizontal disc of iron to act as an armature. By means of the winch I lower this disc down to the top of the electro-magnet. The current is turned on; the disc is attracted. On winding up the winch I increase the upward pull until the disc is detached. See, it required about 9lb. to pull it off. I now slip over the electro-magnet, without in any way attaching it, this loose jacket of iron—a tube, the upper end of which stands flush with the upper polar surface. Once more I lower the disc, and this time it attaches itself at its middle to the central pole, and at its edges

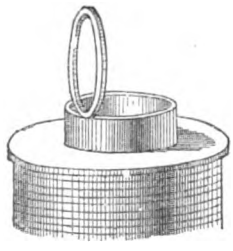

FIG. 40.—Experiment with Tubular Core and Iron Ring.

to the tube. What force will now be required to detach it? The tube weighs about ½lb., and it is not fixed at the bottom. Will 9½lb. suffice to lift the disc? By no means. My balance only measures up to 24lb., and even that pull will not suffice to detach the disc. I know of one case where the pull of the straight core was increased 16-fold by the mere addition of a good return-path of iron to complete the magnetic circuit. It is curious how often the use of a tubular jacket to an electro-magnet has been re-invented. It dates back to about 1850, and has been variously claimed for Romershausen, for Guillemin, and for Fabre. It is described in Davis's "Magnetism," published in Boston in 1855. About 16 years ago Mr. Faulkner, of Manchester, revived it, under the name of the *Altandae* electro-magnet. A discussion upon jacketed electro-magnets took place in 1876, at the Society of Telegraph Engineers; and in the same year, Prof. Graham Bell used the same form of electro-magnet in the receiver of the telephone which he exhibited at the Centennial Exhibition. But the jacketed form is not good for anything except increasing the tractive power. Jacketing an electro-magnet which already possesses a return circuit of iron is an absurdity. For this reason the proposal made by one inventor to put iron tubes outside the coils of a horse-shoe electro-magnet is one to be avoided.

We will take another paradox, which equally can be explained by the principle of the magnetic circuit. Suppose you take an iron tube as an interior core; suppose you cut a little piece off the end of it; a mere ring of the same size. Take that little piece and lay it down on the end. It will be struck with a certain amount of pull. It will pull off easily. Take that same round piece of iron, put it on edge-wise, where it only touches one point of the circumference, and it will stick on a good deal tighter, because it is there in a position to increase the magnetic flow of the magnetic lines. By concentrating the flow of magnetic lines over a small surface of contact increases B at that point, and B^2, integraded over the lesser area of the contact, gives a total bigger pull than is the case when the edge is touched all round against the edge of the tube.

Here is a still more curious experiment. I use a cylindrical electro-magnet set up on end, the core of which has at the top a flat circular polar surface about two inches in diameter. I now take a round disc of thin iron—ferrotype or tin-plate will answer quite well—which is a little smaller than the polar face. What will happen when this disc is laid down flat and centrally on the polar face? Of course you will say that it will stick tightly on. If it does so, the magnetic lines which come in through its under surface will pass through it and come out on its upper surface in large quantities. It is clear that they cannot all, or even any considerable proportion of them, emerge sideways through the edges of the

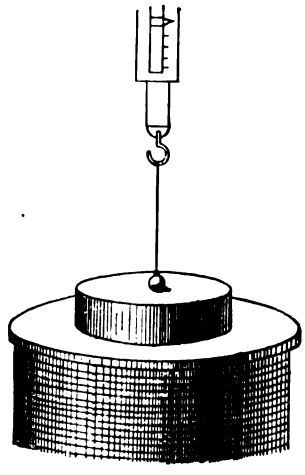

FIG. 41.—Exploring Polar Distribution with small Iron Balls.

thin disc, for there is not substance enough in the disc to carry so many magnetic lines. As a matter of fact the magnetic lines do come through the disc, and emerge on its upper surface, making, indeed, a magnetic field over its upper surface that is nearly as intense as the magnetic field beneath its under surface. If the two magnetic fields were exactly of equal strength, the disc ought not to be attracted either way. Well, what is the fact? The fact, as you see now that the current has been turned on, is that the disc absolutely refuses to lie down on the top of the pole. If I hold it down with my finger, it actually bends itself up, and requires force to keep it down. I lift my finger, and over it flies. It will go anywhere in its effort to better the magnetic circuit rather than lie flat on the top of the pole.

Next I invite your attention to some experiments, originally due to Von Kolke, published in the "Annalen" forty years ago, respecting the distribution of the magnetic lines where they emerge from the polar surface of an electro-magnet. I cannot enumerate them all, but will merely illustrate them by a single example. Here is a straight electro-magnet, with a cylindrical, flat-ended core (Fig. 41). In what way will the magnetic lines be distributed over at the end? Fig. 41 illustrates roughly the way in which, when there is no return-path of iron, the magnetic lines leak through the air. The main leakage is through the ends, though there is some at the sides also. Now the question of the end-distribution we shall try by using a small bullet of iron, which will be placed at different points from the middle to the edge, a spring balance being employed to measure the force required to detach it. The pull at the edge is much stronger than at the middle, at least four or five times as great. There is a regular increase of pull from the middle to the edge. The magnetic lines, in trying to complete their own circuit, flow most numerously in that direction where they can go furthest through iron on their journey. They leak out

Digitized by Google

more strongly at all edges and corners of a polar surface. They do not flow out so strongly at the middle of the end surface, otherwise they would have to go through a larger air-circuit to get back home. The iron is consequently more saturated round the edge than at the middle; therefore, with a very small magnetising force, there is a great disproportion between pull at the middle and that at the edges. With a very large magnetising force you do not get the same disproportion, because if the edge is already far saturated you cannot by applying higher magnetising power increase its magnetisation much, but you can still force more lines through the middle. The consequence is, if you plot out the results of a succession of experiments of the pull at different points, the curves obtained are, with larger magnetising forces, more nearly straight than are those obtained with small magnetising forces. I have known cases where the pull at the edge was six or seven times as great as in the middle with a small magnetising power; but with larger power not more than two or three times as great, although, of course, the pull all over was greater. You can easily observe this distribution by merely putting a polished iron ball upon the end of the elecro-magnet, as in Fig. 42. The ball at once rolls to the edge, and will not stay at the middle. If I take a larger two-pole electro-magnet (like Fig. 11) what will the case now be? Clearly the shortest path of the magnetic lines through the air is the path just across from the edge of one polar surface to the edge of the other between the poles. The lines are most dense in the region where they arch over in as short an arch as possible, and they will be less dense along the longer paths, which arch more widely over. Therefore, as there is a greater tendency to leak from the inner edge of one pole to the inner edge of the other, and less tendency to leak from the outer edge of one to the outer edge of the other, the biggest pull ought to be on the inner edges of the pole. We will now try it. On putting the iron ball anywhere on the pole it immediately rolls until it stands perpendicularly over the inner edge.

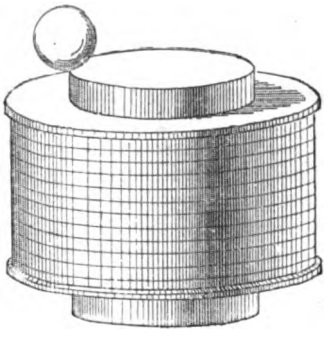

Fig. 42.—Iron Ball attracted to edge of Polar Face.

The magnetic behaviour of little iron balls is very curious. A small round piece of iron does not tend to move at all in the most powerful magnetic field if that magnetic field is uniform. All that a small ball of iron tends to do is to move from a place where the magnetic field is weak to a place where the magnetic field is strong. Upon that fact depends the construction of several important instruments, and also certain pieces of electro-magnetic mechanism.

(To be continued.)

SECONDARY CELLS.*

BY W. J. S. BARBOUR STARKEY.

The author in this Paper limited himself to a description of his own experiences in regard to secondary cells, primarily with a view to provoke discussion on the subject. Soon after the introduction of M. Faure's cells his attention was drawn to the hard film of sulphate of lead formed on the plates, which materially interfered with their efficiency; and, as a result of experiments, he ascertained that the addition of a small quantity of carbonate of soda to the dilute acid served to remedy this evil, even when the cells were allowed to remain idle for a considerable time. Subsequently, in the case of a small installation of 22 E.P.S., 350 ampere-hour cells, the plates of which showed signs of sulphating, carbonate of soda ordinary washing soda), was added in small quantities, and on proceeding with the charging the plates were restored to their original condition. The cells thus treated have since been in use for a period of five years, and are now in perfect condition. The subsequent experiments on this subject by Mr. Preece were then alluded to. The author advised that large cells be used for stationary work, and that they be both charged and discharged at low rates. Various details in regard to the management of cells were discussed, the practice of packing the plates in a solid though porous mass formed by mixing plaster of Paris and sawdust being specially recommended. The Paper concluded with the expression of a hope that a thoroughly practical cell for traction purposes might be introduced —one which will stand rough usage and be free from the defects which characterise those at present in use.

* Abstract of a Paper read before the British Association in Section G Leeds, September, 1890.

ON A MERCURY ELEMENT IN RELATION TO TEMPERATURE.*

BY F. STEINITZ.

The combination $Ag/AgSO_4/Hg_2SO_4/Hg$, which exhibits a marked change under different temperatures, seemed to the author peculiarly adapted for the study of Helmholtz's theory, that the difference between the electrical and the chemical energy of an element is equivalent to the product of the absolute temperature and the differential coefficient of the difference of potential between the poles. If the chemical energy overcomes the electrical energy, in which case a current is generated, the coefficient is negative; if the reverse is the case, it is positive. The elements used consisted of two glass vessels, 6·5 cm. high and 2·5 cm. wide, connected by a capillary tube. In both vessels was placed mercury, into which in the second vessel was plunged a platinum wire. On the mercury in the first vessel was placed a layer of paste of mercurous sulphate and silver sulphate, and on this the silver sulphate solution was carefully poured. In the silver sulphate solution a silver wire spiral and a thermometer were immersed. The whole was put into a copper vessel containing water.

The changes in the E.M.F. varied considerably with the time. The first reading was ·0295 volt at 13·8°C. The tests at various temperatures give rise to the assumption that the E.M.F. is a linear function of the temperature. The results show that the agreement between the theory and the experiments is complete in cases of actions of a reversible nature. It would also seem that even with actions not belonging to this class the theory would lead to correct conclusions.

* From the *Wiener Berichter.*

ON THE CONDUCTIVITY OF SOLID AND FUSED SALTS.†

BY L. GRATZ.

The data hitherto published on the conductivity of solid and fused salts differ for each salt when determined by different observers. The author was extremely careful to keep the salts at constant and accurately measured temperatures. The salts were fused in a small porcelain crucible 2·8 cm. high and 2·2 cm. diam., heated equally in a sand bath. In the salt were placed stout, square, platinum electrodes of 2·25 square cm. surface. The electrodes were freshly platinised before each test. To prevent cooling of the electrodes by conduction of heat through the connecting wires, about 20 cm. of the latter were also put in the same bath. The resistance of the salt was measured by the alternate current and an electro dynamometer. The capacity of the crucible was determined by a solution of magnesium sulphate. All readings were taken with decreasing temperatures.

In spite of the fact that many of the salts on solidifying showed porosity, a general agreement was found between the results for the same salt in the solid and fused state. With some salts, just at the point of fusion, a remarkable change occurs in the volume or in their conductivity; with others, the conductivity alters rapidly at a temperature below the fusing point; and with a third group, a steady change only is observed. It appears, therefore, that the only difference between salts in the solid and fused state is due to an action of an electrolytic nature, as Warburg has already proved in the case of glass and crystal. Clausius' theory, therefore, that in solid bodies the molecules oscillate about a position of equilibrium, but cannot separate from their own group, cannot be accepted. The idea of a sharply-defined difference between solids and liquids must also be abandoned, as it seems to have no existence in Nature. Liquid molecules exist in every solid, even when the latter show no approach to the softened state.

REVIEWS.

Elementary Manual of Electricity and Magnetism. By ANDREW JAMIESON, M.Inst.C.E. (Griffin and Co., London, 1890.)

It appears to be inevitable that as many elementary text books must be written as there are technical colleges. If all these were of the highest quality the "unattached" student would have a wide choice, though the members of the respective institutions must needs pay attention to those of their teachers if they desire to distinguish themselves in the examinations. The book before us, though in some respects open to criticism, may certainly be classed among the best. But it is difficult to estimate its value, since it is merely an introduction to a more advanced textbook which is in preparation. It consists of three parts, each divided into lectures. It is a pity that a list of contents is given separately at the commencement of each section, and that there is no index whatever.

Reduction Tables for Readings by the Gauss-Poggendorff Mirror Method. By Dr. PAUL CZERMAK. (Berlin: 1890.)

The Gauss-Poggendorff mirror method is the correct but little-used name for the arrangement of mirror, scale, and telescope, which are employed in all laboratories for the measurement of the deflections of various instruments. The tables are for facilitating the reduction of readings to tan ϕ, sin $\phi/2$ and ϕ in degrees, where ϕ is the angle through which the mirror moves. The tables give the distance of the mirror from the scale at every 10cm. from 1m. metre to 2m., and at every 20cm. from 2m. to 4m. The scale readings are given at every 10mm. up to 500mm. Linear interpolation may be used between these without appreciable error.

The tables are preceded by a description of the adjustments and corrections. The limits of accuracy for various scale distances are discussed, and it is suggested that the scale itself should be used in determining the scale distance, &c. The corrections are of a rather hair-splitting order, but it is useful to have them on record, clearly discussed with approximate formulæ for their elimination. For the displacement of the ray due to a parallel piece of glass in front of the mirror, one-third of its thickness should be subtracted from the scale-distance, and for similar reasons it is shown that those who may care to do so should add the thickness of the mirror to the scale distance. Corrections for curved glass in front of the mirror, for inclination of the mirror from the vertical, for its eccentricity and curvature are given. The whole of the work is written in parallel columns in German, English, and French.

Tables to find the Working Speed of Cables. Comprising also data as to diameter capacity and copper resistance of all cores. By ARTHUR DEARLOVE. (Spon and Co., London, 1890.)

This little pocket book of 20 pages has been computed from results recently obtained in the commercial working of cables. The first table gives the number of words per minute for cables of from 100lb. to 500lb. of copper, various weights of G.P., various diameters of cores, and gives also the ratio of copper to G.P., the C.R. per unit at 45°F. and at 75°F., the capacity per unit, and the C.R. × capacity × length^2. Five letters are reckoned to a word for ordinary work, and it is pointed out that experience has shown that where a code is used the words will average about eight letters. The second table gives reduction to knots up to 4,000, enabling the speed for a cable of any length to be easily computed.

AMERICAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

NEW YORK, *October* 10, 1890.

Meeting of the National Street Railway Association.—The electrical event of the coming week is the meeting of the National Street Railway Association in Buffalo. A large number of electrical people will attend, as much of the interest of the meeting centres about the developments of electric street railroads. Several of the Papers read will deal with various aspects of the subject, and it is highly probable that some very interesting facts will be elicited. Two years ago the electric motor hardly had a place in the deliberations of this body, but to-day the horse is pretty completely in the background and receives only passing attention.

The Westinghouse Traction Motor.—Some few details of the Westinghouse street railway motor have now been made public. It differs in general appearance very little from the forms already familiar, but the mechanical construction is somewhat peculiar. A single casting supports the car axle and gearing, and the armature spindle, which is in the form of a square frame, and the motor proper is carried within it, the pole-pieces being hinged at the back and clasped together about the armature by being screwed to a brass block which secures them to each other and to the front of the casting. By removing the retaining poles the pole-pieces can be swung back and the field coils pulled all over them if there is need of removing them for any cause. The same process allows a most easy removal of the armature. It is a heavy solidly-built machine, with many good mechanical features.

The "Portelectric."—The New England Portelectric Company has been trying some fairly successful experiments recently. The portelectric, it will be remembered, is a motor device in which a long iron car is acted upon directly by the attraction of solenoids distributed along the track. In the Portelectric system these solenoids are about 6ft. apart, and the car is about double that length, cylindrical in form, with pointed ends. It is intended, of course, not for the transport of passengers, but for carrying mail in small packages. As the car is pulled forward by the attraction of one of the solenoids, it shifts the current on to the solenoid immediately preceding, and so continues its motion. An oval track about half a mile long has been erected, and the speed of nearly 40 miles an hour has been already attained, with every prospect of doubling it when the track is levelled up and got into better condition. The amount of copper required is considerable, of course, each

Digitized by Google

solenoid having about 20lb. of No. 14 wire upon it. The scheme is an ingenious one, but the cost of construction is rather forbidding.

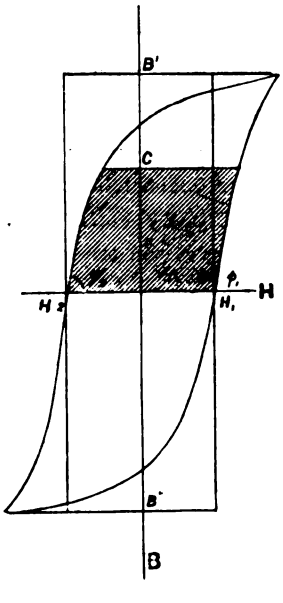
New Street Railway Motors.—Two or three new street railway motors are in process of evolution, the effort of the various inventors being to dispense as far as possible with gearing. The Wenstrom and Baxter Companies are each bringing out a motor which is geared but once to the driven axle, while a truck is under consideration which will be equipped with a pair of the remarkable Duncan motors of which something was heard a few months ago. This machine bids fair to work something of a revolution in electrical traction, for it gives a high efficiency with a speed which permits it to be placed directly upon the axle. It is not an "American novelty," but a very substantial, scientific, and business-like machine.

CORRESPONDENCE.

LOSS BY HYSTERESIS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your editorial notes last week you take exception to Mr. Tesla's statement that the loss by hysteresis, within certain limits, depends upon the square of the magnetomotive force. Mr. Tesla obviously means the limits within which the induction B may be considered proportional to H, in other words the approximately straight line parts of the permeability curves.



In the figure the straight line parts of the top part of a magnetic cycle of a closed circuit transformer are supposed limited by an induction b. Since in reality the angles ϕ, and ϕ_2 are nearly equal, the loss of energy for these parts of the cycle, represented by the shaded part of the figure, is nearly equal to $\frac{1}{4\pi}(H_1 + H_2)\,b$, so it is not at all proportional to the square of H, as stated by Mr. Tesla. This same formula may serve as a rough approximation of the total cyclic loss, E, or $E = \frac{1}{4\pi}(H_1 + H_2)(B' + B'')$, the error will generally not surpass 10 to 15 per cent.

In the case of open circuit transformers, H must be increased to get the same B as in a closed circuit one, the increase corresponding with the magnetic irresistance. The energy integral will now partly consist of a factor $\left[\frac{p B^2}{2}\right]$, p being a constant; for a complete cycle this factor becomes zero. Consequently the increase of H in an open circuit transformer has no effect on the cyclic loss.—Yours, &c.,

Amsterdam. G. L. F. PHILIPS.

TELPHER AND ELECTRIC RAILWAYS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We were somewhat astonished to read the strictures in your last week's issue on the purely descriptive paper we read before the Scottish Society of Arts on the telpher and electric railways of the Edinburgh Exhibition.

We must confess that the points referred to by you in your Notes fail to convey to us the deductions you make, and we believe will likewise fail with those of your readers who are at all familiar with the subject, either from a commercial or electrical point of view; indeed, we feel there is so little that requires serious refutation that we do not propose to occupy your valuable space with a lengthy reply.

We should, however, like to draw your attention to one or two of the points you refer to, which are not altogether in accord with the knowledge of the present state of the art.

We may state definitely that the only type of motor applicable to the satisfactory hauling of a telpher train is a series-wound motor. Surely you do not propose to tell us that any other method than stopping the supply of current to the motor could be used to prevent its tendency to indefinite acceleration; hence the existence of the Fleeming-Jenkin governor, or some other automatic equivalent.

It is news to us, indeed, that hanging a weight at the end of the stand rope adds to the complications of the line; on the contrary, it appears to our poor understandings as a simple and effective method of anchoring the rope, and one not likely to give any trouble in practical working. No doubt it adds vastly to the complications of the line to space the locomotives at definite distances apart, instead of letting them lie peacefully where they happen to come.

We are glad to be able to inform you that telpherage has advanced "beyond the toy stage," and is making progress perfectly satisfactory to the Electrical Engineering Corporation.

We think we were, perhaps, presumptuous in entering into commercial matters with which we may not be so well acquainted as with the technical portions of the subject; and here we may need correction, but we did think we were safe in taking the cost of maintenance in the United States on their electric tramways, where both labour and materials for maintenance are much higher in price than in this country, to compare with the cost of horse traction in this country, a large proportion of which cost is made up in labour at distinctly cheaper rates than in the States.

The energetic Council of the Edinburgh Exhibition can best reply to your last paragraph about the provision of the tramway line for the benefit of those interested in electrical traction. Strangely we thought that they were playing a very laudable part in bringing home to the minds of tramway directors in its proper place—an Electrical Exhibition—a cheap system of electrical traction applicable—we venture to re-assert eminently applicable—to small towns and country districts, which they could not be expected to adopt until they had examined it in actual operation.—Yours, &c.,

J. G. STATTER.
E. MANVILLE.

Princes Mansions, 68, Victoria-street, S.W., London,
October 22, 1890.

TRADE NOTES AND NOTICES.

[*Notices for insertion under the above heading must reach the Office not later than first post Thursday morning.*]

TENDERS WANTED.—The Streets Committee of the Commissioners of Sewers of the City of London notify that tenders are wanted for lighting by electricity the Western District of the City. Further particulars are given in our advertisement pages; and the conditions of the contract, which are similar to those arranged for the Eastern and Central Districts, may be seen at the office of Mr. H. Blake, Clerk of the Commissioners of Sewers, Guildhall, E.C. Tenders must be sent in to Mr. Blake not later than 2 o'clock on the 28th November next.

SALES BY AUCTION.—Messrs. Wheatley Kirk, Price and Goulty announce that the date of the sale, by public auction, of the high-class modern electrical plant, formerly the property of the

Digitized by Google

City of Westminster Electrical Syndicate, upon the premises of the new Electric Supply Station, Eccleston-place, Eccleston-street, Buckingham Palace-road, S.W., has been fixed for Friday, October 31st, commencing at 11 for 12 o'clock prompt. The plant will be on view on Thursday, 30th October, and morning of sale. Particulars and catalogues can be obtained of the auctioneers, at either their London or Manchester offices.

SALES BY AUCTION.—Messrs. Furber, Price and Furber will sell by auction on the premises, 42, Eagle-street, Red Lion-street, on Thursday next, the 30th inst., at one o'clock, the electrical generating plant, including reservoirs, batteries, vats, lamps, instruments, &c., connected with the Perreur-Lloyd's system. Further particulars are given in our advertisement columns.

SURPLUS PLANT.—The Liverpool Electrical Supply Company announce that they have a quantity of surplus plant for disposal, particulars of which will be found in our advertisement columns.

THE BREWERS' EXHIBITION.—This Exhibition was opened on Monday last, and will close to-morrow (Saturday). We have again to chronicle the almost complete absence of any electric light display, which we have previously referred to in regard to the many Exhibitions which have been held at the Agricultural Hall, Islington. Messrs. Paterson and Cooper have a small installation of the electric light; Mr. Napier Prentice employs at Stand 175 a small motor for driving steam crushing machinery; and there is a 50-light Prentice dynamo at the stall of Mr. E. S. Hindley, who has a number of his well-known engines on view. Messrs. Crossley Brothers show a pair of engines, with the latest improvements. Amongst a number of other gas engines which may be mentioned is a new patent portable hydro-carbon gas engine, made by Messrs. S. Griffin and Co., of Bath, and shown at Stand 172. We may also mention the excellent exhibits of Messrs. Pontifex and Wood, and that of Messrs. Isler and Co. The latter firm has on view the new pumping engine and boring gear which the St. James and Pall Mall Electric Light Company are about to use to secure a good supply of water at their central station.

W. T. HENLEY'S TELEGRAPH WORKS COMPANY (LIMITED).—We have just received the October Price List and Catalogue of this Company, which came into operation on the 15th inst. The Catalogue contains exhaustive tables of insulated electric light cables and wires (both indiarubber and vulcanised indiarubber), jointing material, wood casings, &c.

GENERAL ELECTRIC SUPPLY COMPANY.—We have received a copy of the fifth edition of the catalogue of this Company. It has been greatly enlarged, and contains 126 pages, with over 1,000 illustrations. It contains every possible requisite, including dynamos, switches, lamps, cables, cutouts, meters, engines, accumulators, and a very handsome selection of fittings, and instructions for tending a dynamo. We understand this Company have acquired the sole agency for the sale of the Crocker-Wheeler Motor, which is largely used in America.

MR. CARL OPPERMANN.—Mr. Oppermann announces his removal to larger premises, at 2, Wynyatt-street, Clerkenwell, London, E.C., where he has laid down plant for the construction of complete electro-plating fittings and dynamos for small installations.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

13,485. WHITE. Electrical glow lamp conductors. (Price 6d.)

COMPANIES' MEETINGS.

Eastern Extension, Australasia, and China Telegraph Company (Limited).

The thirty-fourth ordinary general meeting of this Company was held on Wednesday, at Winchester House, Old Broad-street, under the presidency of Sir John Pender, K.C.M.G.

The SECRETARY (Mr. F. E. Hesse) read the notice convening the meeting and the minutes of the last meeting, which were now approved.

The CHAIRMAN: Gentlemen, you have had the report in your hands for some days, and I presume you will take it as read; but if anyone desires to have it read that shall be done. The report is a full one, but nevertheless I shall follow my usual custom of going over some of the details, in order that our shareholders may have such information as may, I hope, increase their confidence in the working of this great submarine telegraph system. The gross receipts for the half-year amounted to £254,856, against £256,75 for the corresponding period of 1889, showing a decrease of £1,901. Our revenue for the past half-year has, in fact, been practically stationary. During the current half-year, however, the receipts show a considerable increase over those for the corresponding period of 1889. We are also benefiting from the recent substantial rise in the value of silver, as, instead of remitting our money home from India, China, and the Straits Settlements at a loss, which in 1889 amounted to as much as £11,000, we have lately made a small profit on exchange. We do not look upon this as permanent, for we are witnessing a phase of things respecting which time alone will tell us on which side the balance is likely to be. The working expenses have been £76,670, against £73,773 for the corresponding half-year, or an increase of £2,897. This is mainly accounted for by the cost of repairs having been heavier last half-year than in the corresponding period of 1889, and by the establishment of an agency at Melbourne. Part of the increased expense is also due to the new Roebuck Bay station. The net revenue has amounted to £136,675, against £138,736 for the corresponding half-year; showing a decrease of £2,061, due to the causes already explained. Two interim dividends at the rate of 5 per cent. per annum have been paid for the half-year under review, amounting to £62,500, leaving £71,820 to be carried forward. The laying of the duplicate cable between Australia and New Zealand, to which reference has been made on previous occasions, but more particularly at the last general meeting, has been successfully completed during the half-year, together with the partial renewal of the Madras-Penang section. The cost of these two operations, amounting to £269,281, has been debited to the general reserve fund, which, after being credited with £21,103, the profit made on the sale of investments, and £10,778 for interest received on investments during the half-year, now stands at £472,713. I have already explained to you that the great object of this Company is to maintain its system in a thoroughly satisfactory manner without increasing the capital. In that way we are enabled to maintain dividends which I trust are satisfactory to the shareholders, and at the same time to put by such an amount as will always be a reserve in case of such impor-

Digitized by Google

tant works as those I have just mentioned becoming necessary. It will be seen from the revenue account that we have received a smaller amount of subsidy in respect of the Manila cable during the last six months than in previous half-years. This is owing to the subsidy arrangement having expired in May last; but as all the Five per Cent. Debentures issued to provide the capital for the Manila cable are now paid off there will be no further contributions required for the interest and sinking fund; and in future, therefore, there will be a saving effected on this account of about £5,000 a year. I referred even as far back as two years ago to the question of the redemption of the Six per Cent. Debentures, and the time is now drawing near when these Debentures will, I hope, be changed into Perpetual Debenture Stock, bearing 4 per cent. interest. We prefer this method of paying off the Six per Cent. Debentures to taking the money from the Reserve Fund. We hope, therefore, to issue this amount of Perpetual Debenture Stock at 4 per cent., while the holders of the ordinary stock will be receiving 6 to 7 per cent. The operation, therefore, is a good one, and at the same time it will not increase our capital in any way. The revenue will benefit to the extent of £6,000 per annum by the saving that will be effected by issuing Four per Cent. Mortgage Debenture Stock, in place of the Six per Cent. Debentures, which fall due on February 1st next. The necessary resolution authorising this issue will be submitted at the extraordinary general meeting to be held at the conclusion of the present meeting. With reference to our cable renewals, the policy of strengthening the system without adding to the capital has been continued during the half-year, when, in addition to the partial renewal of the Madras-Penang cable already referred to, 67 nautical miles of cable were inserted in the Tonquin-Hong Kong section, which has given trouble of late, and is at present interrupted; and the operation will be continued as opportunities occur until the line is put into thorough order. This is another instance showing the necessity of duplicating our system, so that our income may not be disturbed; for when one cable is interrupted, in nine cases out of ten the other is working, and our revenue is maintained. Although the Company's maintenance ships have been employed on various cable repairs during the past six months, no interruptions materially affecting revenue have occurred. Since the close of the half-year, however, Australia has unfortunately been cut off from telegraphic communication for nine days, owing to the sudden and simultaneous interruption, through volcanic action, of the Company's three cables between Java and Australia, near Banjoewangie (Java). The three cables were interrupted at the same time; but owing to a cause that has rarely occurred. In fact, only two interruptions from volcanic causes have previously happened on the Company's system during a period of nearly twenty years. However, this occurrence only again shows the importance of duplicating the cables, for in this case, as I have said, we had three cables, and they were all interrupted. It is in one sense a misfortune, but not so in another. It is a great satisfaction to know that we can effect the repairs quickly and thoroughly, and to know that any Company having only a single line could not live or compete with us. That is our strength. We are not monopolists; we have no exclusive concessions; but we have so fortified ourselves by having such an abundant supply of carrying capacity, that we consider ourselves in a tolerably sound position. A matter that has been a great deal talked about of late, especially during the last six months, is the question of reduced tariffs to Australia. Our present tariff is 9s. 4d., to which we reduced it five years ago from 10s. 8d. Three years since we recouped the loss we thus made, and then another agitation began for a further reduction. We had several conferences with the Agents-General of these Colonies in London, who are all men eminently qualified to look after the interests of their Colonies, and submitted a proposal for attaining the desired object. We believe in the vitality of the traffic, and that the merchants who now spend thousands a year in telegraphing will continue to do so; and probably increase their expenditure if the rates are reduced. Our proposal was to test the effect of a substantial reduction in the rates under a Government guarantee, and was submitted to the Australasian Governments, backed by the support of the Colonial Agents. The result was that a conference was held in Adelaide, at which a resolution was passed adopting the proposal. We are now in course of negotiating with the Colonial Governments. Some of the colonies think that the Home Government should have taken a part of the responsibility; but, for reasons best known to the latter—and probably in the long run, wise reasons—the request was declined. My impression is that they will act independently of the Home Government, and I think the probability is that before I address you again, six months hence, we may be able to tell you that these negotiations have been successfully completed. If so, the result will be that we shall have a 4s. tariff instead of 9s. 4d.; but we shall have the guarantee of the Colonial Governments to make up half the amount of money with the 4s. tariff that we receive at the present moment. We are taking the other half of the risk of any loss that may be incurred, and we feel that we are justified in doing so, for the reasons I have already mentioned, namely, the vitality and competition for business in the Colonies, and the belief that we entertain that the merchants will not only continue, but will materially increase the expenditure on telegraphic messages. In that case the result will be that we shall get our present income, and the value of our property will be increased by the guarantee of the Colonial Governments. Looking at the present state of the negotiations, the favourable view which the Colonies take of our proposal, and the more favourable view which the press of the Colonies take of it, we feel pretty confident that we shall see this matter carried through. It would be a new departure in telegraphy that would create an enormous change. I may add that if we had not fortified ourselves by duplications we could not have undertaken to carry the increased traffic which the reduced rates are likely to bring about. As it is, we have the cables ready to be employed, and we have practically paid for them. The last time I addressed you reference was made to the Conference which was to be held in Paris, and a great deal was said as to these Conferences being a serious business for the Cable Companies. I told you then that we should do the best we could for the Company, and I am pleased to tell you that we did not suffer unduly. We did all we could to make the Conference pass off well. Before going to the Conference we had several interviews with the Indian Government Delegate. The Governments are beginning to realise that we are something more than an ordinary combination—that we are not only a great power for bringing the nations of the world so closely together, but that we are a power with whom they have to reckon, and we think they are disposed to reckon with us on fair terms. Before going to Paris we had several interviews with the Indian Government delegate, and our relations with the Indian Government were very much strengthened through what passed at those interviews and at the Paris Conference, the result being that satisfactory arrangements were concluded for reductions in the Indian transit and terminal rates, and for generally improving the international service. These arrangements include the duplication of the Madras-Penang cable, a contract for which has been entered into with the Telegraph Construction and Maintenance Company; and the abolition of our Elephant Point station at the mouth of the Rangoon River, the existence of which had long been threatened by the rapid encroachments of the sea at that place during the last few years. I will now conclude by proposing the following resolution:—

"That the report and accounts of the Directors now submitted be received and adopted."

Mr. F. A. BEVAN: I have much pleasure in seconding the resolution.

The CHAIRMAN: If any shareholder desires to make any remarks on what I have said or on the report, I shall be happy to hear him.

Mr. JOHN NEWTON: It is very satisfactory to see that you are going to pay off these Six per Cent. Debentures, and that you can now issue Four per Cent. Stock. Still you are now mortgaging our property, and as a shareholder I object to the mortgaging of any of our property. I think it would be better to issue ordinary shares and pay off your mortgage. You would have a stock then which would have a freer market, on account of their being more of it. I think your experience of Conferences have been this—though you have got out well from the last one—that when you get up to a 7 per cent. dividend, those attending the Conferences say that that return is too much to pay to your shareholders, and they knock down your tariffs so as to reduce your dividend. It seems to me that, however friendly Governments may be to you, they do their best to prevent your paying a substantial dividend, which shareholders in telegraph companies are entitled to, seeing the enormous risk they underwent when they first took part in these enterprises. I think, with the force that is behind you, which takes away your revenue from you because they consider that your tariffs are too high, it would be better to issue the balance or a portion of the unissued amount of your shares. You could do that and obtain a premium of 2 on them, which would give you a substantial sum to add to your reserve fund. Besides, the Four per Cent. Debenture Stock will be a first charge on your property, and in the event of a difficult time coming you have not that security to offer. You will be creating a first-class security when it is not necessary to do so, and it will increase your ordinary revenue. You will then have to reduce your profits. Those who belonged to this Company at the outset must have seen with surprise what you can now do; but the ordinary shareholders are not getting the benefit of your progress.

Mr. SAMUEL SMITH: Do you not think that this is a question which ought to be raised at the extraordinary general meeting?

The CHAIRMAN: Yes, you are quite right.

Mr. SMITH: I wish to ask the nature of the guarantee which the Australian Governments will give us in respect of the proposed change in the tariff, and also whether the Colony of New Zealand, to which we have been so liberal, will take part in the guarantee.

The CHAIRMAN: I think we had better discuss Mr. Newton's question when we come to the extraordinary general meeting. As to the question about the guarantee, I suppose that any one of us would be delighted to take as a guarantee the resolution of the Parliaments of the Colonial Governments. As to New Zealand joining in the proposed arrangement, we are negotiating with the Government of that Colony. So far New Zealand has stood apart from the other Australian Colonies. I cannot tell you all that I might about this matter; but when these negotiations are carried through, it will, I believe, be so much for the interest of New Zealand to take part in it that I have no doubt myself that she will do so.

A SHAREHOLDER: Will you tell us where the three cables were broken, and at what distance from each other the breaks occurred?

The SECRETARY: Near Banjoewangie. It is stated in the report.

The CHAIRMAN: The breaks all occurred at the same instant.

The SECRETARY: Within a few miles of each other.

The CHAIRMAN: As I have already pointed out, this is an occurrence we need not anticipate every day. He then put the resolution to the meeting in the usual manner; and having declared it carried unanimously, said: We now come to the special meeting; and the Secretary will read the resolution to be proposed.

The SECRETARY thereupon read the following resolution, viz.:—

A. "That the Board of Directors be, and are hereby authorised from time to time to create and issue Mortgage Debenture Stock of the Company to an amount not exceeding one-third of the share capital of the Company for the time being issued and paid up, upon the terms that the aggregate amount of the said stock for the time being in issue, and the interest thereon, shall rank pari passu *as a first charge on the undertaking and revenue of the Company, the stock to be issued at such times, in such amounts, and on such terms and conditions as the Board shall from time to time determine, for the purpose of redeeming, by exchange or otherwise, the outstanding Debentures of the Company, or any other purpose to which the capital of the Company may be lawfully applicable.*

Digitized by Google

B. "That the Board be and are hereby authorised to make such provision as they think fit for the registration and transfer of Mortgage Debenture Stock, and for the delivery of certificates thereof, and for the payment of the interest thereon, and generally as to the form and incidents of all documents relating to the said stock, but so that no such provision be inconsistent with paragraph A of this resolution."

The CHAIRMAN: I propose that resolution, and I think I may now reply to Mr. Newton. We do not admit of sentiment coming into our calculations in dealing with this question. I think that every man enjoying private property will sleep more soundly and be happier if he has no mortgage on his property; but here are we, a company with our capital of £2,500,000, and all the mortgage we have on it at the present moment is this £320,000. Now would it be wise on the part of your Board to pay 7 per cent. on that portion of the capital, instead of 4 per cent.? I think you will all agree with me, looking at this insignificant sum, and remembering that this Company must continue to exist and roll on, that this £320,000 is but a bagatelle compared with the large capital that we have.

A SHAREHOLDER: And the reserve fund.

The CHAIRMAN: Yes. We might if we choose use that reserve fund and pay off this amount, but would it be wise to do so? I think myself that it would be a very unwise proceeding to do that. I look upon this £320,000 as a sum that does not in the slightest degree interfere with us; but still, as I stated a little while ago, by paying off the Six per Cent. Debentures we are saving £6,000 a year, which the general body of shareholders will get the advantage of. I am quite sure that Mr. Newton will agree with us if he thinks the matter out, and puts the little sentiment aside, in which, however, he is quite right. The fewer mortgages people have the better, but this is a mortgage that I should think rather ballasts the ship than lightens it; and I think it would be best to pass the resolution which has been read, seeing that the saving effected by it for the Company will be £6,000 a year.

Sir JAMES ANDERSON: I beg to second the resolution.

A SHAREHOLDER: It seems to me that Mr. Newton's objection, as far as the present shareholders are concerned, would to a very large extent be obviated if the Directors were to issue this Debenture Stock to the present shareholders. Then any shareholder who might feel that his position was injured by the issue of this Debenture Stock would be able to fortify himself by taking up his proper proportion of Debenture Stock.

The CHAIRMAN: That is exactly what we are going to do. The suggestion is a very proper one. We think this Debenture Stock is a good security, and the shareholders will all have the first offer of it.

A SHAREHOLDER: The shareholders will have the option of subscribing for it?

The CHAIRMAN: Yes. We have always given the shareholders the first option. I have not the slightest doubt that the stock will all be taken up.

A SHAREHOLDER: Will the present holders of the Six per Cent. Debentures have any preference?

The CHAIRMAN: We do not know who they are. We recognise our shareholders first. If any applications come from those who hold the Debentures now, they will come in for their proportion of this stock after the shareholders are satisfied.

Mr. SMITH: As an ordinary shareholder, I am entitled to my proportion; but I have had the gratification of receiving 6 per cent. for my money in the existing Debentures for 15 years, and I am very sorry to lose that. (Laughter.)

Mr. NEWTON: It does remove a certain amount of my objection when I hear that you are going to give the ordinary shareholders a priority over the holders of the existing Six per Cent. Debentures to take up this stock. I held Seven per Cent. Debentures in a telegraph company. They paid them off, and issued others bearing 6 per cent., and then they paid those off and issued Five per Cent. Debentures, but the holders were not entitled to have the new Debentures in priority to the shareholders. It does remove the objection I had from the point of view that I can take some of this stock if I like; but it does not remove what I said, that the Governments do come in if you advance your dividend to anything like 10 per cent., which I expected in a telegraph company; and it was a reasonable expectation to look for, but the moment you come to 7½ per cent. you are stopped. I see by this saving you will make £6,000 a year, and the saving you make by the redemption of Debentures you will get 7 per cent., and then you will have a strong attempt made at the next Conference to put down your tariffs. It is very satisfactory to see from this proposed arrangement with the Australian Colonies what you can do. If you issued your ordinary shares at 2 premium a dividend of 7 per cent. would not be a dividend of 7 per cent. on the capital as it would be on £12 and not £10. I recognise, and I think the Directors ought to recognise, the fact that the capital in this enterprise is represented in two ways. One is in capital and the other is in reserve, and the latter is what is represented on the Stock Exchange. When I take the capital value of my shares here I do not do so at £10, because if I sell a share I can get more than £10 for it.

The CHAIRMAN: It is not often that a chairman has to argue with a shareholder who is opposed to a high dividend. I rather think, Mr. Newton, that the time was when I thought 10 per cent. was the lowest rate we ought to have got in our submarine system. I may quote Mr. Newton again, for at a meeting not long ago he said that a 7 per cent. dividend now was as good as 10 per cent. a few years ago, such is the change in the value of money, and I think Mr. Newton will admit that to-day. Paying now 7 per cent. and putting by such a reserve as we are doing, not adding to our capital, but adding to the strength of the Company enormously by putting down new cables, I think we are showing a system of management, which, if all Companies were conducted on the same principle and had the same results, would cause them to hold a very proud position; and in our own case the test of that position is the very fact of our being able to issue this Four per Cent. Debenture Stock, as I feel sure we shall be able to do. It shows the position we occupy in the Money Market. If, after all, our property is at the bottom of the sea, still, we know where it is, and we know how to get at it and mend it if necessary. You can all take your share of this stock, every man according to his holding. We shall issue a notice to every shareholder, and shall tell him what his *pro rata* share is. If he wants any more he can say so; and then after the shareholders are satisfied according to their holdings, there will be an appropriation again. I thank Mr. Newton for his suggestion; and I now put this motion, and I do so in the thorough belief that it is a good thing for the Company, effecting a very material saving for the Company, and that you will receive it with acclamation. He then put the motion, and declared it carried unanimously. There must be another meeting of the shareholders within a month to confirm this. I do not think it will be necessary to go to the expense of engaging a room for that meeting, but purpose holding it upstairs in our own office.

Mr. NEWTON: I propose a vote of thanks to the Chairman and the Directors for the way in which they have safeguarded our undertaking. I hope they will preserve a steady dividend, and not let the Conference reduce our tariff.

A SHAREHOLDER: I have the greatest pleasure in seconding the resolution.

The resolution was carried unanimously.

The CHAIRMAN: I am very much obliged to you, and I thank you on behalf of my colleagues and myself. I only regret that my voice has been so bad to-day, or I might have made the strength of our position clearer. I appreciate your kindness, and your appreciation of the work we have been doing for you in the last few years.

The proceedings then terminated.

Brazilian Submarine Telegraph Company (Limited).

The thirty-fourth ordinary general meeting of the shareholders of the Brazilian Submarine Telegraph Company (Limited) was held at Winchester House, Old Broad-street, on Wednesday, under the presidency of the Right Hon. Viscount Monck.

The SECRETARY (Mr. Richard Collett) read the notice convening the meeting and the minutes of the last general meeting, and the report of the Directors was then taken as read.

The CHAIRMAN said that a very short cursory observation of the report and accounts showed that they had nothing except what was satisfactory to report with respect to the actual working of the past half-year. They paid a dividend of 7½ per cent., added £40,000 to the reserve fund, and had paid off debenture debt to the amount of £15,300; and he might add that the receipts of the current half-year, as far as known, justified them in expecting that they would be in a position to do as well in this half-year. The receipts of this half-year were considerably larger up to this date than they were at the same period of last year. However, notwithstanding these satisfactory evidences, they had undoubtedly a rock ahead in the termination of their Brazilian concession, which ends in about two years, and that from the Portuguese Government in about four years. Many things were being done with reference to this event, and he could only assure the shareholders with respect to it that the Directors were watching with the utmost vigilance to maintain the shareholders' interests when the time for proper action arrived. At the last general meeting some observations were made with reference to statements in the original prospectus of the Company. That was a subject upon which he was rather sensitive, because he was then as now chairman, and, of course, was responsible for anything which was stated in the prospectus. He had not a word to say against the disposition of the gentleman who made these observations, for he exhibited the utmost good feeling towards the Directors in reference to the management by the latter of the business of the Company. The gentleman in question, however, said, and said truly, that there were statements made with reference to a yield of probably 14 or 15 per cent. What was done in connection with this matter was this: they endeavoured to establish relations between the general mercantile movements in the country and the telegraphic communications to which they gave rise. They did this on the experience of others, and he did not think they would disagree from him when he said that that was not a bad way of ascertaining what their profits might be from the experience of others. The Board stated from that experience—from the figures then open to all to whom the prospectus was addressed—that the trade from and to South America might be expected to yield 15 per cent. That meant the general yield—not merely the net profit to be derived from the transactions, but the general yield which the traffic would give. It had not yet arrived at the point to which they referred, but it was very nearly approaching to it; and he did not think when they considered what had been done in the Company that their management would be regarded as in any way objectionable. During the period they had been in existence, which was now 16 or 17 years, they had paid dividends never less at any time than 5 per cent., on many occasions they had been 6, 7, and 7½ per cent. They had duplicated the whole of the system principally out of revenue, and if the balance of the sum of the Debenture Debt, raised for the purpose of the duplication, were now paid off, they would still have in hand a sum of £200,000 for reserve. He did not think if they consulted shareholders in other similar Companies that they would be told that the management of this Company had been defective. Their plant was in excellent order, and the lines were all working well. The receipts for the half-year of June, 1890, showed an increase over those of the previous half-year of £755. The general expenses in London exhibited a decrease of £213, which was accounted for by the absence of special law charges, which were less this year than last year by £235. The working expenses of the stations showed a decrease amounting to £696. The total expenses exhibited an increase of £1,291, which was more than accounted for by the laying of six new land lines at Pernambuco, costing £1,907. This, however, was an extraordinary item of expenditure which was not likely to occur again. Since their last meeting Dr. Taylor, who had been their Director in Brazil, had died, and they had now appointed Senhor Andrade Pinto as their representative there. Senhor Pinto is the son of the gentleman who was formerly the Company's Director there, and he believed he would be found of great use to them. At the Paris Telegraph Conference their Company was represented by Sir James Anderson and the Managing Director. He concluded by moving the following resolution:—

"*That the Report of the Directors and the accounts to June 30, 1890, now submitted, be approved and adopted, and that a dividend be now declared of 3s. per share (making, with the interim dividends already paid, a total dividend of 6 per cent. for the year ended June 30, 1890), and also a bonus of 3s. per share in respect of the profits for the year ended June 30, 1890, the said dividend and bonus to be respectively free of income tax.*"

The VICE-CHAIRMAN (Sir James Anderson) seconded the resolution, which was adopted unanimously.

On the motion of the CHAIRMAN, seconded by the Hon. W. St. JOHN F. BRODRICK, M.P., Sir James Anderson was re-elected a Director of the Company, as was also Mr. Frederick Youle, on the motion of the CHAIRMAN, seconded by the MANAGING-DIRECTOR (Mr. Thomas Fuller).

Dr. TREWHELLA then proposed and Mr. C. S. HAWKES seconded the re-election of the auditors, Mr. Henry Dever and Mr. John Gane.

Captain BLAKEY, R.N., afterwards proposed a vote of thanks to the Chairman and the Directors for the admirable way in which they had managed the affairs of the Company.

Dr. TREWHELLA seconded the motion, which was unanimously adopted.

The CHAIRMAN acknowledged the vote; and assured the shareholders that the Directors would combine to do their utmost to promote the welfare of the Company.

The proceedings then terminated.

Direct Spanish Telegraph Company (Limited).

An extraordinary general meeting of this Company was held at the offices, Winchester House, Old Broad-street, on the 21st inst., under the presidency of Sir James Anderson, for the purpose of confirming the following special resolution passed at the extraordinary general meeting held on the 30th ult:—

"*That Article 71 of the Articles of Association of the Company be and is hereby repealed, and instead thereof the following be a regulation of the Company:—*

"*The Directors shall receive, as remuneration for their trouble in the execution of their office, the sum of £600 per annum, or such other sum as the Company in general meeting may from time to time determine, and such remuneration shall be apportioned by the Directors among themselves in such manner as they shall from time to time think fit.*"

On the motion of the CHAIRMAN, seconded by Mr. LEWIS WELLS, the resolution was unanimously confirmed.

A vote of thanks to the Chairman closed the proceedings, which were purely formal.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended October 17th amounted to £1,891.

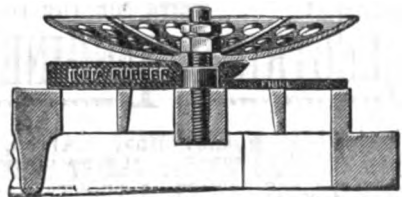
CONSOLIDATED TELEPHONE CONSTRUCTION AND MAINTENANCE COMPANY.—This Company has declared an interim dividend for the past half-year at the rate of 5 per cent per annum, payable on the 14th prox.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ending October 17, 1890, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £3,842.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY (LIMITED).—The Directors of this Company will, at the forthcoming meeting of the shareholders, recommend a payment of 6s. per share to June 30th last, on the First Preference Shares of the Company, and £3 per share on account of arrears on the Second Preference Shares. £1,500 is placed to the reserve fund, and £322 carried forward. The meeting of the shareholders will take place early in November.—The receipts of this Company for the half-month ended October 15th amounted to £2,887, as compared with £2,064 in the corresponding period, an increase of £823.

NEW VALVE

No Rubber, Percha, or Leather.



One-half the price of Rubber or Metal.

FOR CIRCULATING AND AIR PUMPS.

Unaffected by any Lubricating Oils. Does not Expand in diameter. Feed Water may be worked at any temperature Suitable for any shaped guards. Only one quality manufactured.

"12, John-street, Sunderland, 20th Sept. 1886.

"DEAR SIRS,—In reply to your letter of the 25th inst., the Valves I got from you have done their work well, and ARE AN UNQUALIFIED SUCCESS. I will continue to get them from you as required.—Yours faithfully, JAMES WESTOLL."

For further Testimony and Prices, apply to MOSSES & MITCHELL, 68-71, Chiswell Street, London.

THE ELECTRICIAN:

A WEEKLY ILLUSTRATED JOURNAL OF

ELECTRICAL ENGINEERING, INDUSTRY AND SCIENCE.

No. 650.—Vol. XXV. FRIDAY, OCTOBER 31, 1890. Price Fourpence.

NOTES.

We are glad to be able to announce that the City and South London Railway will be opened on Tuesday next by the Prince of Wales, thus disposing once for all of the many rumours of hitches, for which at no time was there any genuine foundation. Although several years have elapsed since the line was commenced, the work has progressed as fast as is possible where so many contractors are employed. For some time past the engines and dynamos have been in regular work, ten electric locomotives having been delivered, while four more will shortly arrive. The carriage-sheds, when we visited the works last week, were full of rolling-stock in a complete state, and the stations were being painted, nearly all the structural work being finished. A mere glance at the immense lifts, the stations and their fittings, the signal-box at the western terminus with no less than 24 levers, was sufficient to show us that the work is on a scale which removes it from comparison with any mere tramway work. No precaution has been neglected to ensure regular service when once the line comes into operation; trains have been running frequently in order to accustom the staff to the work, and every appliance connected with working of the system has been thoroughly tested.

Another step will be made in the progress of the electric lighting of London next week, by the closing of the central station at the Grosvenor Gallery, and the transference of the work to what Dr. Fleming calls the eccentric station at Deptford. We have within the last few days heard of the Ferranti mains spoken of as though they were still in an experimental stage, and have been asked whether any satisfactory method of making the joints has yet been discovered. The fact is that when a short length on one of the bridges has been completed, no less than 30 miles of Ferranti main will be actually laid. Of upwards of 8,000 joints, only 15 have been found to be faulty. Several of these have been due to no electrical difficulty, but to the carelessness of the men in forgetting to remove the cotton waste from the socket end. There has been but one single fault from the inner to the outer conductor, and this was due to moisture.

Those who were unwise enough to prophesy before they knew, said that the joints which are made with a plug in the inner tube, and a sleeve burnished or rolled down on to the outer conductor, would offer a considerable resistance, on account of imperfect contact and the absence of solder. It may interest these prophets to learn that the calculated resistance of the mains was 2·16 ohms, and the actual measured resistance is 2·2 ohms. The mains on one occasion were warmed up by a huge current, and as many joints as were accessible were felt, but no difference whatever could be detected. Immediately after this test, a pressure of 20,000 volts was put on without disclosing any defect.

The question of the choice of "Lighthouse Illuminants" would not appear at first sight to have any more important side than that of the beneficent philanthropy which guides the mariner to the haven and warns him from the hidden rocks and sands. But, strangely enough, this very question has given rise to contentious discussions, and quarrelsome controversies; it has allowed eminent scientific men in their wrangles and wordy altercations to lose sight of the humane ends in view, and to reveal a pettiness no less surprising than deplorable. It is to be hoped that the report which has been presented to the Board of Trade by the President of the Royal Society and two of his most distinguished colleagues will bring back the matter to a simply scientific issue; and that their verdict, together with the report of Trinity House which they have confirmed, will be taken as conclusive.

That electric light would be proved by the North Foreland tests to be superior to oil or gas was an issue which found no excited advocate, nor was the cause supported by the use of modern machinery. Patentees of gas and oil lamps brought out their latest improvements, but the electric current was generated by the de Meritens machines, which if not still used in a few lighthouses, would have long ago been obsolete. The fact that the rays of higher refrangibility in which the light of an electric arc is so rich are the first to be cut off by a fog, is counterbalanced by the enormous quantity of light initially given out by the apparatus; and it is further to be remarked that the residue of yellowish rays which have succeeded in passing through a haze are well qualified to continue their course, and are on a fair footing with those emitted from a gas or oil lamp.

Sir George Stokes, Lord Rayleigh, and Sir William Thomson state that an arc light is at a disadvantage compared with gas or oil lamps since the angle in a vertical section of the beam must be sufficient to allow the light to strike the sea from the horizon of the lighthouse to a

Digitized by Google

point at a moderate distance from its base; and they observe that the angle of the beam from an arc is less than that of an oil or gas burner, since the luminous area is smaller. It appears to us that this is the fault of the optical apparatus rather than of the source of light. Not only can lenses be readily designed to give any desired angle, but the electric beam should be far more uniform than that of a large flame, or rather a group of flames, since they cannot all be brought into the focal plane or planes. Every ray of light that (after allowing for refraction) passes above the horizon is wasted. The clean cut beam from an arc could be arranged to fall just where it is wanted with little or no scattering above and below the useful angle.

It is with regret that we learn that the Bristol-road electric tramways at Birmingham are already in difficulties; but it does not appear that the electrical part of the work is at fault. The lines are laid in wood pavement of an inferior description, and with every change of weather the gauge varies. This, of course, puts a severe side pressure on the wheels, and entails a great expenditure of power. Some idea of the strain to which the cars have been subjected may be obtained from the fact that strips of steel have actually been torn by the wheels from the new steel rails. The Jarman car at Clapham has experienced similar difficulties. There the gauge has not altered, but the rails are too narrow in the groove, and the wheels being too light to stand the strain have repeatedly broken. We understand that these rails have occasioned similar accidents with the horse-cars. These unfortunate mishaps do much mischief to the cause of electrical traction, since the public only see the breakdowns, and find the service disorganised. Nor can they be expected to inquire whether the causes are mechanical or electrical, and they are justified in expecting that the engineers in charge of the business should be competent to look after both departments.

We publish this week an article by Mr. Blakesley, in which he shows how to determine the energy lost in electro-magnetic cores, when alternating currents are traversing the coils. The process consists of an ingenious modification of Mr. Blakesley's well-known method for finding the difference in phase of two alternating currents by the use of three dynamometers; and the energy wasted in the core is expressed in terms of the lag between the two currents.

Many meanings have from time to time been given to the phrase "magnetic lag." Mr. Blakesley apparently only uses the term to represent the difference in phase between the curves representing the magnetisation of the core, and the exciting current flowing in the coil. We need not enter into Mr. Blakesley's views regarding the cause of magnetic lag, since they are debatable; it suffices to say that whenever hysteresis occurs with alternating currents, such a difference in phase must exist, and, further, if energy is lost in Foucault currents the lag must be correspondingly increased. Mr. Blakesley assumes that the currents vary with the time in the manner represented by a sine curve. This postulate has often been criticized, and may be compared with the predetermination of steam-engine diagrams by drawing adiabatic or other assumed lines. That it is sometimes far from being the case, a reference to the Paper of Messrs. Humphrey and Powell, printed in *The Electrician* for July 18th last, will readily show. Measurements of the difference of phase are nevertheless important, since, from its value, a good approximation may be made to the energy lost in Foucault currents and hysteresis. These losses are very difficult to measure when alternating currents are employed; for although Prof. Ewing's researches enable us to calculate with accuracy hysteresis losses occurring with slowly varying currents, it is quite uncertain how far these results are applicable to alternating currents of frequencies such as are used in practice.

A lengthy and somewhat acrimonious correspondence is being carried on in the Brighton local press with regard to the present position and future policy of the Brighton Electric Light Company. It is now nearly nine years ago that the historical firm of Messrs. Hammond and Co. commenced to run a small arc light installation in that town; and it is this "pioneer" installation, considerably enlarged and modified of course, which is now in danger of extinction. In 1881 there was no Electric Lighting Act, and the Brighton Company ran its wires pretty well as it pleased. In 1883 or thereabouts the Corporation obtained a Provisional Order, but finding subsequently that the electric lighting business was not the El Dorado predicted, prudently refrained from making use of its powers. Last year, however, stirred into action by the Board of Trade, who said an Order would be granted to the Brighton Company unless the Corporation commenced operations, active steps were taken by the municipality, the outcome of which was the electric lighting scheme, which is to be formally inaugurated on Tuesday next by the Mayor and Corporation.

But apparently the Brighton Company does not intend to fall in with this little arrangement. Trammelled neither by Provisional Order nor Licence, it can, provided the Brighton Corporation does not possess a special Act, giving it power to deal with overhead wires, by securing contracts for lengthened terms with its present subscribers, and by making the utmost use of the flexible qualities of the transformer system, prove a formidable competitor with the Municipality. The Company will have, of course, to comply with the Board of Trade regulations with regard to overhead wires, and to run the risk of being refused way-leaves, and harassed by indictments, injunctions, and other legal weapons. A compromise is, however, proposed by the Company. If the Corporation will support the Company in obtaining an Order for the area not as yet included in the Municipal scheme, the Company will abandon all idea of competition within the Municipality's district. Such a concession on the part of the Corporation would undoubtedly be generous; but the past history and struggles of the Company entitle it, in our opinion, to more generous treatment than has hitherto been accorded it by the Brighton Corporation. However, be the outcome what it may, the situation at Brighton is decidedly instructive; from it electric supply companies can learn what treatment to expect at the hands of Local

Digitized by Google

Authorities; and it may also afford a test of the possibility of an unlicensed Company competing successfully with an overbearing Municipality.

THE unfortunate result of the Edinburgh Exhibition should be a warning to those who, from public spirited motives, start a guarantee fund, and to those who for less praiseworthy reasons like to add their names to it. That it will be a warning to professional Exhibition promoters is not to be expected. A dinner and a cheque for somebody is always ready before the fabric is dismantled. The Exhibition was, to begin with, professedly electrical. The two representative bodies of the electrical trades and profession, however, gave it no encouragement whatever, and one strongly expressed the feeling that no such Exhibition was necessary. No promises of a selection of the best things from the Paris Exhibition, or the transference of the complete Edison exhibit could warm unwilling manufacturers into enthusiasm. But a few north-country firms, who have had no opportunity of exhibiting on an extensive scale before, have probably learned the lesson that their London friends have already been taught, as to the commercial value of an exhibit and a medal.

Dewsbury.—The Town Council have decided to apply for an electric lighting order.

Kidderminster.—The Town Council have decided to apply for an electric lighting order.

Gloucester.—At the last meeting of the City Council it was decided to apply for a Provisional Order.

Weston-super-Mare.—The Improvement Commissioners have decided to apply for an electric lighting order.

Croydon.—The Croydon County Council have decided to apply for an electric lighting order.

Brighton.—The Mayor will lay the foundation stone of the Corporation Generating Station on Tuesday next.

Hanley.—The Town Council at its last meeting decided to obtain an electric lighting order.

Personal.—The degree of Doctor of Science was yesterday conferred on Mr. J. T. Bottomley, F.R.S., by the Royal University of Ireland.

Electric Light Signalling.—Experiments have been made during the past week in electric light signalling from Hindhead to Aldershot, a distance of 12 miles.

Hamburg.—The municipal central station, which already supplies 7,500 lights, is about to extend the length of its mains by 2,000 metres, and it will then supply current to 2,000 more lamps.

Royal College of Science, London.—The Queen has been pleased to direct that the Government Institution now known as the Normal School of Science and Royal School of Mines shall in future be called the Royal College of Science, London.

The Halifax-Bermudas Cable.—The Halifax and Bermudas Cable Company's cable has been duly tested by the Government, who paid the first quarterly subsidy last week, according to the terms of their agreement with the Company.

National Telephone Company Appointment.—Mr. John D. Miller, district manager of the National Telephone Company, Dundee, has been appointed the Company's general manager for the division of Scotland north of the Forth.

Electric Light in Coal Pits.—The Fife Coal Company have arranged for the introduction of the electric light into their pits at Leven, in place of each miner carrying his own lamp. It is proposed to light the roads, the lamps to be 15 yards apart.

Loss by Hysteresis: a Correction.—In Mr. G. L. F. Philips's letter on "Loss by Hysteresis," which appeared on p. 721 of our last issue, the words "magnetic irresistance," in the last paragraph, should read "*magnetic air resistance.*"

Electric Lighting of Aldershot Camp.—A proposal, it is stated, has been made, and is now under consideration by the military authorities, to carry out the lighting of the whole of Aldershot camp by means of electricity, and it is expected that a preliminary trial will shortly be made.

Preston.—The Streets and Buildings Committee of the Corporation have approved of a temporary installation for the lighting of Fishergate, the principal thoroughfare of the town, by electricity. Current is to be supplied by the National Electric Supply Company.

Church Lighting.—St. Stephen's, Westminster, which was closed during August for repairs, was reopened last week. This church, which was erected in 1850 at the expense of the Baroness Burdett-Coutts, has undergone considerable improvement, the principal innovation consisting in the substitution of the electric light for gas.

Barmen.—The municipal installation is to be increased next year so as to provide for the lighting of Oberbarmen and Unterbarmen. For this purpose four accumulator stations, with the necessary engine and boiler plant, dynamos, cables, distributing boxes, &c., will be provided by Messrs. Schuckert and Co., at a cost of £70,000.

The Lighting of the City.—The Streets Committee of the Commissioners of Sewers will meet on Friday, November 28th, at the Guildhall, and open tenders for lighting the western district of the City by electricity. The conditions are similar to those in respect of the eastern and central districts. Tenders may be sent in up to two o'clock on the day mentioned.

Heckmondwike Local Board.—At a meeting of this Board, held on Monday, a long discussion took place respecting the electric lighting project. The Chairman moved that steps be at once taken for making application to the Board of Trade for a Provisional Order. The motion was carried by the casting vote of the Chairman.

Grosvenor Gallery.—The supply from the Grosvenor Gallery will be discontinued after next week, and the machinery will be removed to Deptford. The pressure on the Deptford mains will probably be raised to 10,000 volts in order to avoid overloading the dynamos with current. The armatures, though designed for 100 amperes, are found to carry 160 without overheating.

Telegraphists' Strike in America.—A *Times* telegram states that all the Western Union Company's operators at St. Paul, Minnesota, struck on Monday night because six of their number belonging to the new secret order of telegraph operators were discharged. There have been similar dismissals in other cities. The Omaha operators are out also. The business of the Western Union Company is stated to be partially crippled.

The Iron and Steel Institute at the Edison Laboratory.—On Friday, October 2nd, the members of the Iron and Steel Institute, now in America, paid a visit to the Edison Laboratory. About 200 visitors were expected, but no fewer than 500 arrived. Before leaving all gathered together again in the library, where Sir John Kitson, president of the Institute, thanked Mr. Edison, in its name, for the pleasure he had given them all.

Telegraphy in the Transvaal.—There are now 31 telegraph offices open in the Transvaal, and in the quarter ending March this year 149,377 messages were despatched, while 141,229 were received. In these totals Johannesburg figured with 76,388 and 71,373 telegrams respectively. The amount received for the telegrams despatched from the Transvaal during the three months ending March 31st this year was £12,417. 15s. 2d.

Moss Side Local Board.—At the last meeting of this Board a letter from the Manchester House-to-House Electricity Company, under date October 13, was read, asking the Clerk to bring the matter of street lighting before the Board with a view to opening negotiations for the substitution of the electric light, either arc or incandescent, for gas. It was decided that the plans asked for should be supplied to the Company, and every facility afforded it for lighting the township with the electric light.

Digitized by Google

Owens College, Manchester.—A prize of £10 has been offered by Mr. William Mather, M.P., for the best essay on some subject connected with the technical applications of electricity, the competition being open to students working in the Physical Laboratory of the Owens College during the day or evening. The award is to be given at the end of the present session, and Dr. Edward Hopkinson has offered a similar prize to be awarded next session. The subject for the present session is "Recent Progress in the Science of Magnetism."

Electrical Engineering Corporation.—Mr. Carl von Buch, of Messrs. Foote and Von Buch, electrical engineers, 11, Queen Victoria-street, E.C., has joined the Board of the Electrical Engineering Corporation. This corporation has for the last nine months been making considerable extensions at their works at West Drayton and these are now complete. In the course of a week their new machinery will be put to work, and among the new machine tools there will be some of the largest employed in the electrical industry.

Telephone Wires in Sheffield.—The Highway Committee of the Sheffield Town Council have declined to grant permission to the National Telephone Company to erect poles in Ecclesall-road, but have granted an application of the Company for permission to lay underground wires in the centre of the town. It was also decided that in future the Committee should not approve the further erection of poles, but, so far as practicable, give every facility for placing the wire cables under the surface at the uniform rate of 20s. per mile per annum.

"The Iron and Coal Trades Review."—The potential capabilities of electricity as applied to mining and kindred operations have evidently impressed our mining contemporary, which in its last issue brought out a twenty-page special supplement, a large proportion of which was devoted to matters electrical. Amongst the electrical articles was one on "Electric Light and Power in Mines," and another entitled "A Practical Guide to the Electric Lighting of Mines and Collieries," specially written for the supplement.

The Electric Light and the Defence of the Thames.—The Commander-in-Chief has sanctioned the carrying out of important experiments in connection with the electric light and its efficacy in protecting the entrance to the Thames. Major-General Goodenough, commanding the Thames District, is in charge of the operations, which will be carried out at various points below Gravesend. Torpedo boats have been requisitioned to furnish a supposed enemy, and the operations are to be made with a view to determine the best positions at which electric search lights could be placed.

Electric Welding Progress.—A welding machine will soon be turned out at the Lynn works of the Thomson-Houston Company, intended for welding sections of 6in. extra heavy pipe together endwise. The current developed in this machine is expected to reach 70,000 amperes, though its normal work will demand somewhat less than this. Great attention has also lately been given to the development of machinery for chain work, and a small apparatus has been constructed which takes wire from a reel and turns out lengths of chain with electrically welded links, the operation being automatic throughout.

Bath.—At the last meeting of the Surveying Committee the bills presented included £523. 19s. 4d., being Mr. Massingham's quarterly bill for the electric light. Mr. Sturges said he had gathered from the police report book that there had only been two failures of the electric light since March, while, on the other hand, there had been 28 cases of gas failures in the same period. Mr. Massingham had done his best to make the light a success, and to be over particular in the first quarter would perhaps be more nice than wise. In future, however, he must be given to understand that all failures must be paid for. The bill was passed, and referred to the Finance Committee.

Richmond.—At the last meeting of the Vestry the report of the Electric Lighting Committee was read. It stated that the draft contract submitted to them by Messrs. Latimer Clark, Muirhead, and Co., had been fully considered by the Committee, with the assistance of Mr. J. N. Shoolbred. A letter, dated October 7th, had also been received from the Board of Trade, requesting to know whether any steps have or are proposed to be taken to give effect to the Provisional Order granted to the Vestry in 1883. The Committee expressed a hope that the new Town Council would proceed with the matter from the point now arrived at by the Committee.

Sunderland.—At the last meeting of the Town Council the Highway Committee recommended that all the necessary notices should be given, and steps taken in order to obtain an electric lighting Order. Mr. J. Harrison, in moving the adoption of the report, said that when they got the order, they would light up the centre of the town and both sides of the river. If they subsequently found that it was beyond the practical ability of the Council to control the works for the supply of electricity, they were at liberty to dispose of their powers to a company. After some discussion, the report was put and carried.

Destruction of Electric Light Wires by Firemen.—Owing to the heavy losses suffered by American electrical companies, whose wires are hastily and clumsily cut by firemen whenever a fire occurs in a city, the electrical companies are thinking of adopting some means of preventing this destruction of their property. At the recent convention of fire department chiefs in Detroit, it was suggested that the electrical companies should keep a corps of men, with waggons equipped with appliances for cutting wires, who should go to fires and do all the handling of wires necessary. Another idea is, for the electrical companies to keep a man at each engine-house to go with the engine to fires and direct the wire cutting operations.

Cable Extensions.—The French Government has decided to sanction the laying of a new cable between France and Denmark, in order to obviate the frequent interruptions of communication at present occurring between the two countries, and to establish telegraphic communication between Marseilles and Tunis, and Marseilles and Oran. In pursuance of an Imperial order, the Turkish postal authorities are about to connect the island of Crete with Benghazi by a submarine cable. Telegraphic communication is also to be established between Benghazi and Tripoli. The Telegraph Construction and Maintenance Company are about to make and lay, for the Eastern Telegraph Company, a quadruplicate cable from Suez to Perim and Aden.

The City and South London Railway.—Two summonses were heard against the City and South London Railway Company at Lambeth this week for building stations at the corner of New-street, Kennington-park-road, and Harleyford-road beyond the line of frontage, and without the consent in writing of the London County Council. These stations, it was contended, had been built upon the old forecourts of houses and brought out right to the garden rail, and beyond the original and proper line of frontage. The County Council considered the Company had built such stations without sanction, and contrary to the Building Act. The defence was that the Company had powers under their own Act of Parliament to do as they had done. After lengthy arguments on either side the further hearing of the matter was adjourned.

Presentation to Mr. A. R. Bennett.—On October 23rd a deputation, consisting of about 20 of the National Telephone Company's *employés* in Scotland, comprising all the principal district managers and engineers, waited on Mr. Bennett and presented an illuminated address recapitulating his services to the Company during the eight years of his administration as General Manager of their affairs in Scotland, and expressing regret at his resignation and good wishes for the future. The address was accompanied by a set of Sir William Thomson's electrical testing apparatus, manufactured by the India-Rubber, Gutta-Percha, and Telegraph Works, of Silvertown. The presentation was acknowledged by Mr. Bennett in suitable terms, and he was afterwards entertained to luncheon at the Windsor Hotel.

Loughborough.—At the last meeting of the General Purposes Committee of the Town Council, the application of the Loughborough Electricity Supply Company for the consent of the local authority to their Provisional Order was considered. It was unanimously decided that the committee should report to the Council that they are of opinion there is not at present such a demand for the electric light as would justify either the Corporation or the Brush Electrical Engineering Company in obtaining electric lighting powers, and to recommend the Council to request the

Digitized by Google

Company to withdraw their present application on condition that the Corporation will themselves apply for a Provisional Order next year, or consent to the grant of such order to the Brush Company on terms and conditions to be defined before October 1, 1891; the Corporation undertaking to refuse their consent to the grant of a Provisional Order or licence to any other company pending the negotiations with the Brush Company.

The Paris Telephone System.—On and after Monday next any subscriber to a telephone, and any person entering the telephone offices, will be allowed to speak to any of these offices a message to be transcribed and conveyed to a person living in the district. The charge will be 50 centimes for five minutes, and the message will be limited to 100 words—The work of altering and enlarging some of the main sewers, with a view of facilitating the connecting of the new central telephone exchange in the Rue Gutenberg with the various subsidiary exchanges, is now being vigorously pushed on. In some instances the sewers will be entirely transformed. Thus in the Rue Faubourg-Montmartre the tunnels will be about 13ft. broad by 10½ft. high, with a cunette 4ft. deep in the middle. On either side of this cunette there will be a platform 2ft. wide, one of which will be used by the Municipal Sewers Department, while the other will be given over to the telephone service. The roof of the tunnel will rest on cast-iron pillars, and on brackets fixed to these will be run the Patterson 50-wire telephone cables. These Patterson cables, which are of American make, are manufactured as follows:—The cabled wires, each of which is first covered with ordinary cotton, are placed inside a lead tube, and paraffin is then forced into the interstices between the conductors and the lead covering. The cost of this work will be shared between the Municipality and the Postal Telegraph Department.

Bradford.—In their annual report to the Town Council the Gas and Electricity Supply Committee state that since the opening of the electricity works on September 20, 1889, the supply of electricity has been continued regularly on all week-days. To meet the convenience of many of the consumers the supply, since the 13th of May last, has been commenced at 10 a.m. and continued to 11 p.m. on the first five days of the week, and to 11:30 p.m. on Saturdays. Owing to the rapid increase in the demand for a supply of electricity, the whole of the plant, including the spare machinery, was in use by the end of December last. To meet the increasing demand the committee ordered from Messrs. Siemens' Brothers and Co. an additional Willans' engine of 300 indicated horse-power, coupled direct to a Siemens' dynamo capable of developing 240 electrical horse-power, together with the necessary feeding mains and instruments. A set of storage cells which has been ordered from Messrs. Crompton, Howell and Co., is now being fixed at the works for the purpose of supplying current at any time when the demand is not sufficient to keep the engines fully employed. These cells will have a capacity of 1,000 ampere hours. Between two and three miles of distributing mains have been laid during the past year. The plant, which will be available for the ensuing winter, will consist of three mild steel Lancashire boilers of 180 indicated horse-power each, and four steam engines of the inverted vertical type, three of 150 indicated horse-power each, and one of 300 indicated horse-power, working at 120lb. steam pressure. Three of these engines are by Messrs. Willans and Robinson, and the fourth is by Messrs. Marshall, Sons, and Co. Each engine is coupled direct to a Siemens' dynamo, three being capable of developing 120 electrical horse-power each, and the fourth 240 electrical horse-power.

Technological Examinations.—It is now just twelve years since the City and Guilds of London Institute started their system of technological examinations. The 202 candidates of 1879 multiplied themselves, two years later, into 1,563, and this again was more than doubled in 1884, when 3,365 papers were worked. The rapid increase continued till 1888, when the number 6,166 was reached, and for the last two years the numbers have gone up, though less rapidly, 6,781 being the total for the present year. That the percentage of failures is greater than last year may presumably be attributed to a raising of the standard. In the first years of the examinations the percentage was about 40; now it has reached 48·2. Out of the 54 subjects included in the programme, examinations were held in 49. The most popular subject was mechanical engineering, for which 972 candidates entered, but of these no less than 701, or 72 per cent., failed. Cotton-spinning comes next, with 949 candidates, of whom 525 passed. Carpentry and joinery, as might be expected, had a large number—707. In plumbing 569 entered for examination, though less than half—233, or 41 per cent.—passed. Electric lighting attracted 256. The practical tests which it has been found possible to introduce into some of the subjects form an important feature. The difficulty of carrying out such tests effectively is obvious when it is remembered that the examinations are carried out simultaneously in 176 towns scattered all over the Kingdom, and under the supervision of committees not professing any knowledge of the subjects of examination. However, to a certain extent the difficulty has been surmounted. Of the candidates examined, but 16·6 per cent. are not taught in the special classes established by the Institute. Of these classes there are now 483, attended by no less than 12,022 students. Just half these students were examined last year, and half again of those examined passed. There were 32 Colonial candidates examined at Sydney, simultaneously with those in England; 19 of them passed. Last year 29 were examined, of whom 23 passed. From some other Papers, presented with the annual report, from which the figures are taken, it appears that there were, up to the 4th inst., 154 students at the central institution of the Guilds Institute at South Kensington. The numbers at the Finsbury Technical Schools are considerably higher. There 1,152 students attended during the last completed year, 1889-90.

Edinburgh Exhibition.—Mr. Lee Bapty, general manager of the Exhibition, was entertained at dinner last week by the exhibitors in the Royal dining-rooms, and presented with a cheque for £500. —The Edinburgh correspondent of *The Times* states that it was officially announced on Monday that the letters of the guarantee fund of the Edinburgh International Exhibition had been hypothecated to the British Linen Company Bank in security of advances, and that this was accepted as a confirmation of the disquieting rumours that had been flying about for some time as to the large deficit that the balance-sheet of the Exhibition was likely to disclose.—In the first division of the Court of Session, on Tuesday, Messrs. Drysdale and Gilmour, contractors, presented a petition for the judicial winding-up of the Edinburgh International Exhibition Association. The petitioners, who erected the Exhibition buildings, stated that there was still a balance of £9,000 due to them, which the Association, although called upon, have failed to pay. They stated further that the amount of the guarantee fund of the Exhibition was £26,000, and the only assets were this fund and the Exhibition buildings, which at the close of the Exhibition on Saturday must be broken up and sold. On the other hand, there were debts amounting to £43,961, including petitioners' debt and £20,000 advanced by the bank. The petitioners stated that the Exhibition would result in a large deficiency and heavy loss to the creditors; and they asked the Court to appoint a judicial liquidator, in order to prevent the bank and other creditors obtaining a preference. The Court adjourned the consideration of the petition.—On Wednesday the petition came before the Second Division of the Court. After some discussion Lord Young, in giving judgment upon the application, said he thought that, without deciding anything about the propriety of the merits of this application for the judicial winding up, they should grant the usual formal order for intimation and service upon the respondents. Their lordships concurred. Answers were ordered to be lodged to the petition within eight days.—On the same day Lord Stormonth Darling heard counsel in the Bill Chamber of the Court of Session in connection with a petition by Gilroy and Company, contractors, against the Edinburgh International Exhibition for intimation and service of the petition and interim interdict against that day's drawing at the Exhibition being paid the British Linen Bank. After a discussion interim interdict was granted on caution being found, answers to be lodged in 24 hours.

MAGNETISM IN IRON AND OTHER METALS.*—XXXIV.

BY PROF. J. A. EWING, F.R.S.

(*Continued from page 671.*)

§ 122. **Effects of Longitudinal Push on the Susceptibility and Retentiveness of Nickel.**—The reduction of susceptibility and retentiveness in nickel by longitudinal stress is associated with an equally striking augmentation of susceptibility and retentiveness by longitudinal compressive stress. Fig. 97 shows an arrangement by which nickel rods have been tested,† under compression, within a yoke of wrought iron, by means of

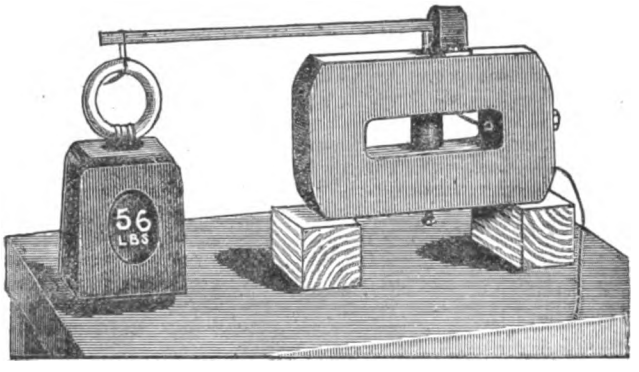

FIG. 97.
Arrangement for testing magnetisation of metals under compression.

the method described in § 58, the total magnetisation being determined ballistically by reversing **H**, and the residual magnetisation by deducting the ballistic effect got by removing **H** from half the ballistic effect got by reversing **H**. The influence of a number of loads was examined, ranging up to 19·8 kilos. per sq. mm. Every addition of load produced a decided increase of susceptibility, and caused an increasing fraction of the whole magnetism to be retained on the withdrawal of the magnetising force, until finally, under the heaviest load, the

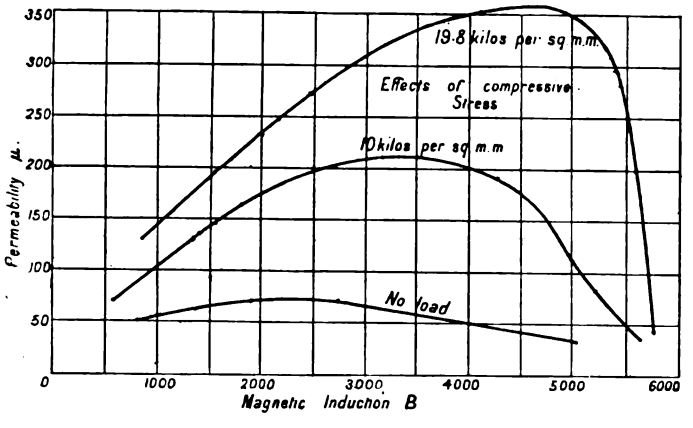

FIG. 100.
Permeability of Nickel in the hard state.

magnetisation curve rose with remarkable steepness, and the maximum proportion of residual to total induced magnetism reached the astonishingly great value of 0·96. In this group of experiments the nickel rod was in a hard (unannealed) state.

The results of the observation are shown in Figs. 98 and 99.

Fig. 98 gives the induced magnetism **I** in terms of **H**, under each amount of longitudinal compressive stress; and Fig. 99 gives the residual magnetism, which was observed in the usual way by withdrawing **H** at a number of stages during the taking of each magnetisation curve. Especially to be noted is the sharpness with which the curve of induced magnetism, under the heaviest stresses, bends over when **H** is about 20. The approach towards saturation is extremely rapid, and the change from a highly susceptible state to an insusceptible, because nearly saturated, state is remarkably abrupt.

Fig. 100 shows the result of the same experiment in a different way: the permeability μ is plotted there in relation to **B** for three conditions of stress which are specified on the curves.

Fig. 101 records a corresponding set of observations made on a nickel rod in the annealed state, under compressive stresses ranging up to 6 8 kilos. per square mm. The curves of μ and **B** which relate to this experiment have already been shown in Fig. 41, § 75.

§ 123. **Effects of Cyclic Variation of Longitudinal Stress on the Magnetism of Nickel.**—As might be anticipated from the curves that have been given above, a magnetised nickel wire subjected to cyclic variations of pull by loading and unloading it with suspended weights suffers much reduction of its magnetism when the weights are put on, and much increase of its magnetism when the weights are taken off. This happens whether the magnetism be induced or residual.

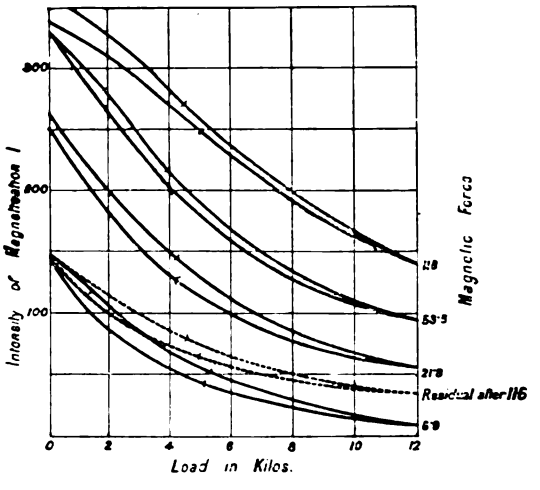

FIG. 102.
Effects of Loading and Unloading Nickel Wire in Various Constant Fields.

In Fig. 102 a number of curves are drawn to show the observed effect (upon **I**) of applying and removed loads while the magnetising force specified in the margin of the figure remained continuously in action. The dotted curves in the same figure show how the residual magnetism which was left after the action of the strongest force (**H** 116 C.-G.-S.) was affected by loading and unloading. In this experiment each kilogramme of load corresponds to a stress of 2·75 kilos per square mm. When these curves are compared with corresponding curves for iron, which will be given later, it will be seen that there is comparatively little hysteresis of magnetism with respect to stress in these.

There is, however, some hysteresis; the curve for the process of loading invariably lies above the curve for the process of unloading, even when the cyclic variations of stress are repeated often enough to make the magnetic changes become strictly cyclic. With hardened nickel wire, tested under a wider range of stresses, there is even less hysteresis than here.

ON THE ELECTRO-DYNAMICS OF STATIONARY BODIES.*

BY H. HERTZ.

(Concluded from page 637.)

PART B.

EXPLANATION OF THE PHENOMENA BY MEANS OF THE FUNDAMENTAL EQUATIONS.

Steady Flux of Magnetic Force.—If the values of u, v, and w are known, we may most readily obtain the components of the magnetic force by making use of an auxiliary quantity called vector potential, whose components U, V, W are given by the equations

$$U = \int \frac{u}{r} d\tau, \quad V = \int \frac{v}{r} d\tau, \quad W = \int \frac{w}{r} d\tau \quad . . (37)$$

These integrals are supposed to be extended throughout all space. From (32) it follows that

$$\frac{dU}{dx} + \frac{dV}{dy} + \frac{dW}{dz} = 0 \quad . . . . (38)$$

and, by making use of this equation, it can be shown that (30) will be satisfied if

$$\left.\begin{aligned} L &= A\left(\frac{dV}{dz} - \frac{dW}{dy}\right) \\ M &= A\left(\frac{dW}{dx} - \frac{dU}{dz}\right) \\ N &= A\left(\frac{dU}{dy} - \frac{dV}{dx}\right) \end{aligned}\right\} \quad . . . (39)$$

where

$$\frac{dL}{dx} + \frac{dM}{dy} + \frac{dN}{dz} = 0 \quad . . . . (40)$$

As an example, let us consider the force exerted by an element of current at a distant point $x'\ y'\ z'$. If the strength of the current is i, and the element ds has components dx, dy, dz, we may in (37) substitute $i\,dx = u\,d\tau$, $i\,dy = v\,d\tau$, $i\,dz = w\,d\tau$; and, if we regard the magnetic force exerted by the current as the sum of the forces exerted by each element separately, we obtain for the element in question, when the point $x'\ y'\ z'$ lies in the plane $x'\ y'$

$$L = 0 \qquad M = 0,$$

$$N = A\,i\,dx\frac{d\frac{1}{r}}{dy'} = -\frac{A\,i\,dx}{r^2}\frac{y'}{r}$$

which expresses Ampère's rule, and the law of Biot and Savart.

Reference to equations (30) will show that whenever u, v, and w vanish, as they do outside a conductor, the values of L, M, N can be obtained by differentiating a potential function, ψ, with regard to x, y, z respectively, and afterwards changing the sign. If the forces are the result of a single closed current, i, the potential ψ takes the form

$$\psi = -Ai\int \frac{d\frac{1}{r}}{dn}\,dw + \text{a constant} \quad . . (41)$$

Where dw is an element of a surface bounded by the current contour; n is a length drawn in the direction of the normal; and the integration is extended all over the surface so bounded. That side of the surface is to be considered positive from which the current appears to circulate in a clockwise direction. The derivatives of ψ are finite and continuous everywhere outside the currents; and, if at the surface, w, the value of ψ becomes discontinuous, we may regard the constant as not absolutely fixed, and by increasing its value by $4\pi A\,i$ each time the path of integration crosses the surface, the function ψ becomes quite continuous from point to point, although it is many-valued.

The integral expression for ψ is susceptible of several interpretations. In the first place, we may consider it as the potential due to a double magnetic layer, and this view leads naturally to Ampère's theory of magnetism.

On the other hand, we may consider, with Gauss, that the value of ψ represents the spherical angle subtended, at the point in question, by the current contour. This method of regarding the matter enables us to see the exactitude of the statement that the value of the integral at any point is equal to the number of the lines of force which start from a unit pole placed at the point, and are enclosed by the current contour.

It is, moreover, always true that the difference in the value of ψ at two points is equal to the product of $A\,i$, and the number of lines of force which cut the electric circuit when a unit magnetic pole is moved in any way whatever from the first point to the second.

It is this last interpretation which it is most useful for us to consider. It follows that the mechanical work necessary to bring up a magnetic pole or other invariable magnetic system to a circuit traversed by a constant current i, is measured by the product of $A\,i$ and the number of lines of force due to the magnetic system, which are cut, during the movement, by the electric circuit. Similarly, the mechanical work required to displace a circuit through which a constant current i is flowing, is measured by the product of $A\,i$ and the number of lines cut by the current during the displacement.

Finally, the mechanical work required to displace two electric circuits traversed by constant currents is equal, either to the product of the constant A, the strength of the first current, and the number of lines due to the second current and cut by the first during the displacement, or to the product of the constant A, the strength of the second current, and the number of lines due to the first current and cut by the second as the result of the movement The two expressions lead to the same result; for, if we distinguish by dashes quantities referring to the second current, we have for the first expression

$$A\,i\,i'[L'\cos(n,x) + M'\cos(n,y) + N'\cos(n,z)]\,dw,$$

and this, by suitable transformations. can be shown to be equivalent to

$$-A^2\,i\,i'\iint \frac{\cos\epsilon}{r}\,ds\,ds',$$

where ds, ds' are elements of the two electric circuits, at a distance r from each other, and inclined at an angle ϵ. Since this expression is symmetrical for the two circuits, the foregoing statement is verified. The product of $A^2\,i\,i'$ and the variation of Neumann's potential represents the work needed to produce any displacement, and its rate of variation thus determines the mechanical force exerted between the two circuits when at rest. The expression for the force thus obtained contains all that we know with certainty regarding the mechanical forces exerted by currents.

Dynamical Phenomena.

Up to the present, among the great variety of possible forms of the variable state, only a very small group of phenomena has been observed.

Induction in Closed Circuits.—The electric forces arising in a variable magnetic field are in general very feeble, because they contain a very small factor, the constant A [*see* (10) and (11)]; and the perception of these forces is only possible when they produce currents in closed circuits, or when their actions accumulate in linear circuits which are well nigh closed.

The actions which can be measured in researches are always the result of the integral action of the electric force taken around a closed circuit, and represented by the expression

$$\int (X\,dx + Y\,dy + Z\,dz).$$

By transforming this line integral into a surface integral, and by making use of (10), it is possible to show that this expression is equivalent to

$$A\frac{d}{dt}\int [L\cos(n,x) + M\cos(n,y) + N\cos(n,z)]\,dw,$$

or to the product of A, and the rate at which lines of force cut the circuit.

In particular, if the induction is produced by a variable closed current, and if there are no magnetisable bodies in

* An abstract of a paper published in the "Nachrichten von der Königlichen Gesellschaft, der Wissenschaften," for March, 1890; and reprinted in *La Lumière Électrique*, July, 1890.

Digitized by Google

the neighbourhood, the induced electromotive force is equal to the product of A^2, the time rate of change of the inducing current, and the potential of Neumann with reference to the two circuits.

These two principles, of which the former is the more general, embrace all induction phenomena which have been observed in stationary conductors.

The induction which takes place in moving conductors is, strictly speaking, not included in the field covered by the present Paper. We may, however, for linear conductors, connect this case with those already studied, by making use of the following principle. The electromotive force induced in a circuit will have the same value, whether the variation of the surrounding magnetic field is produced by the movement of ponderable bodies, or by purely electro-magnetic phenomena, provided only that the variations is the same in the two cases.

It follows that the electromotive force generated in a moving circuit is equal to the product of A, and the rate at which lines of force are cut by the circuit. The product of this electromotive force and the strength of the current in the moving conductor represents the rate at which chemical or thermal energy is generated by the induction.

This energy can also be shown to be equal to the mechanical work done by the exterior moving forces during the motion. Thus if a circuit conveying a constant current is moved in the neighbourhood of a fixed magnet, the work required to produce the movement is the exact equivalent of the thermal or chemical energy generated in the circuit, provided the magnetic energy of the system does not change. If, on the other hand, two circuits conveying constant currents are moved with reference to each other, the thermal or chemical energy appearing in one of the circuits compensates the mechanical energy absorbed by the motion, while the energy appearing in the other circuit compensates exactly the loss of the electro-magnetic energy of the system. In other words, the total energy produced is the exact equivalent of the energy destroyed.

Unclosed Circuits.—The extent of this subject is apparently the largest of all, as it embraces all those problems which cannot be considered as particular cases of the other subjects. However, having regard to the experiments actually possible, this subject is the poorest of all.

The oscillations which are produced in unclosed induction coils, or by the discharge of Leyden jars, can be studied with sufficient approximation by means of the principles established in the preceding sections. Properly speaking, electrical waves and the oscillations occurring with short waves belong to this chapter. It must be observed that a division of the electric force into an electrostatic force, and an electrodynamic one in these general problems, has no clear or precise physical significance, nor does it yield any valuable mathematical advantage. This method of study we therefore abandon in favour of others which are more convenient and fruitful.

Movement of Light in Isotropic Bodies.—We consider the domain of optics to embrace all electro-dynamic movements which are periodic with regard to time, and which are so rapid that at least a thousand million periods occur in a single second.

Let us restrict ourselves to bad conductors, which are homogeneous and isotropic. We then obtain from equations (1) and (2) by elimination

$$A^2 \epsilon \mu \frac{d^2 \theta}{dt^2} = \Delta \theta \quad . \quad . \quad . \quad . \quad . \quad . \quad (42)$$

where Δ stands for the operator $\frac{d^2}{dx^2} + \frac{d^2}{dy^2} + \frac{d^2}{dz^2}$, and where we may substitute for θ either L, M, N, X, Y, or Z.

We also have from (3)

$$\frac{dL}{dx} + \frac{dM}{dy} + \frac{dN}{dz} = 0 \quad . \quad . \quad . \quad . \quad . \quad (43)$$

$$\frac{dX}{dx} + \frac{dM}{dy} + \frac{dN}{dz} = 0 \quad . \quad . \quad . \quad . \quad . \quad (44)$$

The solution for θ in (42) is a periodic function, representing a wave whose vibrations are transverse to the direction of propagation. The velocity of propagation is for all possible waves equal to the reciprocal of $A\sqrt{\epsilon\mu}$, and the phenomena of rectilinear propagation, reflection, interference of natural and polarised light, and various types of polarisation can all be explained as a consequence of such wave propagation. On further reference to equations (1) and (2) we see that at each point on a plane wave the directions of the simultaneous electric and magnetic forces are perpendicular to each other.

Suppose that the surface separating the two non-conductors is the plane of $x\,y$. We have in this case, since we are only considering periodic movements—

$$L_1 = L_2 \qquad X_1 = X_2$$
$$M_1 = M_2 \qquad Y_1 = Y_2$$
$$\mu_1 N_1 = \mu_2 N_2 \qquad \epsilon_1 Z_1 = \epsilon_2 Z_2$$

Each of these systems of equations which hold at the surface in conjunction with those which are true within the media yield the laws of reflection, refraction, and of total reflection; that is to say, the fundamental laws of geometrical optics. Each of these systems shows also that the intensities of reflected and refracted waves depends on the plane of polarisation. They yield the same formulæ as Fresnel gave for these relations, and also for the retardation of phase occurring in total reflection.

If to obtain these formulæ we make use of the electric forces (equations (42) and (43) substituting L, M, or N, for θ) we pursue a method analogous to that of Fresnel. If, on the contrary, we make use of the magnetic equations [*see* (42) and (44) substituting X, Y, or Z for θ] we follow a course pursued by Neumann in obtaining Fresnel's formulæ. From our point of view, not only must the two methods yield the same result, but they can be described as being equally correct. It is, however, the electrical properties of bodies which mostly determine their optical behaviour. In the phenomena of reflection actually observed the electrical and magnetic forces have not exactly the same effect since the magnetic constant of nearly all bodies is close to unity, while the electric constant varies enormously for different media.

If the plane of $x\,y$ separates a bad conductor from a perfect conductor, we have

$$W = 0 \qquad X = 0 \qquad Y = 0.$$

These equations, in conjunction with those holding good for the interior of bad conductors, show that reflection is total at the separating surface, whatever the angle of incidence and the azimuth of the plane of polarisation.

It is known that real conductors occupy an intermediate position between bad conductors and perfect ones, and this is why reflection at their surface is a mixture of total reflection, and reflection such as occurs ordinarily at the surface of transparent bodies. As metallic reflection behaves in the same way, we can conclude that it is represented by our equations.

Optics of Crystals.—In the interior of homogeneous, perfectly transparent crystals, we shall make the supposition that the axes of symmetry of the electric energy coincide with the axes of symmetry of the magnetic energy. We shall take these axes as our axes of x, y, z; and, since for crystals the value of ϵ and μ vary with direction, we shall have to substitute μ_1, μ_2, μ_3 for μ in the three equations (1), and ϵ_1, ϵ_2, ϵ_3 for ϵ in equations (2) Solving these new equations, and obtaining the wave-surface for periodic disturbances, we obtain a surface represented by an equation of the sixth degree. This, however, reduces to the well-known surface of Fresnel, if we put $\mu_1 = \mu_2 = \mu_3$, which is very approximately true. Thus all the phenomena of double refraction, and of reflection and interference occurring with crystals, can be explained on ordinary optical methods. With reference to the wave-surface, we can establish the following statements:—The magnetic force is perpendicular to the electric polarisation, and the electric force to the magnetic polarisation. The direction of the two forces is, in general, outside the surface of the wave; but each direction of polarisation is tangential. The direction perpendicular to the two polarisations is consequently normal to the wave; while the direction perpendicular to the two forces is that in which energy is being propagated, and, in optics, this latter direction is called the direction of the luminous ray.

THE APPLICATION OF ELECTRICITY TO CRANES.

BY H. D. WILKINSON, M.I.E.E.

In the discussion which followed the reading of Mr. Reckenzaun's comprehensive Paper before the Society of Arts some three years back, on the subject of "Electric Tramways," the question of steam *versus* electrically driven trams or street railways came up; and during the course of the discussion one of the speakers denounced the idea that electricity as a motive power would ever supplant steam. "Not in my time, gentlemen, nor in yours," the speaker went on to assure the meeting, would this take place, if, indeed, it was ever likely to do. The Chairman (Mr. Preece) thereupon showed, in a few sentences, the incorrectness of the idea, popularly held, that electricity is in itself a motive power. In electricity we have an agent which serves as a means for the conveyance of power, in many cases a very convenient one, and more suitable than water, air, wire-rope, or other means, for accomplishing the same object. In hydraulic, pneumatic, or wire-rope transmissions, it is only when mechanical power is supplied to the system that the water, air, or cable become, so to speak, sources of power; and in a similar manner electricity itself requires mechanical or chemical means to produce the difference of potential or pressure necessary to develop power by its agency. There are not wanting signs in this country of activity in many branches to which electrical power can advantageously be applied. From America we have reports that the motor industry is almost on a scale with that of lighting; while in France there has been for some time amongst engineers an enterprising spirit and a willingness to put electricity to the test in various industrial applications. This was to some extent made evident last year at the Paris Exhibition. The two 10-ton electric travelling cranes, although manifestly capable of improvement, were in themselves a powerful demonstration of the facilities offered by electrical power for this class of machinery. One point which could be remedied by altering the ratios of gearing was in the speed of travelling, this being only at the rate of some 95ft. per minute with the fastest gear, or less than half what is usually required. The cranes did excellent work both in erecting and removing machinery, but the painfully slow process was more particularly felt at the removing, many firms having to wait their turn to get their machinery moved to the railway lines. Some interesting points were elicited from the experience gained in the working of these two cranes, which were on entirely different systems. There were one or two exhibitors showing machine tools driven electrically, and some very handy forms of electrical winches and vertical cranes. Perhaps the most demonstrative pieces of electrical work were the transmissions of power in the Swiss, French, and American sections. These were on no small scale, the Oerlikon Works alone driving 200ft. of shafting electrically, and this supplied the whole of the Swiss and part of the Belgian section. Close on 200 horse-power was taken off on this shafting for driving a number of looms, flour mills, brick and tile making, silk weaving and other machines. The plant consisted of a 250 horse-power dynamo and motor of the Oerlikon 4-pole build, working at 600 volts. These machines had armatures of Gramme type measuring 22in. in length and 37in. outside diameter. Another transmission was by Marcel Deprez machines, which convey considerable power to the remotest part of the Exhibition for running agricultural machinery; and another transmission covering the same distance by an aerial conductor was done by Thomson-Houston machines, delivering about 45 horse-power, at a working pressure of 500 volts. It is somewhat surprising that nothing of the kind was attempted at Edinburgh this year. The telpher line electric tram and launch and the driving of some sewing machines were the only conspicuous examples of the employment of electrical power.

In the cranes and windlasses mentioned above the general practice seemed to be to allow the motor to run continuously in one direction, supplying its power in most cases to a countershaft. From this again power could be taken off as required, and in the case of a travelling crane in any of the three directions required.

Various methods were noticeable in different exhibits for throwing the motor in and out of gear, and for reversing. Amongst these the types of portable cranes and winches shown by M. Guyenet, of Paris, were fitted with very handy gear. In one case, that of the crab or winch, the motor was movable bodily about a central axis through its bedplate, parallel to the armature shaft, and at either end of its shaft were fitted 3½in. friction pulleys. The hauling-drum was mounted centrally on a separate shaft, at either end of which were fixed 4ft. pulleys, having 4in. grooves or slots recessed in their inner faces. The small friction pulleys on the motor spindle engaged within these recesses, and by the amount of play allowed (about ¼in. each way), it was only necessary to rock the motor by a very slight amount in either direction about its central axis, to cause the friction pulleys to engage with either the outer or inner sides of the recesses in the large pulleys, and consequently start the winding drum revolving in one direction or the other. By one-hand lever the drum could be thrown in gear and run either way according to the way the lever was turned, and whichever way this was turned the counterpoise of the brake was raised and the brake released; also when the lever was let go the counterweight came into action, causing the brake to grip the wheel again and the lever to be restored to the neutral or off-gear position. In the hands of an ordinary workman, therefore, the control of such a machine would be of the easiest possible description. Instead of one hand being employed in managing the steam admission valve for stopping and starting, the other hand for the reversing lever and the foot for the brake as in the case of a steam winch, only one hand was required. By means of the large pulleys in which the small friction pulleys on the motor engaged, the necessary reduction of speed between the motor and hauling-drum was effected in a simple manner. The machine was designed for raising a load of 3cwt. at a speed of 200ft. per minute, and therefore would exert 2 horse-power effective. The motor speed was from 1,200 to 1,500 revolutions.

The portable crane exhibited by the same engineer was specially designed to be employed in stacking bales, an operation which ordinarily takes so much labour and time in grain, wool, and sugar warehouses It consisted essentially of an upright post of channel iron, supporting at the top the jib and counterpoise and mounted for convenience on a trolley, on which it was capable of turning on a vertical axis. The motor ran a small countershaft by belting, which, by another belt, drove the winding drum. This second belt was normally loose, the pulleys being double-flanged to keep it in place, and the throwing-in gear was effected by tightening the same. A third flanged pulley was employed to effect this by taking up the slack. The whole control of the crane was manipulated conveniently by a cord, on pulling down which a lever was raised which first released the brake and then tightened the belt. The load was then lifted, and at any required height stopped by letting go the cord. Similarly, for lowering loads the cord was held with sufficient tension to release the break to the necessary degree but not sufficiently to tighten the slack belt, a perfectly simple means of control. Up to last year, these appliances had been in pretty extensive use in different warehouses in Paris, Rouen, Havre, Tergnier, and Roubaix, and at wharves for the purpose of unloading and stacking goods. There must be many cases in which the portability of power in this manner would be of great service in warehouses and factories. Instead of fixtures like steam-piping and counter-shafting, a couple of well insulated leading wires are all that is necessary to follow the machine about to any spots where power is required.

In overhead travelling cranes driven electrically the most convenient practice is to fix the motor on the crane girders at one end, and connect it by speed-reducing helical or friction wheels to a shaft, which may be termed the power shaft, lying parallel to the direction of the track. This shaft carries nests of bevel or friction gear, which, controlled by suitable levers, transmit the motion to one or all of the separate motion shafts in either direction. The electric current must be in connection with the motor all along the track, and for this purpose a bare conductor laid along the track on one side is necessary. The Paris cranes were each worked by two bare copper conductors, No. 5 B.W.G., one for the return circuit, and these were laid on porcelain reel insulators, but not fixed thereto. On the cranes gun

Digitized by Google

metal hooks bolted to wood blocks were fixed at one end, and the bare conductors rested in them. The hooks were adjusted at such a height that the conductors were lifted off the reels as the cranes passed, and this slight upward pressure produced a good rubbing contact. Stranded cables were tried first, but the continual rubbing caused the strands to part. Mr. E. W. Anderson, M.I.C.E., in his electrically driven 20-ton crane at the Erith Iron Works Foundry, put up lengths of 2in. angle iron for his conductor. These lengths were connected electrically by copper staples, and the whole mounted and insulated on wood blocks along the track. Continuous rubbing contact was made with this conductor, which was ground up on one face, by means of brass blocks carried on the crane, and pressed against the conductor by a flat spring. In this crane the return circuit was made through the rails of the track, contact being effected by a wire brush rubbing on the rail, and connected to the body of the crane and one of the wheel axles. This arrangement was found by Mr. Anderson to be very reliable in action. In his crane the motor and dynamo were shunt-wound, resistances being used for regulation in the armature-circuit of the motor, but its field being always in circuit and excited. When the crane, which itself weighed 18 tons and covered a span of 39ft., was travelling along the track at the rate of nearly 84 feet per minute, with a load of over 19 tons on the hook, the motor absorbed close on 7 electric horse-power, the current supplied being 46 amperes. The dynamos and motors on both of the cranes at Paris were series-wound, and the starting and stopping of the motors effected through multiple switches, which gradually introduced or withdrew resistance. In these cranes the current absorbed was from 25 to 28 amperes, when travelling at 95ft. per minute along the track, and carrying a load of 8 tons, though, of course, at starting it frequently reached double that amount. The motors were capable of giving out 12 horse-power effective, but not more than one-third of this was taken off with the above load. The cranes were used during the Exhibition for the conveyance of passengers; and the above load, which represented about 120 persons, was an evenly distributed one. The weight of each crane was 30 tons, the spans being 59ft. The series-wound dynamo supplying current to the Mégy crane had an additional winding on the field taken as a shunt from the brushes in order to prevent the machine reversing when the speed of the motor suddenly increased.

With reference to the mechanical gear the last-mentioned crane was fitted with an excellent form of friction clutch, which also served the purpose of imposing automatically a safe limit to the load put on. Briefly, each bevel wheel in the nest gear on the power shaft was enlarged on one side, in form like a pulley of the same diameter, loose on the shaft. Inside this pulley, with a bearing surface equal in width to its inside face, was a steel spring faced with leather, and fast with the shaft. The manner of mounting this on the shaft and controlling its action on the pulley was as follows: A sleeve keyed to the shaft supported the fulcrums of two levers fixed at right angles to the shaft, the short arms of which were jointed to the free ends of the spring, and the long arms provided at their ends with rollers between which a wedge could be conveniently forced in or withdrawn. The wedge was carried by a collar which could be shifted along a feather on the shaft by a forked lever. When the wedge was introduced between the long arms of the levers the short arms approached each other and compressed the spring, leaving the pulley free; and when withdrawn the spring became expanded so as to grip the pulley with any predetermined amount of frictional adhesion, and run it fast with the shaft. One collar carried two wedges, one for each bevel wheel in the nest; and when in a central position between the two the wedges were inserted within each pulley, so that both ran loose, and either one was put in gear by moving the lever, so as to withdraw the wedge from that pulley. On the main hoisting gear, which was conveniently fitted with single and double purchase gear, one of these springs was fitted within a pulley, that is to say, the power used in hoisting a load was all transmitted through one of these internal springs. Slip would occur if the load exceeded the maximum allowable, and the crane thus refuse to raise a load exceeding a predetermined safe limit. The levers controlling the three directions of movement and the two changes of speed were all worked from a platform below the crane body on one side; but they could also be worked from the floor level by chains, as in hand-power cranes. This is more essential for erecting-shops, where often a very slow movement is required, such as in lowering a cylinder on to its studs, and these slight movements are best controlled by a man on the ground close to the work. For foundry work this is, of course, not so necessary.

Messrs. Mégy, Echevarria, and Bizan, who were the makers of the above crane, had installed up to last autumn a 25-ton electric crane for the engineering firm of Farcot and Co., also two 6-ton cranes for the printing machine works of Marinoni.

The gear on the other crane, that of Messrs. Bon and Lustremant, was entirely by friction pulleys, both for the nests and for fast and slow speed gear. The surfaces were faced with paper, leather having been tried and found wanting. Upon throwing into gear, the slip which occurred before actual grip took place was an advantage in preventing any sudden strains. In this crane worm gearing was interposed between the power shaft and the separate motions with good results. The hoisting chain was anchored at one end of the crane, whence it passed over the pulleys, and falling block on the carriage to the driving shaft at the other end. On this shaft it was wound round through link guides which only permitted it moving as the shaft revolved, and the slack was contained in a long tubular guide. The above firm had installed up to last autumn a 20-ton crane of 50ft. span on this principle, with Gramme motor at the Canon Foundry of Bourges, and one of 8 tons and 104ft. span for the Great Eastern Railway Company's shops at Romilly, used for unloading trucks and stacking.

Whatever comparison may be drawn between the rope, square shafting, and electrical methods of driving overhead cranes, there appears to be a decided advantage in the electrical method over that in which the crane carries its own steam engine and boiler. The dynamo generator can be put down in the most convenient part of the works, and the necessity for raising fuel and water to the crane, and lowering ashes done away with. Also the engine driving the dynamo being supplied with steam from the works' main boilers, avoids the expenditure of time otherwise taken in getting up steam on the crane. For driving by square shafting, or rope, the engine must be either in the same shop with the crane or not very far away; at any rate, the crane must be within reach of countershafting, while in the electrical method the source of power, the dynamo, with its steam engine, may be placed anywhere most convenient, and its power used for motors in other parts of the works. In cases also where the crane rails are affixed to wooden staging, or inflammable material is being dealt with, and corresponding risk is incurred by the use of self-contained steam cranes, there seems to be a special field for the application of electricity. Mr. Crompton's first electrical travelling jib crane was designed to take the place of self-contained steam driving, which, by the nature of the staging and surroundings where the crane was at work, occasioned considerable risk.

THE CENTRAL STATIONS OF THE METROPOLITAN ELECTRIC SUPPLY COMPANY.

BY DR. J. A. FLEMING, M.A.

(Continued from page 707.)

The arrangements in the dynamo room for effecting all the necessary interconnections and changes between dynamos, exciters and feeders, have been elaborated with great care, and the arrangements at Sardinia-street are the outcome and final result of an immense and expensive experience in other places. The process of evolution of machinery is always, or almost always, from the complex to the simple, the process of discarding or shedding off unnecessary organs, and reducing the parts to the fewest possible, is one in which advance shows itself.

On entering the dynamo-room of the Sardinia-street Station, we are struck at once by the immense and handsomely

Digitized by Google

finished switchboard. It occupies a great part of the length of one side of the dynamo-room, and is about 54 feet long, and 11 feet in height. It stands away from the wall by about a couple of feet, allowing sufficient room for workmen to pass behind it, and to make or renew all the multitudinous connections which are made by highly insulated cable behind this board. The front of the switchboard is divided into twenty panels, the base of each panel being of enamelled slate framed in polished wood. From the dynamo-room proceed twenty feeders, or primary mains, and as there are ten alternators and three exciters, the combinations which have to be effected are as follows:—(1) Any group of alternators must be capable of being excited by any exciter. (2) Any one or group of feeders must be capable of being worked off any alternator or group of alternators. (3) Any given alternator must be capable of being made the "stand-by," or reserve machine, to any working dynamo or group of dynamos; and, lastly, any group of alternators must be capable of being worked in parallel together on any primary main or mains. (4) All these changes have to be made instantly, certainly, and without confusion, by one person.

We shall best explain the principle on which this is done by giving a diagram and description of *a small portion* of one half of a single panel of the switchboard. We shall limit our attention to a combination, first, of a single feeder and three alternators, and show how these changes are effected. Referring to Fig. 6, let 1, 2, 3, 1^1, 2^1, 3^1, be the leads from three alternators, No. 1, No. 2, and No. 3. These leads are terminated on brass plug blocks, a_1, b_1, c_1, a^1, b^1, c^1, fixed on the panel. On either side of this group of blocks are four common

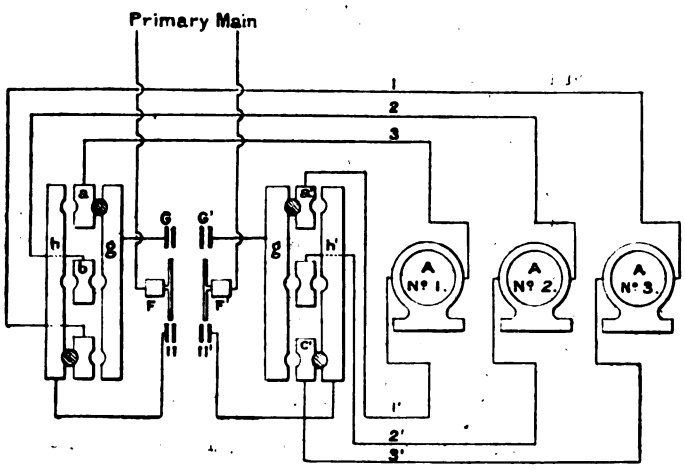

FIG. 6.

bars, h_1, g_1, h^1, g^1, and plugs can be inserted in the holes to connect a_1, b_1, c_1, &c., with g_1, h_1, &c. The primary main F_1 F^1 terminates on the centre of a duplex double-pole switch between the bars. When this switch is thrown up it connects F_1 F^1 with bars g and g^1. When it is thrown down it connects F and F^1 with bars h and h^1. The handle of this switch has three positions in which it will stand firm: 1st, one in which F and F^1 are both disconnected from G and G^1, and also from H and H^1. 2nd, an upper position, or one in which F and F^1 are connected to G and G^1; and 3rd, a lower position, or one in which F and F^1 are connected to H and H^1.

This being understood let us suppose that plugs are inserted in the four holes marked with a shaded circle, and let the centre switch be in the upper position. Then alternator 1 is connected with the primary main F, F^1, and may be considered to be working on it. Let alternator No. 3 be kept turning slowly round, and let us suppose something goes wrong with No. 1 machine. The engineer simply calls down for the alternator No. 3 to be run up to full speed, which can be done in a few seconds. He then snaps over the centre switch from top to bottom position, and the instant result is that the main line is changed over from machine No. 1 to machine No. 3. Let us also imagine that it is required to run alternators No. 1 and No. 2 in parallel, and to have No. 3 as a reserve. This can be effected by putting plugs in the holes joining blocks b and b^1 to bars g and g^1, in addition to those already in.

This being clear, all that remains to be said is that at Sardinia-street each semi-panel of the switch board contains two such rows of ten blocks, like a, b, c, &c., and four bars like g, h, g^1, h^1, and a centre switch, as shown in Fig. 7.

Each complete panel is the double of this, and supplies a pair of primary mains, making the two to each dynamo, and the ten double panels correspond to the twenty mains. On looking at the board when the dynamos are working we see a set of plugs plugged-in to join the dynamo blocks a, b, c, &c., to the omnibus-bars g g^1, &c., and we see a plug in the corresponding holes of all the panels, which is the plug belonging to a spare machine. We can thus have the feeders grouped in any way

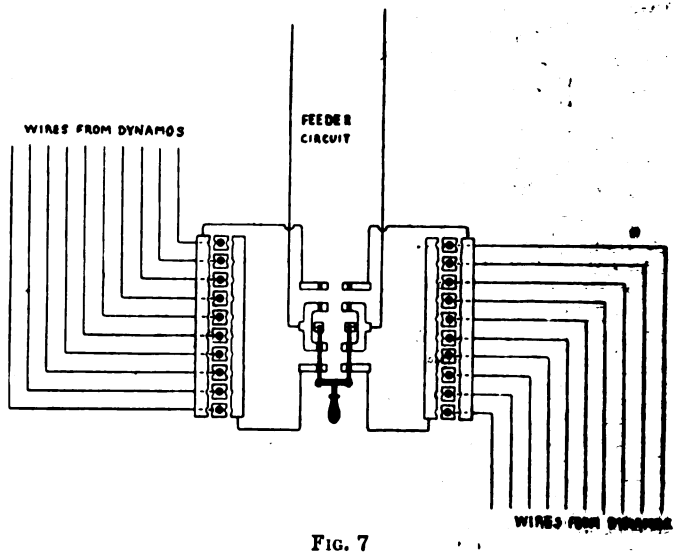

FIG. 7

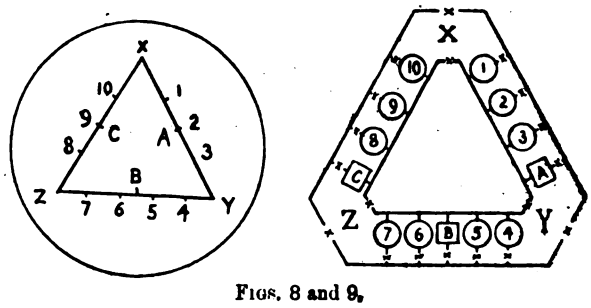
on the working dynamos, and we can have a spare machine which, as it were, waits on all of them, and is ready instantly to take the place of any working machine that gives out. Thus we may suppose five feeders—1, 2, 3, 4, and 5—are working off dynamos No. 3, 7, and 9 grouped as follows:—No. 3 works feeders 1 and 2, No. 7 works feeders 3 and 4, and No. 9 works feeder 5. Also let dynamo No. 5 be a reserve machine turning slowly round. If No. 3 dynamo were to be found to be getting hot bearings, No. 5 reserve would be started up, and switches of panels No. 1 and No. 2 thrown over. The reserve machine could then step into the shoes of No. 3. Or, if No. 3 machine were to be found to be overloaded,



FIGS. 8 and 9.

one of its feeders, say No. 1, could be thrown over on to a reserve machine. It will thus be seen that the possible combinations are endless, and that the engineer need never be in a "tight place" by reason of not being able to re-adjust the load, or to relieve a particular machine unequal to its work.

We have next to describe how the exciters are coupled in. This is rendered plain by a diagram of connections engraved on a brass plate and fixed to the switchboard. This diagram is given in Fig. 8. The connections are shown in Fig. 9.

Let three pair of mains be arranged between three double pole switches, X, Y, and Z. When all these switches are closed it forms a closed circuit. Between these mains are joined in parallel all the armatures of the three exciters A, B, and C, and

Digitized by Google

all the fields of the ten alternators, each, however, being capable of being cut out by its own private double pole switch. It will then be seen that by suitably closing the private switches (marked by a small cross in the diagram), and by manipulating the switches X, Y, or Z, that the exciters can be used to excite any group or groups of the alternators in a very varied manner. The five centre panels of the switchboard are devoted to these exciter switches, and the centre panel of all has on it the switches X, Y, and Z. If, therefore, anything goes wrong in the dynamo-room, the engineer in charge flies to the centre panel of the board. From this spot he can see the whole dynamo-room, and every dynamo has its number painted conspicuously upon it. Hence he can see at once what to do to take that machine out of circuit.

Over each panel of the board and in connection with each primary main is an amperemeter, a voltmeter and the voltmeter compensator. This last device which enables the voltmeter in the station to read the volts at the far end of the primary main has already been fully described (*see The Electrician*, Oct. 17, 1890, p. 678).

There is also a standard station voltmeter, by which all the others are adjusted. Underneath the panel there are the variable resistances to be inserted in the field circuit of each alternator as required, and the resistances to be inserted in the field circuit of the exciters for regulating the exciting current. By these resistances the exciting field of any alternator can be controlled independently of all the rest, and the volts at the far end of its associated mains kept to the standard voltage. Also by the resistances in the fields of the exciters the electromotive force of any simultaneously excited group of alternators can be raised or lowered as required. It will thus be seen that a vast amount of thought and skill has been brought to bear on the design of these arrangements with the object of reducing to a minimum the labour required.

The distributing system of mains in connection with Sardinia-street is an underground system. Highly insulated leads, covered with vulcanized indiarubber, are drawn through iron pipes laid under the footways or roadways. The joints in the cables are vulcanised *in situ* by means of a small portable heater. So far this system has given every satisfaction. It is practically very similar to that which has proved itself successful in connection with the House-to-House Station at West Brompton. Westinghouse transformers are used, placed in suitable positions inside or outside of the buildings to be lit, and these transformers, used in about five sizes, transform down from 1,000 to 50 volts. When these stations are all complete, it is in contemplation to connect them together by trunk mains, so that one station can help the other.

It only remains to add that the current is supplied by meter, and that the Shallenberger meter is extensively employed.

(To be continued.)

ON KINETIC STABILITY WITH MAGNETIC FORCES.*

BY PROF. G. F. FITZGERALD.

If a perfect conductor move near a magnet there are currents induced in it which tend to stop the motion. If the conductor be perfect, the kinetic energy of motion will ultimately, if small enough, be all changed into electro-kinetic energy, and the conductor will begin to move in the opposite direction, and when in its former position its electro-kinetic energy will have been reconverted into kinetic energy. For instance, if a perfectly conducting shell were placed near three magnetic poles it would be in a state of kinetic equilibrium if the energy given to it by a small disturbance were not great enough to drive it to infinity, or into contact with the magnet. It is to be remarked that I have assumed the perfect conductor to have been brought within a finite distance of the magnet pole without having had currents induced in it, *i.e.*, I have assumed that the body can be brought up as an imperfect conductor, and then changed into a perfect conductor *in situ*. As the effect of a magnetic pole is to induce in a perfect conducting plane sheet currents which can be magnetically represented by a pole at the reflection of the first pole in the sheet, it follows that with a perfect conducting sheet there would be no action such as, in Arago's experiment, prevents motion of the sheet parallel to itself. There would, no doubt, be a gradual radiation of the energy due to the varying magnetic field. This would have a damping effect on the vibrations much the same as would result from resistance in the conductors.

The system is interesting as an illustration on a large scale of how meteoric swarms have their energy gradually frittered away into electro-magnetic radiations.

* Abstract of a Paper read before the British Association in Section A, Leeds, September, 1890.

REVIEWS.

Sound, Light, and Heat. A Class Book for the Elementary Stage of the Science and Art Department. By J. Spencer, B.Sc. London: (Percival and Co., 1890).

The Science and Art Department are undoubtedly to blame for tempting their teachers to write such books as these. They arbitrarily select certain physical phenomena and brand them "elementary." For a student who is to study acoustics without learning anything of timbre, a representation of a sine curve by a few semicircles is thought good enough. In so small a book there appears to be no room for the common-sense explanation of refraction by the principle of retardation; but being written by a schoolmaster, the law of sines must come in. The book contains several such careless statements as "By heat we mean the sensation of warmth." This class of literature might be checked by a censorship for all books which refer to the Department, in either title page or preface.

Magnetism and Electricity. A Class Book for the Elementary Stage of the Science and Art Department. By J. Spencer, B.Sc. (London: Percival and Co., 1890.)

This book is but little better than the above. The arrangement of the matter in "experiments" is not justified by any increased clearness or convenience. A great deal of space is filled with questions. The subject has been dealt with by others in a much more satisfactory manner, and we therefore cannot see any reason why it should have been written.

MEETINGS OF SCIENTIFIC SOCIETIES, &c.

MONDAY, November 3rd.

ROYAL INSTITUTION.

3 p.m. General Monthly Meeting.

SOCIETY OF ENGINEERS.

7.30 p.m. Ordinary Meeting. Paper to be read on "The Treatment and Utilization of Exhaust Steam." By PERCY GRIFFITH.

TUESDAY, November 4th.

CITY AND SOUTH LONDON RAILWAY.

12.30 p.m. Opening of the Line by H.R.H. the Prince of Wales.

ROYAL VICTORIA HALL.

8.30 p.m. Lecture: "Old Buildings and the Story they tell." By ARNOLD MITCHELL.

THURSDAY, November 6th.

CHEMICAL SOCIETY.

8 p.m. Meeting.

OLD STUDENTS' ASSOCIATION.

CITY AND GUILDS OF LONDON INSTITUTE.

8 p.m. Ordinary General Meeting at Finsbury Technical College. Presidential Address on "Industrialism." By W. B. ESSON.

FRIDAY, November 7th.

INSTITUTION OF ELECTRICAL ENGINEERS.

7.30 p.m. Students' Meeting.

ELECTRO HARMONIC SOCIETY.

8 p.m. Smoking Concert at St. James's Hall.

***** Particulars of meetings to be held or Papers to be read before Scientific Societies during the ensuing week should reach us not later than Thursday, 6 p.m.**

The Electrician.

Published every Friday, Price Fourpence; Post Free, Fourpence Halfpenny.
Editorial, Publishing, and Printing Offices:
SALISBURY COURT, FLEET ST., LONDON, E.C.
Telephone No. 2714. Telegrams: "ELECTRICIAN NEWSPAPER, LONDON."

All Letters relating to Subscriptions, Advertisements and other business matters should be addressed to the Publisher, "THE ELECTRICIAN," *Salisbury-court, Fleet-street, London, E.C. Cheques and Money Orders should be made payable to* "THE ELECTRICIAN" *Printing and Publishing Company, Limited, and be crossed* "*Coutts and Co.*" *All other letters to be addressed to the Editor.*

All letters intended for insertion in "THE ELECTRICIAN," *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

"THE ELECTRICIAN" *is published every Friday morning, in time for the morning mails. Subscribers should receive their copies by the first post on Friday morning.*

"THE ELECTRICIAN" *is on sale at the railway bookstalls throughout the Kingdom on Friday morning, and can be obtained of all Booksellers and Newsvendors; or direct from the Publishing Offices as above.*

New Volumes of "THE ELECTRICIAN" *commence in May and November.*

SUBSCRIPTION RATES.

The rates for Subscriptions to "THE ELECTRICIAN" are as follows:—

	3 months.	6 months.	12 months.
	s. d.	s. d.	s. d.
For the United Kingdom	5 0	10 0	19 6
For Foreign Parts and Colonies:—			
Within Postal Union	6 6	12 6	24 0
Aden, Borneo, Ceylon, China, India, Japan, Java, Labuan, Mozambique, New Caledonia, Persia, Philippine Islands, Siam, Transvaal, and Zanzibar	7 6	14 6	28 0

TO ADVERTISERS.

"THE ELECTRICIAN" *offers exceptional advantages to Advertisers.* **It has by far the largest circulation of any English Electrical paper, and circulates all over the World.**

Particulars relating to Advertisements will be promptly forwarded on application to the Offices as above.

TRADE ADVERTISEMENTS *intended for the current issue must reach the Offices not later than First Post on Thursday morning. Renewals of expiring advertisement orders and alterations to standing advertisements should be in the Publisher's hands by Wednesday at latest. No alteration can be made in Wrapper advertisements after Wednesday evening.*

SMALL PREPAID ADVERTISEMENTS *(for Rates see page xvii.) are accepted up to 4 p.m. on Thursday.*

TECHNICAL PRINTING.

"THE ELECTRICIAN" PRINTING AND PUBLISHING COMPANY (LIMITED) *inform Electricians, Electric Light Engineers, &c., that they make a specialty of Technical Printing, and have a large Staff thoroughly acquainted with Electro-Technology. They can, therefore, promise Accuracy and Despatch in the Printing of Electro-Technical Literature, &c.*

"THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. (Royal 8vo.)

Early in each year is issued "THE ELECTRICIAN" ELECTRICAL TRADES' DIRECTORY AND HANDBOOK. *The* DIRECTORY *was established in 1883, and the 1890 Edition consisted of about 850 pages of printed matter. The names and addresses of all persons engaged in the Electrical Industries at home and abroad may be relied upon as accurate. Useful Tables and Electrical Formulæ, and information specially compiled for this work are given, together with popularly-written Biographical Notices of the leading Electricians, Electrical Engineers, &c., accompanied in many cases by Portraits.*

Orders for the 1890 issue should be forwarded AT ONCE *to the Publishing Offices, Salisbury-court, Fleet-street, London, E.C.*

The 1891 Edition is now preparing, and New Names, &c., can now be received.

ELECTRICAL BOOKS AND PUBLICATIONS.

All Books, Newspapers, and other publications, dealing with Electrical and kindred subjects, can be ordered direct of* "THE ELECTRICIAN" *Printing and Publishing Company, who are proprietors of the well-known* "ELECTRICIAN" *Series of Standard Electrical Works, and are agents for all the leading publishing houses at home and abroad.

CONTENTS OF THE CURRENT NUMBER.

NOTES 727
Magnetism in Iron and other Metals. XXXIV. By Prof. J. A. Ewing, F.R.S. Illus. Con. 732
On the Electro-Dynamics of Stationary Bodies. By H. Hertz. Concluded 734
The Application of Electricity to Cranes. By H. D. Wilkinson, M.I.E.E. 736
The Central Stations of the Metropolitan Electric Supply Company. By Dr. J. A. Fleming. Illustrated 737
On Kinetic Stability with Magnetic Force. By Prof. G. F. Fitzgerald 739
Meetings of Scientific Societies. 739
THE LOCAL AUTHORITIES AND ELECTRIC TRAMWAYS 740
Stations of the Westminster Electric Supply Corporation. 741
The Working of an Electrolytic Copper Refinery. By Dr. G. Gore, F.R.S. 743
The Co-efficient of Mutual Induction of Two Parallel Wires. By Dr. Cary T. Hutchinson. Illustrated ... 746
On the Determination of the Work done upon the Cores of Iron in Electrical Apparatus subject to Alternating Currents. By T. H. Blakesley, M.A., M. Inst. C.E. 746
The Electro-Magnet. By Prof. Silvanus P. Thompson, D.Sc., B.A., M.I.E.E. Illustrated. Continued 747
On the Influence of Electric Pressure on Insulation, Especially with Reference to Cables. By C. Heim. Illus. 751
The Discharge of Accumulators left on Open Circuit. By Gaston Roux 754
German Notes 754
Vienna Notes 754
CORRESPONDENCE—
The Telephone Suggested in 1854—Latimer Clark 755
Trade Notes and Notices 755
PATENT RECORD 756

City Notes, &c. 757
Companies' Share List 758

SPECIAL NOTICE.

The present Number of "THE ELECTRICIAN" completes Volume XXV. With next week's Number will be issued (gratis) the Index to the Volume.

THE LOCAL AUTHORITIES AND ELECTRIC TRAMWAYS.

We have had reason to observe, on more than one occasion recently, that among the difficulties which electric traction has to surmount in this country, opposition on the part of Local Authorities cannot be counted as the least. Indeed, it has been roundly asserted by promoters, and even hinted at by the Press, that the "Vestries," under which designation is included local Corporations of almost every kind, have blocked the way from interested motives, or because their interests have not been squared by a judicious employment of fees. We ourselves attach no importance to these insinuations, which are a trifle too self-righteous in the mouths of those who make them; our belief being that where there are people who can be corrupted, there are always plenty of others to corrupt them—if it is worth while. And the fact that the Local Authorities have maintained their original attitude of hostility is pretty strong proof that either they are incorruptible, or that the friends of electric traction have not the courage to back it with their money. Probably the real cause of the deadlock is something not quite so simple, but a good deal less discreditable. No one can regret more than we do the little headway which this branch of electrical industry has made since its practicability was fully demonstrated. But nothing is to be gained by imputing bad motives, especially those of a personal kind; whilst, on the other hand, if the real reasons are discovered and fairly considered, it may be possible to arrive at a friendly understanding or a working compromise satisfactory to both parties.

It must be confessed, however, that the action of Local Authorities, who have so often, though not, as has been alleged, invariably opposed the introduction of electric power on tram lines, is somewhat obscure to the outsider. Not improbably the real explanation is better known to the electrical promoters than

Digitized by Google

they care to own; and, if that is the case, we should recommend them to take the public into their confidence, and trust to the soundness of their case, if it is as sound as they represent. Anyway, it is no use railing at the Vestries, who, say what we will, have the power vested in their hands for the good of the ratepayers; and who, therefore, if they cannot be conciliated, are not likely to be won by exasperation, or by imputations of bad faith. Certainly the case of the Hammersmith Vestry, mentioned in our columns a couple of months ago in connection with Mr. Lineff's project, was somewhat incomprehensible, the adjoining Vestries having supported, and the Board of Trade and London County Council having sanctioned it. Possibly some local reasons of a more or less legitimate sort may have determined the Hammersmith Vestry to remain obdurate. But it strikes us as rather odd that having secured such powerful support outside Hammersmith, the promoters had not the good fortune, or shall we say the good management, to overcome the one remaining obstacle. Moreover, if the area in question was the one chiefly concerned, it need not surprise us that the cheap approval of outside areas, and the imprimatur of the Board of Trade counted for very little in the eyes of the Hammersmith Vestrymen. They may be supposed to know their own local affairs best; and local circumstances may often very properly have great weight as against general principles. The question is, are these local considerations of real import? When they are so, it will be wise to let them alone, rather than try to force an experiment on unwilling clients. If, however, the objection is groundless, it will be the business of the electrical engineers to prove it to be so by argument and demonstration, and not by abusing the particular local Vestry for having acted independently on its own convictions.

To what extent the foregoing remarks apply to the case of the West Ham Local Authorities in their dealings with the North Metropolitan Tramway Company's scheme for introducing electric traction on their lines, we are not prepared to say; but it must be owned that an explanation from West Ham is very much needed, its conduct as described by the other side being altogether indefensible. It will be remembered that the Tramway Company obtained consent from the authorities to try the Electric Traction Company's system on the Barking section for one year, subject to a 24 hours' notice to quit. The Companies were satisfied with the experiment, and authority was asked and obtained of Parliament to work the whole of the North Metropolitan tram-lines under a licence for seven years. As the power of summary notice was never exercised by the West Ham Authorities, one would suppose that they too were satisfied. But now that Parliamentary sanction is obtained, they positively refuse to extend the permission except on the same conditions and for the same short period as before. The sanction of the London County Council has not yet been obtained; but when it comes, as probably it will, its effect at West Ham may be conjectured from its failure in West London. Of course the Tramway Company cannot proceed on such conditions as these; and there is consequently a very discouraging outlook for what at one time looked like a highly promising field of electric traction operations. The example of West Ham may possibly prove infectious, and in that case the Parliamentary Licence will be wholly confiscated. Were Sir WILFRID LAWSON chairman of the West Ham Vestry, and electric traction a species of intoxicant, its treatment could hardly have been worse.

It is hard to believe that the Vestry can be dissatisfied with the result of an extended trial which so greatly encouraged the Tramway Company; and as a renewal of the earlier licence for one year is offered, we may fairly assume that there are no local objections peculiar to West Ham, and fatal to the system. We are driven, therefore, to the surmise that the true explanation will be found in the proviso of the Parliamentary Licence making it conditional on the consent of the Local Authorities. As in the case of Electric Lighting, this saving clause has inflated the self-importance of the Local Authorities, who, being thus able to give or withhold at their pleasure, esteem it their interest to keep a tight hold of a new industry lest it should expand beyond their reach if left to itself. In short, the Local Authorities are everywhere on the look-out for undertakings which can be brought into the parochial sphere; and as the Tramways Companies' concessions are gradually falling in, they are considered fair game for the modern communistic Vestry. There is no gainsaying the tendency; and we can only recommend our friends to accept the fact and act accordingly. It means, first of all, that the field for financial operations in connection with electrical industries will be to this extent restricted; but it does not necessarily follow that the industries will be crippled. On the contrary, if they are good for anything they have only to prove it, and there will be plenty of work for them to do. As regards electric tramways in particular there is no serious opposition to them as such; they have succeeded elsewhere; and the steps now being taken by the Glasgow Corporation serve to show that where the system can be taken over by Local Authorities it will be included in their programme of public works, and will certainly be tested on its merits. The fact above alluded to that the tramway concessions are expiring may be bad news for promoters; but that would be the case even if there were no electric traction to compete with horse power. It is not of bad omen for electrical power, for an opening will be created to try what it is capable of doing under the special conditions imposed upon it in this country. Those conditions are far more exacting here than in the United States; but if they can be complied with, there is no reason to fear that either any prejudice on the part of the public, or interested hostility on the part of the Local Authorities, will long hinder the natural development of this new and important addition to our powers of locomotion.

THE STATIONS OF THE WESTMINSTER ELECTRIC SUPPLY CORPORATION.

The lighting of Westminster, where engineers "most do congregate," ought to be well done; but until recently the attempts which have been made in the neighbourhood of Victoria-street, the street of electrical engineers, have not been very promising. Two concerns, not counting the now extinct Maxim Company, and the private plant at No. 100, for some time supplied current for a small number of lamps. One of these, the City of Westminster Electrical Syndicate, supplied both direct and alternating current by overhead wires. The Westminster Electric Light Corporation having at that time a small plant in Dacre-street, put in an appearance at the Board of Trade inquiry, and eventually absorbed the rights which the Syndicate had acquired, the most important of these being the lighting of the Houses of Parliament, and the site for a station in Millbank-street, with a river frontage. Fortunately both for the shareholders of the Company and for the future consumers in the large district which has been allotted to it, Prof. A. B. W. Kennedy, F.R.S., accepted the post of engineer, in January last, and under his direction the work has been thoroughly organised, and the design and erection of the stations, together with the planning and laying of the mains, have been making rapid progress. The district, as most of our readers who are interested in the lighting of London are aware, contains the whole of those parts of Westminster and Pimlico between the District Railway and the river, and at its western part extends northwards so as to cover all Belgravia and Mayfair as far as Oxford-street

Digitized by Google

The stations will be three in number. The first, taking them in the order of commencement, is the river-side station at Millbank-street. The general arrangement of the station, which had been commenced before Prof. Kennedy assumed his present position, and which has since been modified in certain particulars, is shown in Fig. 1. The boiler-house contains three Babcock-Wilcox boilers, with room for six more; two alongside of the three which are now at work, and four facing them, with an 11-foot stoking floor between. The working pressure is 160lb. per square inch. An upper floor will form a coal store, the coal of course being brought by water. For the present, the coal will be stored on vacant parts of the boiler-house floor. A Green's economiser is arranged in the main flue. Two main steam pipes run across the top of the boilers, and valves are provided by which any boiler may be connected to either pipe.

Passing to the engine-room, the pair of steam pipes deliver into a ring main through a set of valves with a connecting branch which allows for every possible combination. The ring main is composed of sheet steel welded pipes with copper bends. It has been found to expand one and a-half inches under steam test, and will be suspended freely by links from the level of the traveller girders. A condenser is being set in the engine-room, beneath the floor of which the exhaust steam pipes are laid in chases in the concrete. At each end of the room is a switchboard made by Crompton and Co.; one devoted solely to the House of Commons circuit, and the other for the general purposes of the station. The machinery at present in the engine-room consists of two 45-unit Goolden dynamos, with Willans central valve engines, to which will be added, in a few weeks, the two similar machines which are now supplying the Houses of Parliament; and also two Edison-Hopkinson dynamos, of 112 units, with Willans 200 horse-power engines.

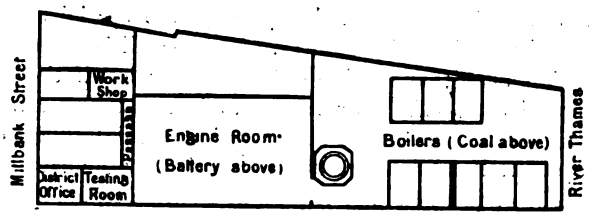

FIG. 1.—St. John's Wharf Station, Millbank Street. Scale, 64 feet = 1 inch.

Above the engine-room is a battery-room. This is practically ready for the reception of the batteries, one set already having been delivered. The batteries will be of the Crompton-Howell type, and each set will provide for a reserve of 500 ampere hours. In this, as in the other sections of the Westminster Company, the batteries are intentionally placed in this position rather than on the ground or in a basement, in order that they may be kept warm, since it has been clearly ascertained that they work better at a fairly warm temperature. At the end of the battery-room a portion is shut off by a partition for the reception of the regulating switches, thus saving the use of an unnecessary quantity of cable. This switch-room will, of course, have independent ventilation. Access to the upper floor is had by means of a stairway winding round a steam-exhaust flue, the architectural arrangement forming a somewhat remarkable feature at the end of the road which runs down the side of the engine-room. The mains run into the basement of the house of the resident engineer through iron tubes, and pass into a space below the floor of the testing-room at the back of this house. This room will contain the terminals of mains and feeders, and will at the same time be used as a testing-room for the circuits and for meters.

The engine-room at Dacre-street has been considerably improved of late, and the two Crompton dynamos and Willans engines are now snugly arranged beneath a gallery containing the switchboard; the whole having the air of an engine-room on board ship. A set of Crompton-Howell accumulators, of a capacity of 500 ampere hours, provides for the lighting of Victoria Mansions, the neighbouring residential flats and hotel, together with other circuits, which extend as far as the west end of Victoria-street, and Messrs. Peto's works in Pimlico. The ordinary full load is now about 600 amperes at 102 volts. This little station will disappear as soon as the current can be supplied from the other stations.

The second station of the Company is situated in Eccleston Place, and is only in an early stage of building at present. The arrangement is shown in Fig. 2. The engine-room and boiler-house are side by side. The batteries will be over the boilers, while a workshop will be arranged over the engine-room. The chimney is situated so as to allow a minimum length of flues. Multitubular boilers by Davey Paxman and Co. will be used, and Crompton dynamos have been ordered. These will be driven by Paxman and by Willans' engines, working at 150lb.

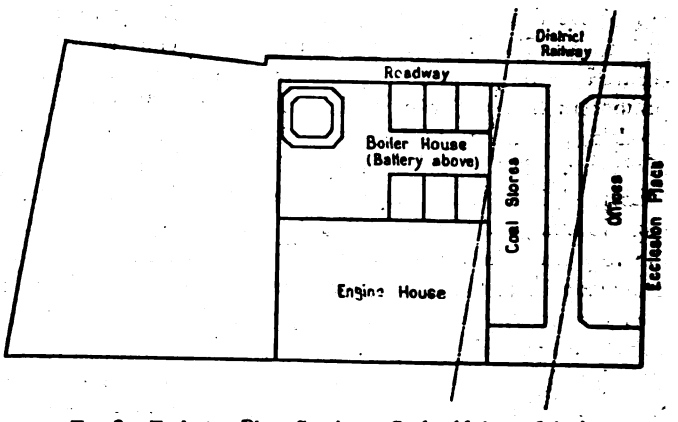

FIG. 2.—Eccleston Place Station. Scale, 64 feet = 1 inch.

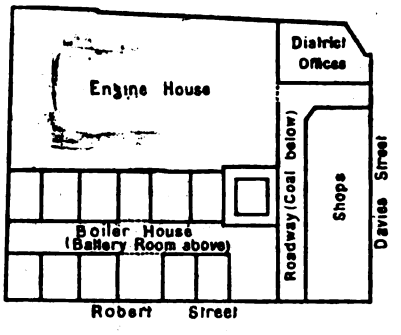
per square inch. The machinery and batteries, which will be put down at first, will provide for about 900 indicated horse-power. The batteries (Crompton-Howell type) will each have a capacity of 500 ampere hours. In order to avoid the unloading of coal in the streets, a road is being constructed, as shown on the plan, and a coal store will run alongside. Later on it is proposed to build offices with a street frontage. On this station will depend for its supply the residential quarter of Belgravia and the adjoining streets. The demand in the best parts will, undoubtedly, be heavy at times, but only during the season, a large number of the better houses being shut up for many months in the year. The building operations are proceeding rapidly, and it is expected that current will be supplied from the station early next year.



Davies Street Station. Scale, 64 feet = 1 inch.

The third station will supply Mayfair and the northern part of the district. The arrangement is shown in Fig. 3. A roadway running behind is provided for coaling, a portion of which is let for shops in Davies-street. The coal storage will be below the road, as in Sardinia-street. The boilers are of the multitubular dry back type, working at 160lb. per square inch. The boiler-house is bounded by Robert-street, the engine-room being at the back. The machine ordered for this station provides for, practically, the same output as at Eccleston-place, and is of the same general type. Dynamos are being made for it by the Electric Construction Company, and by Messrs. Siemens. It is expected that current will be supplied from it early next year.

Digitized by Google

The mains are already laid in about ten miles of streets, and the work is being actively pushed on at several points. The system adopted in Westminster, where Messrs. Crompton and Co. are contractors, is that used by Mr. Crompton in Kensington. In other parts of the district, Messrs. Mowlem are laying mains on a system devised by Prof. Kennedy, in which the copper strip is simply laid on glass or stoneware insulators, and not permanently strained up. When there is not room for concrete culverts and bare strip, Henley's and Silvertown cables are being laid in Callender-Webber casings, and under similar circumstances Siemens' cable is being used for feeders.

The progress of the work under Prof. Kennedy's able *régime* has been very remarkable, and there seems to be every prospect that an extensive and thoroughly reliable supply will be provided in a few months. At present, of course, the three-wire system is not being used, but feeders are extensively and systematically employed, though some of the feeding points are not in their final position. There will be a complete double network throughout the district, and communication will be made by Piccadilly between the two portions into which it is divided by the Parks.

As the current registered is already greater than can be supplied by the small plant at Dacre-street, one of the dynamos at Millbank-street is already working into the same circuit. The Dacre-street machines supply current in parallel with a battery; the Millbank-street machine is connected direct into the system at a feeding point without any battery, the cells at Dacre-street serving perfectly as an "electrical flywheel" to the whole network. Of course the working is guided by the use of potential leads back from the feeding points. The arrangement works perfectly, with none of the pulsation or hunting which was predicted by some engineers from experience of dynamos running in parallel on to omnibus leads.

When the stations to which we have briefly alluded are in full working order we hope to give detailed accounts of them, and are confident that if they are finished as they have been begun, they will be well worthy of careful attention.

THE WORKING OF AN ELECTROLYTIC COPPER REFINERY.*

BY DR. G. GORE, F.R.S.

The entire economy of working depends essentially upon cheapness of motive-power and minimum investment of capital, and nearly every attempt to improve the process, in the direction of such economy, involves a choice between two evils. For instance, if we try to save horse-power by enlarging the electrodes and adding to the number and size of vats in series, we rapidly increase the loss of interest upon capital expended in stock of copper, solution, plant, working space, &c. If we increase the density of current with the intention of working more rapidly with the same stock of copper, solution, &c., we increase the loss of energy by causing polarisation, and run a risk of depositing impure copper. And if we attempt to diminish the resistance by placing the electrodes nearer together, or by quickly stirring the solution, we get dirt upon the cathodes, or short-circuiting occurs; and if we endeavour to decrease it by considerably heating the liquid, we rapidly increase the chemical corrosion of the deposited metal, and quickly alter the chemical composition of the liquid; or if we diminish resistance by large additions of acid, we promote chemical corrosion, polarisation, and separation of gases.

Difference of potential required is a large element in the economical deposition of copper. Whilst the same number of amperes of current passing through the ordinary solution deposits the same amount of copper in all cases, the necessary degree of difference of potential to overcome resistance, &c., varies in different cases; and the greater this difference the larger the cost: double the potential requires double the motive-power. It is desirable, therefore, to lower the difference of potential as much as possible by diminishing the resistance throughout the circuit, and by avoiding all polarisation and counter-electromotive force.

The degree of electromotive force required varies with every different kind of solution, and consequently of anode. It varies according as the anode is composed of pure copper, "black copper," or "copper matte," and whether the anode is clean, or covered with an adhesive badly-conducting coating; it is also much greater when gas is evolved at either electrode.

Influence of Impure Anodes upon the Liquid.—I will only speak of some of those substances which are more or less likely to be present in "black copper," "pimple copper," "Chili bars," "blister copper," containing from 89 to 98 per cent. of copper, and in cruder regulus of reduced pyrites of iron and copper. Those impurities include antimony, arsenic, bismuth, cadmium, carbon, cobalt, gold, iron, lead, manganese, platinum, silver, tin, zinc, suboxide of copper, sulphides of iron, copper, and silver in the particles of unreduced pyrites of those metals, alumina, lime, magnesia, silica, and alkalies in the enclosed portions of slag. Black copper has been found to contain "1·23 per cent. of arsenic, 1·0 of iron, ·54 of sulphur, ·4 silver, and ·011 of gold" (*Engineering*, 1885, p. 306).

In an acidulated solution of blue vitriol, the following of those substances, viz., cadmium, cobalt, iron, zinc, sulphide of iron, alumina, magnesia, and alkalies of the slag, dissolve readily; antimony, arsenic, bismuth, tin, and silica dissolve imperfectly, and partly fall to the bottom; carbon, gold, platinum, and sulphur from the pyrites are insoluble, and precipitate entirely; lead is converted into sulphate, which almost wholly precipitates; silver is changed into chloride, provided a soluble chloride is present, which is usually the case, and is entirely thrown down; suboxide of copper, and the sulphides of copper and of silver, also precipitate. The lime is all changed into sulphate, a small quantity only of which enters into solution, whilst the remainder subsides.

One effect of using an impure metal or an alloy as an anode is, that its different constituents are corroded unequally, both by the ordinary chemical action of the liquid and by the influence of the current. By both these actions the most electro-positive metals are attacked first, and the others in succession, in accordance with the thermal law which governs such actions; and those which are not corroded at all, together with those which form insoluble compounds, either remain upon the surface as a coating, or fall to the bottom as mud. In consequence of this irregularity of action, the anodes are often corroded deeply in places, even whilst containing much metallic copper in their coatings, become rotten, and pieces of them fall to the bottom, and this occurs the most with very impure metal, and especially with cupreous matte. When the anodes are made by fusion of copper pyrites, they often swell on the sides towards the cathode after a few days of electrolytic action. If also the liquid is not kept homogeneous, impure ones are rapidly corroded, and sometimes cut through at the surface of the solution and fall to the bottom.

If arsenic is present, it partly dissolves as arsenious or arsenic acid, and gradually unites with some of the constituents of the mud to form insoluble compounds; arsenious acid is sparingly, and arsenic acid freely soluble. It also partly forms arseniates upon the anode, which are non-conductors, and by adhering to that electrode offer resistance to the current.

Antimony partly dissolves, especially in acid solutions, and partly forms an insoluble basic salt, some of which adheres to the anode, oxidises and increases in weight, and some falls to the bottom; any oxy-salt of antimony appears as a white cloudiness when the liquid is sufficiently dilute.

Bismuth behaves much like tin and antimony; it partly forms an insoluble basic salt, which precipitates, and partly dissolves as an acid salt, which ultimately also becomes basic and falls.

Tin behaves much like antimony; it forms a mixture of proto-salt and basic salt, some of which adheres to the anode and some dissolves; the proto-salt is white when dry, and absorbs oxygen from the air rapidly to form persalt. The presence of dissolved tin in a neutral solution is said to greatly

* Extract from the new volume of *The Electrician* Series, by Dr. G. Gore, entitled "The Electrolytic Separation of Metals." (London: *The Electrician* Printing and Publishing Company.)

Digitized by Google

improve the quality of the separated copper, without the tin itself being deposited; this, however, probably only occurs under particular conditions, because in some experiments I made for the purpose, this effect did not take place. The presence of tin in the anode increases the electromotive force of the current, because tin is more electro-positive than copper in dilute sulphuric acid.

Lead, being also more electro-positive than copper, is attacked before it, and aids the electromotive force; but its sulphate, being very insoluble, falls nearly wholly to the bottom, and only a trace is dissolved. There is but little risk of lead being deposited with copper, not only because its sulphate is so very insoluble, but also because lead is electro-positive to that metal. Lead, by being electrolytically corroded in place of copper, and uniting with acid to form an insoluble salt, diminishes the amount of copper and of acid in solution.

If the anode contains metallic iron and manganese, those metals are dissolved before the copper, and being more electro-positive assist the current; they dissolve as proto-salts, and subsequently become oxidised to some extent, but not completely, to persalts by contact with the air. If, however, the current is very much stronger than that usually employed in refining copper, these proto-salts are also oxidised to persalts at the anode; and in any case their persalts are reduced to proto-salts at the cathode by the current and cause great waste of power. The only way to prevent waste of energy in deoxidising persalts at the cathode is to keep those salts out of the solution. Iron by dissolving in place of some of the copper at the anode, takes up some of the acid, forms green vitriol, and diminishes the solvent power of the water and the amount of copper in solution.

Any suboxide of copper in the anode, being a non-conductor, falls to the bottom, and is subsequently slowly oxidised and dissolved as cupric sulphate by the free acid. If the anode contains much cupreous sulphide, some of it is decomposed by the current, its metal dissolving whilst its sulphur separates and subsides. If its amount is small (as it usually is in "black copper"), being a very inferior conductor it is unaffected by the current, and falls to the bottom as fast as the metal around it is dissolved.

In an anode containing copper, copper oxides and sulphides, the current goes most by the path of least resistance, *i.e.*, very largely by the metal, very little by the sulphides, and much less by the oxides. If, therefore, the anode contains very little sulphide or oxide, the whole of the current travels through the copper, and the oxide and sulphide fall to the bottom; but if it contains much sulphide, some of the current passes through it. At the same time, independently of the action of the current, the liquid is always acting chemically upon each of these substances, whether they form part of the anode or of the sediment.

It is evident that when the anode contains a large variety of impurities the chemical actions going on at its surface must be numerous and exceedingly complex, and modify each other, and make it very difficult to accurately describe them. One effect of those numerous impurities is to cause an almost infinite number of local electric currents all over the anode, attended by corrosion and solution of all the more positive substances without the aid of the external current, thus gradually neutralising the free acid, and saturating the water with metallic salts.

Influence of the Impurities upon the Current.—Provided the anodes are wholly metallic, their lower degree of electric conductivity due to impurities has very little effect upon the total resistance of the circuit, because the resistance of the solution is so very much greater. Consequently, also, it has but little effect upon the kind of dynamo required.

Impurities in the anode, however, have in some cases a great effect upon the electromotive force and upon the strength of current, either by giving rise to polarisation and counter electromotive force, or by the formation or accumulation of badly-conducting substances upon the anode. The greater the number of impurities also the greater the risk of waste of energy.

It is a fact that the electromotive force, and consequently also the strength of current, is increased when the anodes contain as impurities metals such as zinc, cadmium, manganese, or iron, which are more electro-positive than copper in the particular liquid, because they constitute with the copper cathode a voltaic couple sending a current in the same direction as the working one. But this assistance to the current, except with iron pyrites, is usually so very small that it is hardly observable, and the advantage of it is more than counterbalanced by disadvantages. The presence of iron in the anode aids the current to only a small extent, but that of zinc helps it more.

Usually when fresh anodes are put in, the resistance of the vat gradually rises to a maximum, but when the film of impurities is removed from them the resistance falls at once slightly; it also usually increases with the thickness of the coating, but only slowly because the layer is porous and saturated with the solution. The coating acts chiefly by preventing ready access of unexhausted liquid, and thus promotes polarisation.

When the solution contains persalts of iron or manganese those salts are reduced to proto salts at the cathode, and a portion of the current is continually wasted in reducing them, instead of being wholly employed in separating copper, and the copper costs more to refine than when no iron or manganese is present. As long as there is sufficient persalt of iron in the liquid, no hydrogen is evolved at the cathode. With a copper-depositing solution containing much salt of iron, the difference of potential of plates of pure copper of a single vat has been found by experiment to be ·22 volt, with an anode of black copper ·25 volt, and with one of copper pyrites ·5 volt, and when the solution was deficient in free acid, it was ·35 volt with black copper, and ·75 volt with copper pyrites (Kiliani, *Engineering*, Vol. XL., 1885, p. 306).

Effect of Impurities of the Liquid upon Purity of the Deposit. The electrolyte is always less impure than the anode, because various of the impurities of the latter are either loosened by corrosion of the surrounding metal, and separate and fall to the bottom unchanged; or they are separated from their compounds by chemical or electro-chemical decomposition and subside; or they are converted by chemical action into insoluble compounds, which precipitate.

The more impure the anode, the less pure usually is the electrolyte. In addition to the proper constituents of the liquid, viz., blue vitriol, sulphuric acid, and water, there may be present in a dissolved state the sulphates of iron, zinc, manganese, cadmium, cobalt, aluminium, magnesium, calcium, potassium, and sodium, basic sulphates of antimony, tellurium, bismuth, and tin, and arsenious or arsenic acid.

By far the largest in amount of these dissolved impurities is the sulphate of iron; but the most objectionable ones are the compounds of arsenic, antimony, and bismuth, because they are the most likely to yield their metals at the cathode, and thus affect the purity and quality of the deposited copper.

During the process of deposition the electrolyte continually becomes more impregnated with impurities, especially with iron, and, in much less degrees, also with zinc, manganese, cobalt, nickel, tin, arsenic, antimony, bismuth, aluminium, calcium (within small limits), magnesium, potassium, and sodium, and gradually poorer in free acid, and, sooner or later, requires to be purified.

Influence of Impurities of the Liquid upon the Current.—The greater the number of impurities in the electrolyte, the greater the risk of waste of electric energy. All ordinary sulphate of copper solution used in the electrolytic refining of copper contains, after a time, a greater or less proportion of dissolved ferrous sulphate, and this substance gradually combines with the oxygen of the air and becomes persalt. In such a mixture there is liable to occur a considerable waste of current and deficiency of deposited copper—1st, because much of the electric energy is wasted in deoxidising the persalt at the cathode; and 2nd, because a solution of persalt of iron corrodes and dissolves copper; the free acid therefore decreases, and the liquid acquires greater specific gravity. The presence of green vitriol, however, prevents polarisation at the anode, because it absorbs oxygen.

In a solution of green vitriol partly oxidised by the air, and being suitably electrolysed with platinum electrodes, a mixture of iron and hydrogen is deposited at the cathode, and persalt is

Digitized by Google

formed at the anode; and, owing to absorption of oxygen from the air, the proportion of persalt increases.

Purity of the Deposited Copper.—It is a mistake to suppose that electro-deposited copper must be pure; if it has been deposited rapidly from an impure solution it may be very impure. The purest electro-deposited copper is apt to contain traces of tellurium, bismuth, and silver. These have been detected by photographing the spectrum of the copper. The presence of the first two of these would be due either to the density of the current at the cathode being too great, the liquid insufficiently stirred, or the proportion of copper being too small, or to all these causes combined; but most likely to a combination of the first and second. The presence of silver may be due to absence of soluble chlorides, or to sediment falling from the anode.

Of all the various circumstances already described which tend to produce purity of the copper, the most important are:—1. Absence *in solution* of all the metals which are the most readily deposited with it: these are silver, bismuth, antimony, arsenic, and tin; 2, using a sufficiently moderate density of current at the cathode; 3, keeping the solution perfectly clear and well circulated; and 4, not allowing any of the mud from the anode to touch the cathodes. All other conditions being alike, the most slowly deposited metal is the most pure.

There is usually not much risk of depositing any other metal than copper (and silver or bismuth if in solution) under the ordinary conditions of working when the density of current does not exceed 5 amperes per square foot, or the rate of deposition is not more than 70·7 grains per square foot per hour, and the increase of thickness is not greater than 1·07 millimetres, or ·04 of an inch per week of 156 hours. At Stolberg, with an impure solution, and a density of current of 1·482 ampere per square foot, the purity of the deposited copper is stated to be "99·92 and 99·95 per cent. in two analyses." One source of impurity is fine powder from the anodes diffused in the liquid.

The difference of purity of the deposit obtained with different qualities of anodes depends very little upon the electric conductivity of the metal, because with every quality of copper the large mass of the anode has vastly less resistance than the electrolyte; but it depends very greatly upon the kind of impurities. If the impurities are soluble and readily deposited along with the copper, it is then necessary to reduce the speed of deposition, but this greatly increases the cost. According to a German writer (Dingler's *Polytechnisches Journal*, Vol. CCLV., p. 531), the copper deposited at the Oker refinery is extremely perfect, whilst that of some English electrolytic refineries is less so; probably the latter had been too rapidly deposited. Some samples of American-deposited copper have also been found to be impure. A minute proportion of antimony or bismuth destroys the good qualities of copper.

Cost of Electrolytic Refining.—The cost of refining copper by electrolysis varies with the magnitude of the installation, and depends essentially upon the expense of motive-power, and of interest upon invested capital; also largely upon the degree of "commercial efficiency" of the dynamo, and upon the kind and amount of impurities in the crude metal, which are continually varying, because the composition of each batch of unrefined copper differs. The larger the proportion of foreign metals which are easily deposited with the copper, and the purer the refined copper required, the greater the cost of the process, because it must be conducted more slowly. The cost when anodes composed of the unreduced sulphides of copper and iron are employed instead of metallic copper, as in "Marchese's process," is considerably different.

Where motive-power or fuel is cheap, advantage is taken of the circumstance to economise the expenditure upon vats and copper, by using it more freely. At Casarza, where water-power is cheap, the proportion of copper deposited is 1·4lb. per horse-power per hour; at Pembrey, where coal is cheap, it is 2·6lb.; but at Hamburg, where motive-power and fuel are dear, it is 6·87lb. The amount of electric energy and of horse-power consumed in depositing the same weight of copper differs in nearly every electrolytic refinery. Where coal is cheap, and the process is conducted on a large scale, with a good steam engine, at least 110 indicated horse-power is obtained during one week by the consumption of 50 tons of coal, and with good dynamos will deposit 20 tons of copper per week, at a cost of £20. The interest upon capital invested in plant, &c., during the same period will amount to about a similar sum. Or, if we reckon the cost of one mechanical horse power at one penny per hour, the cost of such power for electrolytic refining of copper is about one farthing per pound of that metal refined. Difference of potential required to overcome resistance and polarisation is also an element in calculating the cost of depositing a given amount of copper, because double the electromotive force expended costs quite double the money.

The chief elements of cost are:—1. Interest upon capital expended upon copper, electrolyte, vats, steam-engine, boiler, dynamo, and other plant. 2. Fuel, water, and oil for the engine. 3. Rent and taxes. 4. Labour. 5. Depreciation of steam-engine, boiler, dynamos, vats, &c. 6. Incidental expenses.

The total stock of copper required in order to refine a given amount of that metal per day or week varies in different works. In each refinery, besides the amount of copper in the vats, there is at least an equal quantity in the form of main conductors, raw copper for making anodes, new anodes ready for immersion, and residues of old anodes, also the stock of refined copper. The value of the stock of copper alone in one of the installations at Hamburg has been estimated at "£8,000." Practically, to refine 30 tons a week of ordinary "Chili bars," with a current density of 8 or 10 amperes per square foot, requires a total stock of about 400 tons of copper, which, at £50 a ton, costs £20,000, to which we must add about £10,000 for plant and premises.

A number of workmen are necessary, probably about twenty, working day and night, when depositing thirty tons of copper per week, to manipulate the electrodes, examine the vats, and attend to the steam-engine and dynamo, melt and cast anodes, wash dirty ones, &c. A chemical analyst is also employed to analyse the copper and the electrolyte. As stoppages in the process do not often occur, they are not a large element of expense; there is, however, the cost of occasionally emptying the vats, evaporating and purifying the solution, collecting and treating the mud, &c.

The cost of one of the latest forms of dynamo for electrolytic refining of copper by Messrs. Siemens and Halske, viz., their "H C^{II}" type, constructed to give 1,000 amperes at a difference of potential of 60 volts, was "£420," and that of a 50-unit one, by Messrs. Chamberlain and Hookham, giving 500 amperes at 100 volts, about £400. With large vats, and large currents of low electromotive force, the cost for the same rate of deposition is less, but that of the dynamo and conductors is greater than with small vats and small currents of higher electromotive force. A vat containing one cubic metre costs "about 130fr.," and one of three cubic metres "double that sum." The vats at Biache cost "350fr. each." One cubic metre of the ordinary copper solution costs "about 70fr."

The total cost of M. Hilarion Roux's installation at Marseilles, including the baths, dynamo, and steam-engine to refine "250 kilogrammes per day" (=89½ tons yearly), is stated to have been "£1,000," and the amount of invested capital "£5,000 to £6,000." The "Società Anonima Italiana di Miniere di Rame e di Elettro-Metallurgia," in Genoa, whose works are at Casarza, was established with a capital of 4·8 million marks (=£240,000) (Dingler's *Polytechnisches Journal*, 1885, Vol. CCLV., p. 201).

It might be supposed that the silver and gold recovered constitutes a considerable profit, but all this has to be paid for extra in purchasing the crude metal.

In consequence of the numerous circumstances which affect the cost, an approximately satisfactory estimate of the total amount of capital required to be invested in establishing an electrolytic refinery to deposit a given amount of copper daily, can only be arrived at by means of a knowledge of all the essential particulars in the given case.

Recapitulation.—In establishing an electrolytic copper refinery, the chief points usually require to be settled in the following order:—1st. The amount of copper to be deposited per week. 2nd. Amount of mechanical power required and the kind of motor. 3rd. Degree of purity of the solution and of the crude metal. 4th. Rate of deposition per square foot of cathode

Digitized by Google

surface per week. 5th. Total amount of cathode surface necessary. 6th. Total number of vats in series. 7th. Magnitude of each vat. 8th. Electromotive force and strength of current necessary. 9th. Kind of dynamo. 10th. Magnitude of the main conductors. There are, of course, other important points to be first considered, such as the most suitable locality for cheap motive-power, cheap conveyance, &c., but those do not come within the intended scope of this article.

ON THE DETERMINATION OF THE WORK DONE UPON THE CORES OF IRON IN ELECTRICAL APPARATUS SUBJECT TO ALTERNATING CURRENTS.

BY T. H. BLAKESLEY, M.A., M. INST. C.E.

When the case is one of a transformer the problem may be solved by the employment of three dynamometers in the way I have already* pointed out; but in that of an electro-magnet, where we have only one coil to deal with, the problem still admits of solution if we further employ a condenser of determined capacity, and have a knowledge of the period, by means of some speed indicator. The plan is as follows:—

Arrangement.—Having the machine and magnet in series, insert the three dynamometers in series immediately at one terminal of the electro-magnet, and place one pole of the condenser to the other terminal, and the second pole of the condenser to that point of the middle dynamometer where its two coils join.

Observations.—Obtain good simultaneous readings of the three dynamometers, and if necessary of the speed indicator.

Calculations.—Let α_1, α_2, α_3 be the angles, read upon the instrument (1) in the generating section (2) in the electro-magnet section (3) which has its coils divided.

Let the reducing formulæ for the three instruments be

$$\left.\begin{aligned}(\text{Current})^2 &= k_1\,\theta\\ \text{,,} &= k_2\,\theta\\ \text{,,} &= k_3\,\theta\end{aligned}\right\} \text{ respectively.}$$

Let C be the capacity of the condenser.

R ,, ,, resistance of the electro-magnet section of the circuit.

Then the entire power at work beyond the poles—*i.e.*, the heating of the wire, the heating of the core by induced currents, and the heating of the core due to hysteresis—is expressed by the simple formula:

$$\frac{T}{\pi C}\sqrt{k_1\alpha_1 k_2\alpha_2 - k_3{}^2\alpha_3{}^2}$$

T being the semi-period.

The expression itself is independent of the resistance; but if we desire to know the power heating the core, we must deduct from the above result the power heating the wire—viz., $k_2\alpha_2$ R.

The difference between these two quantities also happens to be proportional to the tangent of the magnetic lag, another proof of the invariable concurrency of lag and loss of power.

* *The Electrician*, Vol. XXI., p. 88.

Electric Light for Diving Apparatus.—Some improvements in diving apparatus have been effected by M. Albert Marcelhacy, a French engineer. Instead of the heavy electric hand lamp hitherto used by divers, he affixes a light but powerful glow lamp on the top of the helmet, so that the diver's hands are both at all times free for work. The lamp is connected by a conductor with a battery either on shore or in a vessel above, as the case may be. These improvements, which have been adopted in the French navy, are being introduced in this country by Mr. R. Applegarth, of 11, Queen Victoria-street, London.

THE COEFFICIENT OF MUTUAL INDUCTION OF TWO PARALLEL WIRES.*

BY DR. CARY T. HUTCHINSON.

Consider two wires running parallel for a distance, l, and at a distance, d, apart. Then, neglecting the effect of the return circuits, it can be shown that the coefficient of mutual induction, M, is proportional to

$$M \propto l\left[\log_e \frac{2l}{d} - 1\right]$$

or

$$M \propto l\left[2.3\log_{10}\frac{2l}{d} - 1\right] \quad \ldots\ldots (1)$$

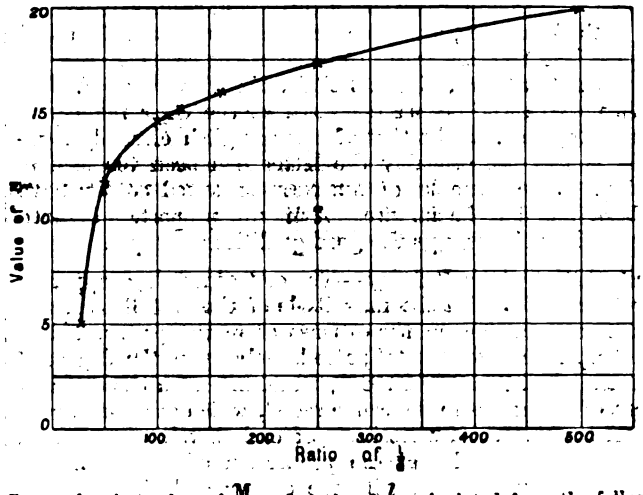
provided d/l is a very small quantity.

This expression would represent, in the simplest conceivable case, the dependence of the disturbing effect of a telegraph or trolley line upon the geometrical constants of the circuits. In applying it to actual cases, the effect of the various telephone wires upon each other and the effect of electrostatic induction are the most important factors neglected; the latter, indeed, has been shown experimentally to be the dominant factor in some cases; yet it is probable that in the actual case the general form of the expression for M would be similar to the above.

A simple consideration shows this to be true. The coefficient of mutual induction is proportional to the number of lines of force linked with both circuits; if then the distance of parallelism and the distance apart be increased in the same ratio, the proportion of lines linked to total lines in one circuit will be approximately the same; but the absolute number of lines, upon which M depends, will be doubled. In no case does the effect vary inversely as the distance apart.

The equation shows that the effect varies directly as the distance of parallelism only when the ratio of this distance to the distance apart is kept constant; that is, if the distance of parallelism is doubled, the distance apart being kept constant, the effect will be considerably more than doubled; but if the distance apart be doubled at the same time, then the effect, always to the degree of approximation mentioned, will be doubled.

The following numerical Table shows all this clearly; it is calculated from (1) the numbers given for M being only proportional, not absolute values, the numbers given in the last column are obtained by dividing by l, and their connection with the corresponding values in the fourth column is shewn in the subjoined curve, which we have added.



Curve showing value of $\frac{M}{l}$ and ratio of $\frac{l}{d}$, calculated from the following

TABLE.

No.	l (feet).	d (feet).	$\frac{l}{d}$	M	$\frac{M}{l}$
1	10,000	20	500	200	20
2	5,000	20	250	88	17·6

* Abstract from the *Electrical Engineer* of New York.

Digitized by Google

Comparing Nos. 1 and 5 shows that increasing the distance 20-fold increases the effect 40-fold ; Nos. 2 and 5 show that increasing the distance 10-fold increases the effect 17-fold, when the distance apart is constant. When the length of parallelism is constant, Nos. 6 and 11 show that increasing the distance apart 10-fold diminishes the effect only to ·61, and not to ·1. This makes the case for telephones very bad, and shows the necessity for metallic circuits—for the telephones, of course.

THE ELECTRO-MAGNET.*

BY PROF. SILVANUS P. THOMPSON.

(Continued from page 719.)

In order to study this question of leakage, and the relation of leakage to pull, still more incisively, I devised some time ago a small experiment, with which a group of my students at the Technical College have been diligently experimenting. Here (Fig. 43) is a horse-shoe electro-magnet. The core is of soft wrought iron, wound with a known number of turns of wire. It is provided with an armature. We have also wound on three little exploring coils, each consisting of five turns of wire, only one, C, right down at the bottom, on the bend ; another, B, right round the pole, close up to the armature ; and a third, A, around the middle of the armature. The object of these is to ascertain how much of the magnetism which was created in the core by magnetising power of these coils ever got into the armature. If the armature is at a considerable distance away, there is naturally a great deal of leakage.

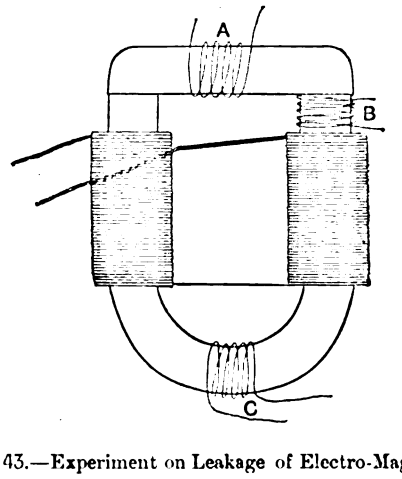

FIG. 43.—Experiment on Leakage of Electro-Magnet.

The coil C, around the bend at the bottom is to catch all the magnetic lines that go through the iron ; the coil B, at the poles, is to catch all that have not leaked outside before the magnetism has crossed the joint ; while the coil A, right around the middle of the armature, catches all the lines that actually pass into the armature and pull at it. We measure by means of the ballistic galvanometer and these three exploring coils how much magnetism gets into the armature at different distances, and are able thus to determine the leakage and compare these amounts with the calculations made, and with the attractions at different distances. The amount of magnetism that gets into the armature does not go by a law of inverse squares, I can assure you, but by quite other laws. It goes by laws which can only be expressed as particular cases of the law of the magnetic circuit. The most important element of the calculations, indeed, in many cases is the amount of percentage of leakage that must be allowed for. Of the magnitude of this matter you will get a very good idea by the result of these experiments following.

The iron core is 13 millimetres in diameter, and the coil consists of 178 turns. The first swing of the galvanometer when the current was suddenly turned on or off measures the number of magnetic lines thereby sent through, or withdrawn from, the exploring coil that is at the time joined to the galvanometer. The currents used varied from 0·7 of an ampere to 5·7 amperes. Six sets of experiments were made, with the armature at different distances. The numerical results are given in the following tables :—

Table I.—*With Weak Current* (0·7 *Amperes*).

These numbers may be looked upon as a kind of numerical statement of the facts roughly depicted in Figs. 31 to 34. The numbers themselves, so far as they relate to the measurements made (1) in contact, (2) with gaps of one millimetre breadth, are plotted out on Fig. 44; there being three curves, A, B, and C, for the measurements made when the armature was in contact, and three others, A_1, B_1, C_1, made at the one millimetre distance. A dotted line gives the plotting of the numbers for the coil C, with different currents, when the armature was removed.

On examining the numbers in detail, we observe that the largest number of magnetic lines forced round the bend of the iron core, through the coil C, was 24,040 (the cross-section being a little over 1 square centimetre), which was when the armature was in contact. When the armature was away, the same magnetising power only evoked 9,795 lines. Further, of those 24,040, 23,660 (or 98½ per cent.) came up through the polar surfaces of contact, and of those again 21,980 (or 92½ per cent. of the whole number) passed through the armature. There was leakage, then, even when the armature was in contact, but it amounted to only 7½ per cent. Now, when the armature was moved but 1 millimetre (*i.e.*, $\frac{1}{25}$th of an inch) away, the presence of the air gaps had this great effect, that the total magnetic flux was at once choked down from 24,040 to 17,220. Of that number only 10,810 (or 61 per cent.) reached the polar surfaces, and only 8,110 (or 47 per cent. of the total number) succeeded in going through the armature. The leakage in this case was 53 per cent. With a 2 millimetre gap, the leakage was 65 per cent. when the strongest current was used. It was 68 per cent. with a 5 millimetre gap, and 80 per cent. with a 10-millimetre gap. It will further be noticed that whilst a current of 0·7 ampere sufficed to send 12,506 lines through the armature when it was in contact, a current eight times as strong could only succeed in sending 8,110 lines when the armature was distant by a single millimetre.

Such an enormous diminution in the magnetic flux through the armature consequent upon the increased reluctance and increased leakage occasioned by the presence of the air-gaps, proves how great is the reluctance offered by air, and how essential it is to have some practical rules for calculating reluctances and estimating leakages to guide us in designing electro-magnets to do any given duty.

* A series of four Cantor Lectures delivered before the Society of Arts, January—February, 1890.

Digitized by Google

The calculation of magnetic reluctances of definite portions of a given material are now comparatively easy, and, thanks to the formulæ of Prof. Forbes, it is now possible in certain cases to estimate leakages. Of these methods of calculation an abstract will be given in the appendix to this lecture. I have, however, found Forbes's rules, which were intended to aid the design of dynamo-machines, not very convenient for the common cases of electro-magnets, and have, therefore, cast about to discover some more apposite mode of calculation. To predetermine the probable percentage of leakage one must first distinguish between those magnetic lines which go usefully through the armature (and help to pull it) and those which go astray through the surrounding air and are wasted so far as any pull is concerned. Having set up this distinction, one then needs to know the relative magnetic conductance, or *permeance*, along the path of the useful lines and that along the innumerable paths of the wasted lines of the stray field. For (as every electrician accustomed to the problem of shunt circuits will recognise) the quantity of lines that go respectively along the useful and wasteful paths will be directly proportional to the conductances (or permeances) along those paths, or will be inversely proportional to the respective resistances along those paths. It is customary in electro-magnetic calculations to employ a certain coefficient of allowance for leakage, the symbol for which is v, such that when we know the number of magnetic lines that are wanted to go through the armature we must allow for v times as many in the magnet core. Now, if u represents permanence along the useful path, and w the permanence of all the waste paths along the stray field, the total flux will be to the useful flux as $u+w$ is to u. Hence the coefficient of allowance for leakage

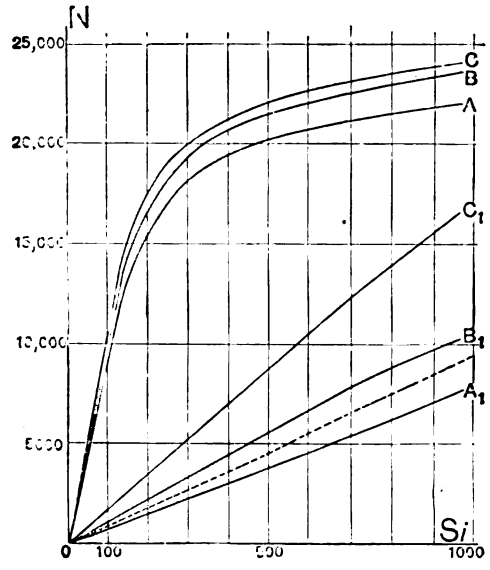

FIG. 44.—Curves of Magnetisation Plotted from Preceding.

v, is equal to $u+w$ divided by u. The only real difficulty is to calculate u and w. In general u is easily calculated; it is the reciprocal of the sum of all the magnetic reluctances along the useful path from pole to pole. In the case of the electro-magnet used in the experiments last described, the magnetic reluctances along the useful path are three in number, that of the iron of the armature, and those of the two air gaps. The following formula is applicable:—

$$\text{reluctance} = \frac{l_1}{A_1 \mu_1} + \frac{2 l_2}{A_2},$$

if the data are specified in centimetre measure; the suffixes 1 and 2 relating respectively to the iron and to the air. If the data are specified in inch measures the formula becomes

$$\text{reluctance} = 0{\cdot}3132 \left\{ \frac{l''_1}{A''_1 \mu_1} + \frac{2 l''_2}{A''_2} \right\}$$

But it is not so easy to calculate the reluctance (or its reciprocal, the permeance) for the waste lines of the stray field, because the paths of the magnetic lines spread out so extraordinarily and bend round in curves from pole to pole.

Fig. 45 gives a very fair representation of the spreading of the lines of the stray field that leaks across between the two limbs of a horseshoe electro-magnet made of round iron. And for square iron the flow is much the same, except that it is concentrated a little by the corners of the metal. Forbes's rules do not help us here. We want a new mode of considering the subject.

The problems of flow, whether of heat, electricity, or of magnetism, in space of three dimensions, are not among the most easy of geometrical exercises. However, some of them have been worked out, and may be made applicable to our present need. Consider, for example, the electrical problem of finding the resistance which an indefinitely extended liquid (say a solution of sulphate of copper of given density) offers when acting as a conductor of electric currents flowing across between two indefinitely long parallel cylinders of copper. Fig. 45 may be regarded as representing a transverse section of such an arrangement, the sweeping curves representing lines of flow of current. In a simple case like this it is possible to find an accurate expression for the resistance (or for the conductance) of a layer or stratum of unit thickness. It depends on the diameters of the cylinders, on their distance apart, and on the specific conductivity of the medium. It is not by any means proportional to the distance between them, being, in fact, almost independent of the distance, if that is greater than twenty times the perimeter of either cylinder. Neither is it even approximately proportional to the perimeter of the cylinders except in those cases when the shortest distance between them is less than a tenth part of the perimeter of either. The resistance, for unit length of the cylinders, is, in fact, calculated out by the rather complex formula:—

$$R = \frac{1}{\pi \mu} \text{ log. nat. } h;$$

Where

$$h = \frac{2a}{b + 2a - \sqrt{b^2 + 4ab}};$$

the symbol a standing for the radius of the cylinder; b for the shortest distance separating them; μ for the permeability, or in the electric case the specific conductivity of the medium.

Now, I happened to notice, as a matter that greatly simplifies the calculation, that if we confine our attention to a transverse layer of the medium of given thickness, the resistance between the

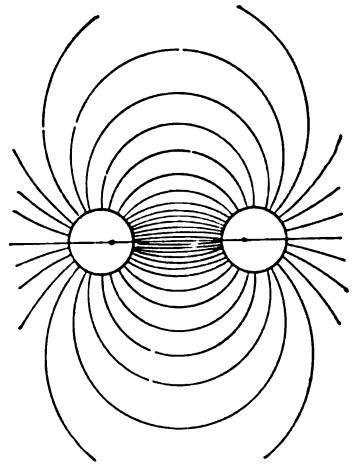

FIG. 45.—Curves of Flow of Magnetic Lines in Air from one Cylindrical Pole to another.

two bits of the cylinders in that layer depends on the ratio of the shortest distance separating them to their periphery, and is independent of the absolute size of the system. If you have the two cylinders an inch round, and an inch between them, then the resistance of the slab of medium (of given thickness) in which they lie will be the same as if they were a foot round and a foot apart. Now that simplifies matters very much, and thanks to my friend and former chief assistant, Dr. R. Mullineux Walmsley, who devoted himself to this troublesome calculation, I am able to give you, in tabular form, the magnetic resistance within the limits of proportion that are likely to occur.

The numbers from columns 1 and 2 of Table VII. are plotted out graphically in Fig. 46, for more convenient reference. As an example of the use of the Table we will take the following:—

EXAMPLE.—Find the maenetic reluctance and permeance between two parallel iron cores of 1in. diameter and 9in. long, the least distance between them being $2\frac{3}{8}$in. Here $b = 2{\cdot}375$; $p = 3{\cdot}1416\, b \div p = 0{\cdot}756$. Reference to the table shows (by interpolation) that the reluctance and permeance for unit thickness of slab are respectively 0·183 and 5·336. For 9in. thickness they will therefore be 0·021 and 48·02 respectively.

When the permeance across between the two limbs is thus approximately calculable, the waste flux across the space is estimated by multiplying the permeance so found by the *average* value of the difference of magnetic potential between the two limbs. And this, if the yoke which unites the limbs at the lower end is of good solid iron, and if the parallel cores offer little magnetic reluctance as compared with the reluctance of the useful paths, or of that of the stray field, may be simply taken as half the ampere-turns (or if centimetre measures are used multiply by 1·2566).

NOTE.—In the above table, unit-length of cylinders is assumed (one centimetre in columns two and three ; 1in. in columns four and five) ; the flow of magnetic lines being reckoned as in a slab of infinite extent, and of unit thickness. Symbols : p = perimenter of cylinder ; b = shortest distance between cylinders. In columns two and three the unit reluctance is that of a centimetre cube of air. In columns four and five the unit reluctance is so chosen (as in the rest of these lectures wherever such measures are used) that the reduction of ampere-turns to magneto-motive force by multiplying by $4\pi \div 10$ is avoided. This will make the reluctance of the inch cube of air equal to $10 \div 4\pi \div 2{\cdot}54 = 0{\cdot}3132$; and its permeance as 3·1931.

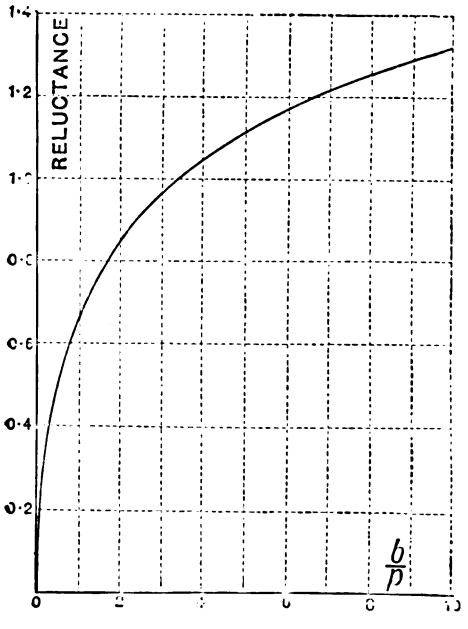

FIG. 46.—Diagram of Leakage Reluctances.

The method here employed in estimating the reluctance of the waste field is, of course, only an approximation ; for it assumes that the leakage takes place only in the planes of the slabs considered. As a matter of fact, there is always some leakage out of the planes of the slabs. The real reluctance is always, therefore, somewhat less, and the real permeance somewhat greater than that calculated from Table VIII.

For the electro-magnets used in ordinary telegraph instruments the ratio of b to p is not usually very different from unity, so that for them the permeance across from limb to limb per inch length of core is not very far from 5·0, or nearly twice the permeance of an inch cube of air.

We are now in a position to see the reason for a curious statement of Count Du Moncel which for long puzzled me. He states that he found, using distance apart of one millimetre, that the attraction of a two-pole electro-magnet for its armature was less when the armature was presented laterally than when it was placed in front of the pole-ends, in the ratio of 19 to 31. He does not specify in the passsage referred to what was the shape of either the armature or the cores. If we assume that he was referring to an electro-magnet with cores of the usual sort—round iron with flat ends, presumably like Fig. 11—then it is evident that the air gaps, when the armature is presented sideways to the magnet, are really greater than when the armature is presented in the usual way, owing to the cylindric curvature of the core. So, if at equal measured distance the reluctance in the circuit is greater, the magnetic flux will be less and the pull less.

It ought also now to be evident why an armature made of iron of a flat rectangular section, though when in contact it sticks on tighter edgeways, is at a distance attracted more powerfully if presented flatways. The gaps, when it is presented flatways (at an equal least distance apart) offer a lesser magnetic reluctance.

Another obscure point also becomes explainable, namely, the observations by Lenz, Barlow, and others, that the greatest amount of magnetism which could be imparted to long iron bars by a given circulation of electric current was (nearly) proportional, not to the cross-sectional area of the iron, but to its surface. The explanation is this. Their magnetic circuit was a bad one, consisting of a straight rod of iron and of a return path through air. Their magnetising force was being in reality expended not so much on driving magnetic lines through iron (which is readily permeable); but on driving the magnetic lines through air (which is, as we know, much less permeable), and the reluctance of the return paths through the air is—when the distance from one to the other of the exposed end parts of the bar is great compared with its periphery—very nearly proportional to that periphery, that is to say, to the exposed surface.

Another opinion on the same topic was that of Prof. Müller, who laid down the law that for iron bars of equal length, and excited by same magnetising power, the amount of magnetism was proportional to the square root of the periphery. A vast amount of industrious scientific effort has been expended by Dub, Hankel, Von Feilitzsch, and others on the attempt to verify this "law." Not one of these experimenters seems to have had the faintest suspicion that the real thing which determined the amount of magnetic flow was not the iron but the reluctance of the return-path through air. Von Feilitzsch plotted out the accompanying curves (Fig. 47), from which he drew the inference that the law of the square root of the periphery was established. The very straightness of these curves shows that in no case had the iron become so much magnetised as to show the bend that indicates approaching saturation. Air, not iron, was offering the main part of the resistance

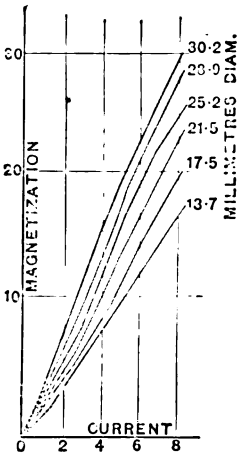

FIG. 47.—Von Feilitzsch's Curves of Magnetisation of Rods of Various Diameters.

to magnetisation in the whole of these experiments. I draw from the very same curves the conclusion that the magnetisation is not proportional to the square root of the periphery, but is more nearly proportional to the periphery itself ; indeed, the angles at which the different curves belonging to the different peripheries rise show that the amount of magnetism is very nearly as the surface. Observe here we are not dealing with a closed magnetic circuit where section comes into account ; we are dealing with a bar in which the magnetism can only get from one end to the other by leaking all round into the air. If, therefore, the reluctance of the air path from one end of the bar to the other is proportional to the surface, we should get some curves very like these ; and that is exactly what happens. If you have a solid, of a certain given geometrical form, standing out in the middle of space, the conductance which the space around it (or rather the medium filling that space) offers to the magnetic lines flowing through it, is practically proportional to the surface. It is distinctly so for similar geometrical solids, when they are relatively small as compared with the distance between them. Electricians know that the resist-

Digitized by Google

ance of the liquid between two small spheres, or two small discs of copper immersed in a large bath of sulphate of copper, is practically independent of the distance between them, provided they are not within 10 diameters, or so, of one another. In the case of a long bar we may treat the distance between the protruding ends as sufficiently great to make an approximation of this law hold good. Von Feilitzsch's bars were, however, not so long that the average value of the length of path from one end surface to the other end surface, along the magnetic lines, was infinitely great as compared with the periphery. Hence the departure from exact proportionality to the surface. His bars were 9·1 centimetres long, and the peripheries of the six were respectively 94·9, 90·7, 79·2, 67·6, 54·9, and 42·9 millimetres.

It has long been a favourite idea with telegraph engineers that a long-legged electro-magnet in some way possessed a greater "projective" power than a short-legged one; that, in brief, a long-legged magnet could attract an armature at a greater distance from its poles than could a short-legged one made with iron cores of the same section. The reason is not far to seek. To project or drive the magnetic lines across a wide intervening air-gap requires a large magnetising force on account of the great reluctance, and the great leakage in such cases. And the great magnetising force cannot be got with short cores, because there is not, with short cores, a sufficient length of iron to receive all the turns of wire that are in such a case essential. The long-leg is wanted simply to carry the wire necessary to provide the requisite circulation of current.

We now see how, in designing electro-magnets, the length of the iron core is really determined; it must be long enough to allow of the winding upon it of the wire which, without overheating, will carry the ampere-turns of exciting current which will suffice to force the requisite number of magnetic lines (allowing for leakage) across the reluctances in the useful path. We shall come back to this matter after we have settled the mode of calculating the quantity of wire that is required.

Being now in a position to calculate the additional magnetising power required for forcing magnetic lines across an air gap, we are prepared to discuss a matter that has been so far neglected, namely, the effect on the reluctance of the magnetic circuit, of joints in the iron. Horse-shoe electro-magnets are not always made of one piece of iron bent round. They are often made, like Fig. 11 of two straight cores shouldered and screwed, or riveted into a yoke. It is a matter purely for experiment to determine how far a transverse plane of section across the iron obstructs the flow of magnetic lines. Armatures, when in contact with the cores, are never in perfect contact, otherwise they would cohere without the application of any magnetising force; they are only in imperfect contact, and the joint offers a considerable magnetic reluctance. This matter has been examined by Prof. J. J. Thomson and Mr. Newell, in the Cambridge Philosophical Society's Proceedings, in 1887; and recently more fully by Prof. Ewing, whose researches are published in the *Philosophical Magazine* for September, 1888. Ewing not only tried the effect of cutting and of facing up with true plane surfaces, but used different magnetising forces, and also applied various external pressures to the joint. For our present purpose we need not enter into the questions of external pressures, but will summarise the results which Ewing found when his bar of wrought iron was cut across by section planes, first into two pieces, then into four, then into eight. The apparent permeability of the bar was reduced at every cut.

Table IX.—*Effect of Joints in Wrought Iron Bar (not compressed).*

H	B				Mean thickness of equivalent air-space for one cut.		Thickness of iron of equivalent reluctance per cut.	
	Solid.	Cut in two.	In Four.	In Eight	Centimetres.	Inches.	Centimetres.	Inches.
7·5	8,500	6,900	4,809	2,600	0·0036	0·0014	4	1·57
15	13,400	11,550	8,900	5,550	0·0030	0·0012	2·53	1·00
30	15,350	14,550	12,940	9,800	0·0020	0·0008	1·10	0·433
50	16,400	15,950	15,000	13,300	0·0013	0·0005	0·43	0·169
70	17,100	16,840	16,120	15,200	0·0009	0·0004	0·22	0·087

Suppose we are working with the magnetisation of our iron pushed to about 16,000 lines to the square centimetre (*i.e.*, about 150lb. per square inch, traction), requiring a magnetising force of about H = 50; then, referring to the Table, we see that each joint across the iron offers as much reluctance as would an air-gap 0·0005 of an inch in thickness, or adds as much reluctance as if an additional layer of iron about one-sixth of an inch thick had been added. With small magnetising forces the effect of having a cut across the iron with a good surface on it is about the same as though you had introduced a layer of air one six-hundredth of an inch thick, or as though you had added to the iron circuit about one inch of extra length. With large magnetising forces, however, this disappears, probably because of the attraction of the two surfaces across that cut. The stress in the magnetic circuit, with high magnetic forces running up to 15,000 or 20,000 lines to the square centimetre, will of itself put on a pressure of 130 to 230lb. to the square inch, and so these resistances are considerably reduced: they come down, in fact, to about one-twentieth of their initial value. When Ewing specially applied compressing forces, which were as large as 670lb. to the square inch, which would of themselves ordinarily, in a continuous piece of iron, have diminished the magnetisability, he found the diminution of the magnetisability of iron itself was nearly compensated for by the better conduction of the cut surface. The old surface, cut and compressed in that way, closes, as it were, magnetically up—does not act like a cut at all; but at the same time you lose just as much as you gain, because the iron itself becomes less magnetisable.

The above results of Ewing's are further represented by the curves of magnetisation drawn in Fig. 48. When the faces of a cut were carefully surfaced up to true planes, the disadvantageous effect of the cut was reduced considerably, and, under the application of a heavy external pressure, almost vanished.

I have several times referred to experimental results obtained in past years, principally by German and French workers, buried in obscurity in the pages of foreign scientific journals. Too often, indeed, the scattered papers of the German physicists are rendered worthless or unintelligible by reason of the omission of some of the data of the experiments. They give no measurements perhaps of their currents, or they used an uncalibrated galvanometer, or

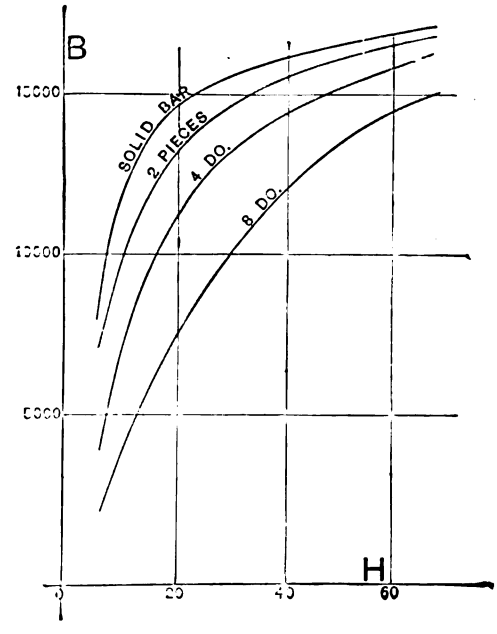

FIG. 48.—Ewing's Curves for Effect of Joints.

they do not say how many windings they were using in their coils; or perhaps they give their results in some obsolete phraseology. They are extremely addicted to informing you about the "magnetic moments" of their magnets. Now, the magnetic moment of an electro-magnet is the one thing that one never wants to know. Indeed the magnetic moment of a magnet of any kind is a useless piece of information, except in the case of bar-magnets of hard steel that are to be used in the determination of the horizontal component of the earth's magnetic force. What one does want to know about an electro-magnet is the number of magnetic lines flowing through its circuit, and this the older researches rarely afford the means of ascertaining. Nevertheless, there are some investigations worthy of study to which time will now only permit me very briefly to allude. These are the researches of Dub on the effect of thickness of armatures, and those of Nicklès and of Du Moncel on the lengths of armatures. Also those of Nicklès on the effect of width between the two limbs of the horse-shoe electro-magnet.

I can only now describe some experiments of Von Feilitzsch upon the vexed question of tubular cores, a matter touched by Sturgeon, Pfaff, Joule, Nicklès, and later by Du Moncel. To examine the question whether the inner part of the iron really helps to carry the magnetism, Von Feilitzsch prepared a set of thin iron tubes which could slide inside one another. They were all 11 centimetres long, and their peripheries varied from 6·12 centimetres to 9·7 centimetres. They could be pushed within a magnetising spiral to which either small or large currents could be applied, and their effect in deflecting a magnetic needle was noted, and balanced by

Digitized by Google

means of a compensating steel magnet, from the position of which the forces were reckoned and the magnetic moments calculated out. As the tubes were of equal lengths, the magnetisation is approximately proportional to the magnetic moment. The outermost tube was first placed in the spiral, and a set of observations made; then the tube of next smaller size was slipped into it, and another set of observations made; then a third tube was slipped in until the whole of the seven were in use. Owing to the presence of the outer tube in all the experiments, the reluctance of the air return paths was alike in every case. The curves given in Fig. 49 indicate the results. The lowest curve is that corresponding to the use of the first tube alone. Its form, bending over and becoming nearly horizontal, indicates that with large magnetising power it became nearly satu-

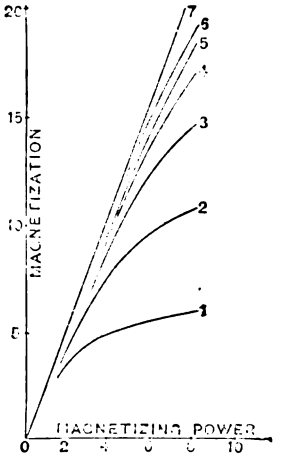

Fig. 49.—Von Feilitzsch's Curves of Magnetisation of Tubes.

rated. The second curve corresponds to the use of the first tube with the second within it. With greater section of iron saturation sets in at a later stage. Each successive tube adds to the capacity for carrying magnetic lines, the beginning of saturation being scarcely perceptible, even with the highest magnetising power, when all seven tubes were used. All the curves have the same initial slope. This indicates that with small magnetising forces, and when even the least quantity of iron was present, when the iron was far from saturation, the main resistance to magnetisation was that of the air paths, and it was the same whether the total section of iron in use was large or small.

I must leave till my next lecture the rules relating to the determination of the windings of copper wire on the cores.

ON THE INFLUENCE OF ELECTRIC PRESSURE ON INSULATION, ESPECIALLY WITH REFERENCE TO CABLES.*

BY C. HEIM, HANOVER.

With the increase in the number and size of electric installations the question of insulation has assumed greater importance. It has been already pointed out by Uppenborn that the insulation resistance is not independent of the pressure, but diminishes as the latter increases. The quantitative results that follow will, however, be of interest, especially as the tendency of late years has been towards a continual increase of the pressure in main conductors, and this interest will be increased owing to the bearing which the tests have on the question as to the durability of the insulation; for since the resistance falls with an increase of pressure, it seems likely that high volts cause a change in the nature of the insulating substance.

It is also to be remembered that these tests have a bearing on telegraph cables in which a high pressure is frequently employed.

Experiments were undertaken with lead-covered and with gutta-percha cables, and tests were also made with the field winding of a dynamo, an ordinary electric light wire attached to a wall, a bell-wire, and an aerial wire suspended on porcelain insulators. As will be seen, the question as to whether the influence varies with the temperature was only investigated in one case—that of the dynamo winding. All the other tests were made at the ordinary temperature of the room.

After I had commenced these investigations, Forderreuther published his observations on "Insulation Measurements of Electric Light Conductors." I, however, continued the work which I had begun, the limit of pressure employed by him having been only 89 volts.

Material Tested.—For my tests on cables I had available two bare lead cables 1,000m. long, by different makers, and a gutta-percha cable 800m. long. The dimensions of the lead cables were:—

No. I.—Diameter of core, 1·4mm.; diameter of insulating sheath, 5·3mm.

No. II.—Diameter of core, 1·1mm.; diameter of insulating sheath, 3·4mm.

Their capacities, as obtained by Thomson's compensation method, were:—

No. I. —0·137 microfarad at 15·5° Cent.
No. II.—0·135 ,, 15·7° ,,

As will be seen from the dimensions, the insulations in the two specimens were totally different. No. II. was in two pieces of 826 mm. and 174 mm. in length respectively. For such measurements as were taken it is clear that these cables were amply large enough. Also the absolute value of the insulation resistance agrees in all cases so long as the proportion between the diameter of the copper core and the insulating sheath remain constant. The gutta-percha-covered cable had a core of seven wires of ·7 mm. diameter covered with two layers of gutta-percha to the diameter of 5 mm. This cable corresponds with the underground cables laid by the German Telegraph Department. The gutta-percha was pure, and the insulation free from faults. The capacity of the cable was ·190 microfarads at 14·5°C.

Measurement.—The measurements were taken with a Thomson's astatic mirror galvanometer. Four shunts were used and a vulcanite commutator, also a rheostat of 100,000 ohms resistance. The galvanometer and shunts, &c., were carefully insulated from earth by means of vulcanite pedestals, and for every observation the leakage current was measured and allowed for. The sensibility of the galvanometer was adjusted by cutting out some of the electro-magnets, when it was made a maximum 100 volts, though a resistance of 500,000 megohms gave a displacement of 1 mm. on a scale 2 metres distant. The battery consisted of 330 small copper elements, to which could be added 60 accumulator cells, so that 460 to 470 volts were available. The Daniell cells were filled with a 5 per cent. solution of zinc sulphate, and in each about 15 grammes of copper sulphate were placed. It was found to remain very constant for three months, the volts in that period falling only from 1·06v. to 1·02v. per cell. The connections were so arranged that the primary cells could readily be switched in or out ten at a time, and the secondary cells in two equal halves.

Tests.—The observations could apparently be most simply carried out by taking a series of measurements of the insulation resistance either with increasing or decreasing pressures. Two points, however, have to be considered. On the one hand, any change of temperature, even if very slight, might utterly upset the results, owing to the high temperature coefficient of the insulation. Consequently, changes of temperature are to be guarded against, and the observations ought therefore to be taken as rapidly after one another as possible. On the other hand, this condition can only be partly complied with, as if a certain time is not allowed to elapse, a residual charge is left in the cable depending in magnitude on the volts and duration of the previous charge, and which may practically operate either to increase or to decrease the apparent voltage.

To keep the temperature constant, the following precautions were taken: The gutta-percha cable was placed in a wooden barrel containing about 70 litres of water. This was enclosed in a wooden casing filled with sawdust, which formed a cover nowhere less than 8 or 10 cm. thick. The two cable ends, about 1 metre long, passed through an opening in the top closed with a cork, and a thermometer was placed in a gas tube lined with cork and passed through the sawdust, the lower end of the thermometer projecting into the centre of the coil of cable.

For the 2-lead cable, corks of sufficient size were not at hand. In their case the temperature was kept constant by wrapping them in a covering of straw 10 cm. thick, which was enclosed in a layer of pasteboard. The cables were placed in a room where very little change in the temperature took place, the greatest variation during 24 hours not exceeding 1deg. For several weeks the temperature remained between 17deg. and 19deg. The ends of the cables were brought into the testing-room through a hole in the wall. During the course of a series of tests, lasting perhaps four or five hours, the thermometer belonging to the gutta-percha cable usually showed no change whatever, whilst that of the thinner of the lead cables was constant within ·1deg. All the cable ends were provided with Frölich's insulating caps, 9 cm. long. One end of each cable was brought to the measuring table, being connected to the instrument by a short length of wire passing through air.

A very exact check on the alterations of temperature in the cables may be obtained from the measurement of the alteration of

* From the *Elektrotechnische Zeitschrift.*

Digitized by Google

the resistance of the copper core. This can be done as follows :—The cable K and a plug rheostat r of German silver wire are connected in series and coupled with a battery (Fig. 1). The cable K and the rheostat r are each put in shunt with one circuit of a differential galvanometer G (in my tests one of Wiedemann's was used). A current of about one-tenth ampere is allowed to flow through K and r. The resistance of r is made equal to that of K within one-tenth of an ohm. The resistance of this part of the circuit can then be made exactly equal to that of K by putting a high resistance R in parallel with r. From the readings taken we get the temperature of r, and thence that of K. The temperature coefficient of German silver being ten times lower than that of copper, an error of ·1deg. in the determination of the temperature of the rheostat only produces one of ·01deg. in that of the cable.

A large number of measurements of the insulation at various pressures have to be taken. At the end of any series of tests, and usually also after the measurement at an intermediate pressure, the insulation resistance is again measured at the low original pressure. From the difference between these two values a very slight alteration in temperature is easily detected, the method being very much more delicate than that of measuring the resistance of the copper core as above explained. This slight alteration having been determined, the correction it necessitates can easily be applied. The exact procedure is as follows :—The interval for discharge has to be suited to the pressure ; thus, if the latter is 50 volts, the cable has both ends connected to earth for 40 minutes ; if 460 volts, for two hours ; 200 volts, for 1¼ hours ; and so on. Consequently the time of the measurement with high volts is nearer to the former than to the latter of those at lower tension ; and this has to be taken into account in deducing the value of the insulation resistance at the low tension for comparison with that at the high tension. If more than two different pressures were tested, all readings were in

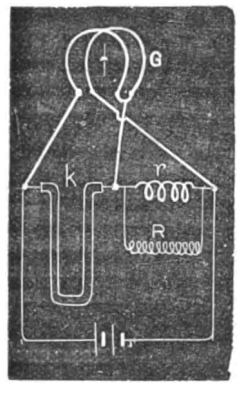

Diagram of Connections for Insulation Tests.

the same way reduced to the time of one, usually the intermediate pressure.

In order to make the residual charge as small as possible, the time of connection to the battery must be short. I therefore took readings one and two minutes after closing the circuit. I did not consider that the former would be sufficient taken by itself, partly because it gave no control or safeguard against error, and partly because the length of time occupied by the swinging of the galvanometer mirror, together with the rapid change in the current passing, made it more difficult to take the reading after one minute than it was after two. It should be observed that the short-circuiting key of the galvanometer was not taken out until 10 seconds after the cable had been coupled to the battery.

In spite of the long time allowed for discharging the cables they showed signs of residual charge, especially after high volts had been used. Immediately before a fresh reading was taken, the cable was connected to earth through the galvanometer and the slight displacement was observed. If this exceeded ½ per cent. of that afterwards obtained. I added it to the latter, and calculated the insulation resistance from the sum. That this method was pretty correct is proved by the following :—In tests during which neither the thermometer nor the copper resistance showed any change of temperature, the insulation resistance at the low-pressure at the end of the series of tests was found without the above correction, always to be lower than that found at the beginning ; whereas if the correction was employed the two values agreed. Moreover, this process seems to be justified by the consideration that the residual charge, supposing that the same pole is used, acts as an opposing electromotive force, and that such residual charges, as Frölich observed, and I myself found, remain for a very long time in cables, and cannot be obliterated even by a short charge from the opposite pole.

For any series of tests on one cable the sensibility of the galvanometer was adjusted one hour before starting, and every correction for resistance in connecting wires, &c., was duly made.

In the case of electric light cables and others carrying a current for a considerable length of time, the value of the insulation resistance after one or two minutes is not so important as that reached after a longer time. Frölich has concluded that in the case of a gutta-percha cable it approaches a constant value. I have made experiments to ascertain if Frölich's results hold good for various temperatures, the cable for that purpose being connected to the battery for a quarter of an hour.

Table I. opposite will show the method of applying the corrections mentioned above in the case of the gutta-percha cable.

Tables II., III. and IV. give the corrected values of the insulation resistances for the three cables at various pressures.

The experiments, therefore, prove that a fall in the insulation resistance does undoubtedly take place as the pressure increases in the cases of the tables that I tested, but that within the limits of pressure I employed the variation is small. It is also clear that this rate of diminution varies for different dielectrics.

It is also interesting to note the influence of the time during which the circuit has been closed on the insulation resistance. As may be seen from Tables II. to IV., this influence is far more noticeable in the 2-lead cables than in the gutta-percha cable. In order to investigate this point further, the observations were carried on for a period of 15 minutes with the results shown in Table VI.

Representing the value of the insulation resistance after one minute by unity, as is done by Frölich, the results for the gutta-percha cable are as follows :—

Observer.	Pressure Volts.	1	2	3	5	10	15 mins.
Frölich	?	1·00	1·11	1·15	1·24	1·33	1·37
Heim	53	1·00	1·13	1·20	1·27	1·35	1·40
	213	1·00	1·14	1·21	1·30	1·38	1·46
	270	1·00	1·13	1·19	1·28	1·36	1·42

My observations were taken at 16·5deg. Frölich gives results for 16deg. and 18deg., from which those given above under his name are calculated. The slight difference is probably due to the nature of the gutta-percha.

For the two lead cables I got

	Pressure.	1	2	3	5	10	15 mins.
Lead cable No. 1	21	1·00	1·25	1·54	1·96	2·83	3·59
	213	1·00	1·25	1·49	1·96	2·88	3·64
	470	1·00	1·25	1·47	1·92	2·80	3·52
Lead cable No. 2	53	1·00	1·37	1·66	2·02	2·74	3·24
	213	1·00	1·42	1·72	2·16	2·82	3.26

It is therefore clear that for conductors supplying current continuously the insulation resistance should be measured not only one and two minutes after closing the circuit, but also say after the expiration of half an hour.

Observations were also undertaken with the view of ascertaining whether changing the direction of the current would produce any alteration in the insulation resistance, but no very marked difference was observable.

For the tests on a dynamo winding, one of Schuckert's shunt-wound disc machines, capacity 100 volts × 5 amperes was used. The readings were taken after the circuit had been closed one minute, precautions being adopted as in the case of the cables and similar corrections being applied. The machine was tested both hot and cold. The field winding, which consisted of 5,500 turns of double cotton covered wire ·8mm. thick, was warmed by passing through it for six hours a current at the rate of 2 amperes per square millimetre of copper section.

The tables opposite show the results obtained.

Two conductors of types usually attached to walls were also tested. A was a flexible cord of 19 wires of 1·2 mm. diam., insulated first with asbestos ribbon, then with india rubber, and covered with yarn. It was 150 m. long, and attached to the wall of a room near the ceiling by twined cleats on wood bases. B was an ordinary bell wire, ·9 mm. thick, insulated with double cotton and paraffin ; it was 170 m. long, and attached to a wall by staples. The tests gave the results shown in Tables VII. and VIII.

THE DISCHARGE OF ACCUMULATORS LEFT ON OPEN CIRCUIT.*

BY GASTON ROUX.

When it is not required to make use of a battery of accumulators during a certain period, what must one do to prevent them from being injuriously affected? That is a question which has often been put to me, and to which I have always replied :—"Charge the battery to "saturation," and leave it to itself." I am aware that this is not the opinion of everyone, and that some recommend that accumulators should be charged to "saturation," and the liquid then emptied out, while others advise substituting pure water for the ordinary solution, and others still the substitution of concentrated acid for the ordinary solution. My opinion was based upon an experiment which I carry out each year at the École de Physique et Chimie Industrielles de la Ville de Paris during the summer holidays. The experiment was repeated as usual this year, and I determined the exact amount of charge lost by the accumulators left on open circuit. The tests were made on two storage cells of the Julien type, having capacity of 200 ampere hours, which were separated from the remainder of the battery. These accumulators are provided with paraffin spray arresters. The cells are of glass, and are contained in wooden boxes filled with sawdust, and supported on oil insulators. The cells, therefore, are thoroughly well insulated. The solution has a density of 1·2, when the cells are fully charged, and contains 6 per cent. in volume of saturated sulphate of soda.

The two cells were charged to saturation on August 5th, discharged on August 6th, and recharged on the 7th of the same month. I then left them to themselves until October 20th, that-is to say, for two months and 13 days, when they were discharged. The discharge was stopped both on August 6th and October 20th, when the E.M.F. had fallen to 1·8 volts per cell. The quantity of electricity was found to be 233 ampere hours on August 6th, and 220 ampere hours on October 20th. Assuming that in each charge the accumulators stored the same quantity of electricity, we may conclude that the accumulators only lost on open circuit 13 ampere hours, or 6 per cent. of their charge during two and a-half months. This result seems to me to prove that accumulators well-made, well-charged, and well-insulated, are not injured by being left on open circuit. It also shows the good quality of these particular cells, and proves again that there is no local action between the active material and the antimony alloy supports. I should have liked to have carried out a similar test on accumulators with plain lead grids, but I had none at my disposal.

* From *L'Électricien*.

GERMAN NOTES.

(FROM OUR OWN CORRESPONDENT.)

October 28, 1890.

The engineers of the Cologne municipal gasworks have commenced to lay the concentric mains for electrical supply in that town. These cables have been manufactured by MM. Chandoir of Neufchâtel, and are the first of their kind laid down in Germany in connection with a Ganz station. The cables must have an insulation resistance of at least 1,000 megohms per kilometre, and are also tested under a pressure of 5,000 volts ; the working pressure being 2,000 volts. The first batch of mains tested under an E.M.F. of 120 volts had a resistance of 16,000 megohms per 1,000 metres. The cables are protected against mechanical injury by wooden troughing, which is filled in with a mixture of resin and oil. The first group of machinery installed will comprise 2,500 horse-power and 1,125 horse-power dynamos. These machines are coupled direct to Sulzer engines, running at 85 revolutions per minute. The alternators have 72 poles, so that the current has a periodicity of 51. The armature of the exciter revolves on the spindle of the field-magnets of the alternator, and the frame carrying the alternator armature coils also carries the eight poles of the exciter. As the Helios Company, which is erecting this central station, make a small arc lamp which burns splendidly with a D.P. of 32 volts, the secondaries of the transformers are wound to give 72 volts, so that two of these lamps may be run in series across the house circuits without excessive waste of power.

Herr A. Schneller has forwarded me the following values for spark-lengths at high voltages. The readings were taken by means of a Cardew voltmeter connected across the primary terminals of a "step-up" transformer. The spark-lengths were fixed beforehand by setting the wires at measured distances apart, and increasing the pressure till a spark took place. The results obtained are shown in the accompanying table :—

Pressure.	Sparking distance mm.	Pressure.	Sparking distance mm.
4,300	4	10,700	16
4,700	6	11,500	20
6,750	10	13,100	22
7,800	16	14,200	24

VIENNA NOTES.

(FROM OUR OWN CORRESPONDENT.)

VIENNA, *October* 25, 1890.

The Vienna streets have been "up" all this summer. Wherever one walks the pavements are blocked, and the work still goes on, day and night. The International Electricitäts Gesellschaft and Messrs. Siemens and Halske are laying electric light cables all over the city; and both firms hope to commence lighting up the districts assigned to them before the end of the year, and both state that they have large orders on hand for private houses and shops. To add to the confusion, the Vienna Telephone Company are extending their underground network, and adding about 2,000 subterranean lines to the present number. All over the Empire there has been great activity in extending the electric light and electric traction. In Vienna the two firms mentioned above divide the city proper, but Messrs. Cappilleri, Holzapfel and Co. have secured the concessions for Wahring Kernals, Ottaking, and Neulerchenfeld, suburbs of Vienna. The Mariahilf district of Vienna is being supplied by a local company. The Agricultural and Forestry Exhibition is, it is needless to say, also lit by electric light, the largest installation there being that of Messrs. Siemens and Halske, who evidently mean to remain the premier firm on the Continent. They have there a 850 horse-power installation, 675 horse-power being used to drive the 16 dynamos, which supply 400 arc and 2,000 glow lamps. The central station of the International Electricitäts Gesellschaft, near the Danube, will have an output of over 2,000 horse-power. The interior installation of the Palace is to begin with 8,000 glow lamps, and the contract for the wiring has been given to the firm of Egger and Co., who have already carried out the installations for the Imperial Court in Gastein, Lainz, and Ischl.

Much surprise has been expressed in Vienna that the Imperial Continental Gas Association have not made better use of their opportunities. They were practically the first in the field here with their splendid central station for lighting up the Court Theatre.

Digitized by Google

They paid the "apprentice money" every new enterprise has to pay, and were in the position to secure the best part of the town; but they seem to have got frightened and missed their opportunity, and to have rested content with what they had, so that they will soon have to encounter serious competition with the various electric light companies.

As to traction work, the Weiner Tramway Gesellschaft has laid a bill before the Austrian Chamber authorising the building of an electric subway railway under the centre of the city.

The Budapest Town Council are building an electric tramway to Steinbruch, three kilometres distant, and are going to use the Ganz system. The Tram Company of the same city have also applied for a concession to run an electric tramway on the right bank of the Danube.

Vienna has not been behind the times in respect of telephony. To-day the best equipped and largest single central station is that in Vienna. It is built for 5,000 subscribers, and fitted up with M. Otto Schaffler's splendid multiple board. Some 3,000 subscribers are already connected up, and cables are now being laid for 2,000 more. The Company expect to fill their exchange by next year, and have already over 1,000 orders on hand. The service is excellent both in Vienna and in Prag, and it has stood the severe test of the use of the long trunk line between these two towns. Over 95 per cent. of the communications over this trunk line were direct communications from a Prag subscriber to a Vienna subscriber, very few using the call rooms. Vienna, besides being connected by special trunk lines with the small towns south as far as Reichenaü, and with Prag and Budapest, has now also been connected by special wire with Brünn, and the Van Rysselberghe mongrel wire is to be reconverted into an ordinary telegraph wire. Prag has also been connected with the North Bohemian coal district, Aussig, Teplitz, &c., and Reichenberg with Gablonz. Next year it is proposed to connect Reichenberg with Prag, and, perhaps, also with Zittai, in Saxony. A special trunk line is also proposed, connecting Vienna with Grez and Trieste, but this will probably take two or three years yet before it is realised. The provincial towns also have not been behindhand, and the subscribers in the eight towns worked by the Telephone Company of Austria have increased to 3,157, with 6,572 kilometres of wire run.

CORRESPONDENCE.

THE TELEPHONE SUGGESTED IN 1854.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We are all familiar with the earlier telephonic experiments of Reis which are given in the *Jahres Bericht des Physikalischen Vereins*, of Frankfort, for 1860-61, and which are regarded as the precursor of the telephone of Graham Bell. Prof. Bell read a Paper on the subject before the Society of Telegraph Engineers on October 31, 1877; and at this lecture I called attention to a still earlier description of a telephone by Charles Bourseul, which is to be found in the second edition of the Comte Theodore du Moncel's *Exposé des Applications de l'Electricité*, published in Paris in 1857 (Vol. III., p. 110). Du Moncel does not give any reference to the original Paper; but in the *Didaskalia*, a weekly paper published at Frankfort-on-Main, No. 232, dated September 28, 1854, there is an interesting account of his invention which I do not remember to have seen printed in England. I am indebted to Messrs. Siemens Brothers and Co. for making the translation which I enclose, and, if not hitherto published, it will, I am sure, interest your readers, as his description of the principle of the telephone is almost as clear as if it were written at the present date. If he had only put his ideas to the test of experiment, we should have had the telephone in 1854.

It would be interesting to find the original source from which Count du Moncel derived his account of Bourseul's telephone.—Yours, &c.,

LATIMER CLARK.

6, Westminster-chambers, Victoria-street, London,
October 28, 1890.

Didaskalia, No. 322, Thursday, September 28, 1854.

ELECTRICAL TELEPHONY.

The number of miracles with which electricity has astonished us lately is said to have been increased by one which would not only cause a revolution in electrical telegraphy, but would add considerably to its utility. The invention in question is nothing less than the electrical transmission of the "*spoken word*." The idea was conceived by an educated and modest young man named Charles Bourseul (now living in Paris), who was a private in the African army in 1848, where he brought himself under the notice of the Governor-General by a course of mathematical lectures which he gave to his comrades in the garrison of Algiers. Possibly Bourseul's scheme, of the practicability of which he is perfectly convinced, may be one of those which learned men will afterwards declare very simple, and which, if troubled about, would have been brought out much sooner. The principle of electro-telegraphy, as is well known, is the following: an electric current passing through a metal wire surrounding a piece of soft iron, transforms the latter into a magnet. The magnetic properties of the iron vanish when the electric current is discontinued. This magnet, called the electro-magnet, can, therefore, alternately attract or repel a movable plate which by its forward and backward movements produces the conventional signals used in telegraphy. It is further known that all sounds are transmitted to the ear through the air vibrating; and that, therefore, sounds are virtually vibrations of the air and that the infinite variety of sounds is solely dependent on the rapidity and strength of these vibrations. If it were possible to construct a metal plate sufficiently sensitive and flexible to admit of the reproduction of the vibration of sounds (like the air), and if this plate could be connected with an electric current in such a manner as to alternately interrupt and continue it according to the vibrations of the air to which it would be exposed, it would be equally possible to electrically affect a similar metal plate so as to repeat exactly and simultaneously the vibrations of the first plate. This would create the impression as if the speaker had spoken in immediate vicinity of the second plate, or, if put differently, the ear would be affected in a similar way as if it had received the sounds through the first metal plate. Electrical telegraphy, which was once academically declared to be almost an absurdity, is now almost universally established; and if we investigate this new idea of the young scientist on the principles of physics, we find that not only no objection could be raised against the soundness of his theory, but that its practicability is more probable than that of electrical telegraphy was only a short time ago. If the theory should prove a success, electrical telegraphy will attain a position of general usefulness. No special knowledge or apparatus will be required, except a galvanic battery, two suspended plates, and a metal wire. Without any other preparation one person will have to speak into one of the plates, while the other person places the second plate close to his ear, thus enabling them to converse as if in private.

The youthful inventor is confident of the success of his invention, and challenges scientists to prove the impracticability of his theory on scientific grounds. In the meantime the invention fully deserves the attention which will, no doubt, be bestowed on it. L.

TRADE NOTES AND NOTICES.

TENDERS WANTED.—The Corporation of Monmouth require tenders for the electric lighting on the low-tension system of the streets of Monmouth. Persons tendering are to supply, erect, and fix all the necessary plant, machinery, engines, boiler, dynamo, conductors, &c. Tenders are to be sent in to the Town Clerk, Monmouth, by Saturday, the 18th November next.

SALE OF ELECTRICAL PLANT.—An unusual opportunity is afforded by the sale, which takes place to-day, for the purchase of some first-rate machinery, which is probably in a better condition than when it left the makers' works. The reason for the sale, of which particulars will be found in our advertisement columns, is that the Westminster Electric Supply Corporation have purchased the business of the Westminster Electric Light Syndicate, but do not intend to use the alternating-current system, which the latter Company was employing.

ELECTRICAL ENGINEERING CORPORATION (LIMITED).—We have been favoured with a copy of a well-illustrated and a very exhaustive catalogue of the manufactures of this Corporation. These manufactures cover a very wide range in electrical engineering, and the catalogue gives very full particulars and prices relating to constant-current dynamos, alternate-current machinery, engines, the telpher system of cheap transport, tramways, light railways, &c., plant for supply stations, machinery for transmission of power, electrical supplies, &c. The book contains nearly 100 large folio pages, and is altogether one of the most complete catalogues we have seen. We notice that the Corporation supply connecting sockets, which are the only proper and thoroughly workmanlike mode of fastening large cables to dynamos and switch-boards. They also supply another useful and little known device—viz., a two-way switch, by which lights may be turned on from one point and turned off from another.

MESSRS. W. H. ALLEN AND CO.—This firm have received the order to fit up the whole of the fleet of steamers Messrs. Harland and Wolff have now on the stocks, six in number, with electric light. Messrs. W. H. Allen and Co. state that they are the only firm in England who manufacture under the same roof the whole of the gear required for marine electric light work, having been manufacturers of both dynamos and engines for some years past. The improvements which they have recently carried out in their governors for marine work enable the engine to be under entire self-control.——Messrs. W. H. Allen and Co. announce that Mr. R. W. Allen, eldest son of the senior partner in this firm, was on the 27th inst. taken into partnership. In the circular notice of this change in the constitution of the firm, reference is made to the

Digitized by Google

large business done by the Company, and to the very large extension of premises which the Company have recently made.

MR. JOHN JARDINE.—We have received from Mr. Jardine his price list and discount sheet of shafting and shafting accessories, of which he makes a speciality. Illustrations of Mr. Jardine's various manufactures are given.

PATENT RECORD.

APPLICATIONS FOR PATENTS.

NOTE.—*The undermentioned applications are not open to public inspection until after the acceptance of the complete specification. The names within parentheses are those of communicators of inventions.*

October 16, 1890.

16,472. B. J. STACEY. London. A new or improved automatic coin-freed apparatus for giving electric shocks.

October 17, 1890.

16,518. J. E. A. GWYNNE. London. Improvements in arc electric lamps.

16,522. G. D. BURTON. London. Improvements in the methods of and apparatus for working metals by electricity.

16,534. A. LONGSDON. New or improved electrical priming, or electrical frictional priming screw plugs (F. Krupp, Germany.)

October 18, 1890.

16,556 W. P. THOMPSON. Liverpool. Improvements in devices for holding the receivers of telephone instruments, or the like (J. T. MOORE, United States.)

16,570. H. GROSWITH. Glasgow. Improvements in electric motors.

16,571. C. W. KENNEDY and H. GROSWITH. Glasgow. Improvements in secondary batteries.

16,603. C. J. HALL. London. Improvements in secondary batteries.

16,607. C. E. BONNE. London. Improvements in or connected with electric switches (W. P. Dorniels, Germany).

16,613 J. MÖHRLE. London. A method of renewing filaments in in candescent lamps.

October 20, 1890.

16,631. G. S. HOOKER. Bath. A switch for interchanging constant current dynamos without breaking the continuity of the circuit on to which they are to work.

16,653. S. C. C. CURRIE. London. Improvements in apparatus for measuring the strength of electric currents.

16,675. W. C. FISCHER. London. Improvements in water motors and in dynamo machines to be driven by same.

October 21, 1890.

16,747. J. R. THAME. London. Improvements in the manufacture of electrical insulating materials.

16,752. T. R. ANDREWS and T. PREECE. Bradford. Improvements in electrical switches.

16,792. A. DE PUYAT. London. An improved arrangement of regulating device for electric arc lamps.

October 22, 1890.

16,809. G. D. BURTON. London. Improvements in electric blank heating and feeding apparatus for forging machines.

16,811. P. G. POCHIN. Sheffield. The improvement of switchboards for the regulation and control of electrical currents.

16,821. T. HESKIN. Preston. Improvements in appliances for producing light by incandescence.

16,835. W. CAVINS and A. F. MABON. Glasgow. An improved electrical conductor for fitting in mine shafts and underground haulage roads for electrical signalling purposes.

16,837. J. E. DOUGLASS. London. Improvements in the manufacture, construction, and building up of secondary battery elements, electrodes, or plates.

16,844. H. WEYMERSCH. London. An improvement in the construction of accumulators or secondary batteries.

16,847. W. LOWNDS, E. EMANUEL, and J. WOOD. Chiswick. An improved electric switch.

LEGAL INTELLIGENCE.

In the Court of Appeal of the Supreme Court of Judicature, on Saturday last (before the Master of the Rolls, Lord Justice Lindley, and Lord Justice Lopes), the action *in re* Brazilian Submarine Telegraph Company (Limited)—Chatenay *v* Brazillian Submorine Telegraph Company (Limited) came on for hearing.

This was an appeal from the decision of Mr. Justice Day. M. Chatenay, who resided and carried on business at Rio de Janeiro, was the owner of 50 shares in the Brazilian Submarine Telegraph Company. In May, 1880, he executed at Rio a "notarial act," which is, in effect, a power of attorney, and which gave power to P. Broë, of London, on behalf of M. Chatenay, of Rio, "to purchase and sell shares in public companies and public funds in conformity with his letters of credit and following his letters of orders and particular advices, which, if necessary, shall be considered as part hereof." Broë made use of this notarial act to transfer the fifty shares without any special order or direction from Chatenay to do so. Chatenay thereupon applied under the Companies Act for an order restoring his name to the register as owner of the shares. After argument in the Divisional Court, Mr. Justice Day held that, as the business was to be transacted in England, it must be construed in accordance with English law, and from this decision the Company now appealed.

In the end, the Appeal Court upheld the decision of Mr. Justice Day, and the appeal was dismissed.

COMPANIES' MEETINGS & REPORTS.

The Monte Video Telephone Company (Limited).

The following is the report of the Directors of this Company to be presented to the shareholders at the annual general meeting, to be held at the offices of the Company, 25, Abchurch-lane, London, E.C., this day (Friday):—

The accounts for the year ending July 31st last show a gross profit of £10,301 5s. 9d., after providing for all working expenses in Monte Video and London.

Off this sum there has been written £114 14s. 8d. for preliminary expenses, and £19 10s. 10d. for depreciation of furniture, leaving a balance of £10,167 0s. 3d. To this must be added the balance from last year, £325 8s. 5d., making a total now to be dealt with of £10,492. 8s. 8d.

The Directors recommend that of this amount the full dividend of 6 per cent. on the Preference Shares, amounting to £8,308 7s. 2d., be declared, that £1,000 be added to the Depreciation Fund, and that the balance, £1,184 1s. 6d., be carried forward.

An interim dividend on the Preference Shares was paid in March last.

During the year the sum of £5,600 6s. 7d. has been expended on capital account, chiefly in consequence of the completion of the fixture of the multiple switchboard, cables, and lines for new subscribers.

The Directors regret that the results for the past year have not come up to their expectations; but bearing in mind the severe commercial depression which for a considerable portion of that year has prevailed in Monte Video, and which has caused very many subscribers to curtail their expenses by relinquishing their subscriptions to the Telephone Exchanges, they cannot but deem it satisfactory to have maintained the profit at above £10,000. For these reasons it has not been deemed advisable to recommend any dividend on the ordinary shares. It is gratifying, however, to report that the latest advices from the manager are to the effect that a large number of subscribers who have left for a variety of reasons, have returned to the Company.

In accordance with the Articles of Association, Mr. Peters retires from the Board, but, being eligible, offers himself for re-election.

The Auditors, Messrs. Gérard Van de Linde & Son, also retire, but offer themselves for re-election.

[There was a dividend of 2½ per cent. paid on the ordinary shares last year.]

NEW COMPANIES REGISTERED.

BRITISH INSULATED WIRE COMPANY (LIMITED).—Registered by Thomas T. Hull, 22, Chancery-lane, W.C., with a capital of £60,000, in £5 shares. Object: to purchase or otherwise acquire any patents, brevets d'invention, licences, concessions, and the like, conferring an exclusive or non-exclusive or limited right to use any inventions capable of being used in the manufacture of wire and wire ropes and cables, or any other invention which may seem to the Company capable of being profitably dealt with. There shall not be less than three nor more than seven Directors; the first to be appointed by the subscribers to the Memorandum of Association. Qualification not specified. Remuneration, £200 and 10 per cent. of net profits after 10 per cent. dividend.

THE ELECTRO-CHEMICAL SYNDICATE (LIMITED).—Registered by Lovell and Trimnel, of Monument-buildings, London, E.C., with a capital of £5,000, in £1 shares. Objects: To acquire and turn to account inventions, patents, &c. Registered without articles of association.

CITY NOTES, &c.

BANKRUPT.—The bankruptcy is announced in Wednesday's *Gazette* of Henry Thompson, electrical case maker, Phœnix-place, Gray's Inn-road, and St. Peter's-street, Islington, London.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ended October 24th amounted to £1,834.

ELMORE'S FRENCH COPPER DEPOSIT COMPANY.—A call of 15s. on 66,750 shares of this Company is due to-morrow (Saturday).

ELMORE'S WIRE MANUFACTURING COMPANY.—A call of 10s. on 150,000 shares of this Company is due to-morrow (Saturday).

INDO-EUROPEAN TELEGRAPH COMPANY.—This Company has declared an interim dividend for the half-year ended June 30th last at the rate of 5 per cent. per annum.

SOUTH OF ENGLAND TELEPHONE COMPANY.—The Directors of this Company have declared a dividend at the rate of 6 per cent. per annum on the Preference shares for the half-year ending the 31st inst.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this Company for the week ending October 24, 1890, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, Limited, were £3,742.

WESTERN UNION TELEGRAPH COMPANY.—The annual report of the President of the Western Union Telegraph Company for the year ended June 30, 1890, shows that the capital stock outstanding is $86,199,852, of which $26,243,000 is in the treasury of the Company. The bonded debt, less sinking fund, amounted to $14,779,528. The business of the year shows:—Revenue, $22,387,028; expenses, $15,074,303; profits, $15,924,126, of which $10,052,983 remains as surplus. The profits show an increase of $1,091,683, as compared with the previous year. The average cost per message to the Company was 22·7c., as against 22·4c. the year before. There has been no increase in rates, but material reductions, the route west of the Mississippi receiving the larger share of the reductions. The additions to the plant were 5,163 miles of line and cables, 3,300 miles of wire, and 912 new offices, at a cost to the Company of $1,778,314, which was paid out of the surplus earnings.

THE NON-CONDUCTOR OF ELECTRICITY.

WAREHOUSE.

VULCANISED FIBRE,

PATENTED.

This new material is supplied in two qualities, Flexible and Hard.

The FLEXIBLE is a substitute for Leather, Rubber, Gutta Percha, &c., and is extensively used by Brass Founders, Axle Makers, Hydraulic, Sanitary, and other Engineers, Pump Makers, Carriage Builders, &c.

It makes the best Hot and Cold Water Packings, and for Axle Washers of all kinds it is unequalled.

The HARD is a substitute for Metals, Hard Wood, Ivory, Vulcanite, Ebonite, &c., and is a good Insulator.

Sold in sheets, 5ft. 6in. by 3ft. 6in., varying in thickness from 1-50in. to 1in.

FLEXIBLE, 2/- per lb.; HARD, 2/3 per lb.

FACTORY.
